EXPERT REPORT OF DR JASON KINDRACHUK

1. My name is Dr Jason Kindrachuk. I am an Assistant Professor and the Canada Research Chair in emerging viruses in the Department of Medical Microbiology & Infectious Diseases at the University of Manitoba.
2. I have been asked by the Respondents to provide my opinion on some of the important issues regarding the virus SARS-CoV-2 and the disease it causes, namely COVID-19, in response to the expert report of Dr Jay Bhattacharya.
3. The substance of my opinion, including the information and assumptions upon which my opinion is based, is contained in **Schedule A**.
4. My qualifications and background are set out in my Curriculum Vitae, attached hereto as **Schedule B**, and the sources used in my report are attached hereto as **Schedule C**.

08 July 2021

Dr Jason Kindrachuk

Schedule A

Background

I am an Assistant Professor and Canada Research Chair in emerging viruses in the Department of Medical Microbiology & Infectious Diseases, University of Manitoba. My field of expertise is the investigation of emerging viruses, the infections they cause and their impact on global health. I am engaged in multiple international scientific outreach activities with regional partners across Africa including Sierra Leone, Gabon and Kenya. I was recently seconded to the Vaccine and Infectious Disease Organization, University of Saskatchewan, Canada, as part of a 12-month research partnership agreement where I lead and facilitated national COVID-19 research response efforts. I also serve as an Associate Professor in the College of Medicine and Allied Health Sciences at the University of Sierra Leone and as a Visiting Scientist at the Centre International de Recherches Medicales de Franceville in Gabon, one of two biosafety level 4 facilities in Africa. I have also served in a volunteer capacity as an infection prevention and control expert for Heart to Heart International, an international disaster response agency, throughout the Covid-19 pandemic. Heart to Heart International, founded in 1992, has shipped more than \$1.7 billion in humanitarian aid across more than 130 countries. It is a global humanitarian organization that focuses on improving public health and responding to the victims of disaster worldwide.

My education is as follows. I completed my undergraduate and graduate training at the University of Saskatchewan and completed my PhD in 2007 in the Department of Biochemistry. Following this, I participated in and led several projects as a postdoctoral fellow in Dr. Robert E.W. Hancock's laboratory, Centre for Microbial Diseases and Immunity Research, University of British Columbia. Here, my work focused on the design and development of novel anti-infective therapeutics and vaccine adjuvants, which are substances that are added to vaccine formulations to help amplify the immune response to the vaccine, for emerging pathogens. During this fellowship, the focus of my research was the investigation of emerging and re-emerging pathogens of importance to global public health, notably antibiotic resistant bacteria. These investigations fostered my commitment to both basic scientific research approaches and application of this research to public health in developed and developing nations. In 2009, I joined the National Institutes of Health (NIH) in Bethesda, MD, USA, as a Visiting Fellow to expand my expertise in the molecular mechanisms that underlie severe infections focusing on emerging and re-emerging viruses. Following this fellowship, I served in multiple senior scientific and leadership capacities, including Principal Research Scientist (NIH Integrated Research Facility-Frederick) and Staff Scientist (Critical Care Medicine Department, NIH). I also volunteered as a Scientific Lead in diagnostic support for the Centers for Disease Control/Department of Defense joint operations in Monrovia, Liberia during the 2014 Ebola virus disease outbreak.

Research History

My research has contributed to our understanding of the complex mechanisms underlying emerging viruses, their transmission and the infections they cause. Research in my laboratory focuses on the circulation, transmission and clinical aspects of emerging viruses that pose the greatest threat to global human and animal health. My current Covid-19 research includes:

- characterization of how SARS-CoV-2 manipulates human immune responses to cause severe disease in high-risk patient populations
- investigation of repurposed drugs as SARS-CoV-2 therapeutics through kinome analysis
- characterization of neurological and reproductive health complications in animal models of SARS-CoV-2 infections. Further, the animal models we are developing will allow us to inform how neurological manifestations associated with Covid-19 occur in humans.

Prior to my work on SARS-CoV-2 and Covid-19, my research focused on viruses that pose the greatest threat to global human and animal health. These included Ebola virus, Middle East respiratory syndrome

coronavirus (MERS-CoV) and influenza viruses. A summary of these research activities follows below.

1) Ebola virus research (basic and clinical) & support efforts. I have conducted extensive research into Ebola (Wahl-Jensen, Kurz et al. 2011, Kindrachuk, Wahl-Jensen et al. 2014, Falcinelli, Chertow et al. 2016, Barnes, Kindrachuk et al. 2017, Kash, Walters et al. 2017, Schindell, Webb et al. 2018, Khurana, Ravichandran et al. 2020) and received a 2018 National Institute of Allergy and Infectious Diseases (NIAID, NIH, Bethesda, MD, USA) Merit Award for my work. In 2014, I served as Scientific Diagnostics Lead in Liberia during the Ebola virus disease epidemic in West Africa. I provided daily situation reports and recommendations to local and international officials. I received a National Institutes of Health Director's Award in 2014 for these efforts. I have also recently received a five-year project grant from the Canadian Institutes for Health Research for my work on Ebola virus persistence, sexual transmission and long-term reproductive health impacts in Ebola virus disease survivors.

2) MERS-CoV efforts. My work on coronaviruses began in 2013 following the emergence of Middle East respiratory syndrome coronavirus. This work culminated in multiple peer reviewed publications on therapeutic screening and identification as well as characterization of molecular pathogenesis (Dyall et al. 2014; Dyall et al. 2017; Falcinelli, Chertow, and Kindrachuk 2016; Hart et al. 2014; Kindrachuk et al. 2015; Willman, Kobasa, and Kindrachuk 2019).

3) Variola virus and monkeypox virus pathogenesis. I developed and led collaborations with the US Centers for Disease Control and Prevention to investigate variola virus pathogenesis, the etiologic agent of human smallpox. This work demonstrated that kinome analysis could be used as a predictive drug repurposing tool for orthopoxviruses. Based on this, I was invited to serve as a member of the US delegation at the World Health Organization Advisory Committee of Variola Virus Research. Meeting reports, including overviews of my work, are publicly available ([WHO Advisory Committee on Variola Virus Research, 14th meeting](#); [WHO Advisory Committee on Variola Virus Research, 15th meeting](#)). My work on monkeypox virus was the first to identify how the West African and Congo Basin virus behave differently at the cellular level and may explain the differences in case fatality rates between the two clades (Kindrachuk et al. 2012).

4) Influenza viruses. I have investigated influenza virus pathogenesis extensively with a focus on influenza-bacterial co-infections (Chertow et al. 2016; Davis et al. 2016; Walters et al. 2016). This included pandemic and seasonal strains, including 1918 H1N1 virus. My work provided increased clarity regarding the mechanisms employed by pandemic and seasonal influenza viruses to infect cells as well as assessing the role of aerosol infection in acute respiratory distress during influenza virus infection in Rhesus macaques, with or without bacterial co-infection. Recently, my group published findings on 2009 pandemic H1N1-*Staphylococcus aureus* co-infections and provided perspectives on the 1918-1919 influenza pandemic (Nickol et al. 2019; Nickol and Kindrachuk 2019).

I have been actively engaged in emerging infectious disease research and response efforts throughout my research career. In 2014, I was as a Scientific Lead in diagnostic support for the Centers for Disease Control/Department of Defense joint operations in Monrovia, Liberia, during the West African Ebola virus disease outbreak. I continue to work with local communities and perform research on the African continent. I have an active research program in Sierra Leone where I am leading investigations that focus on the long-term reproductive health impacts found in Ebola virus disease survivors. Here, we are working with local survivor advocacy groups to identify complications that are faced by survivors through anonymous surveys. My research group is also collaborating with similar advocacy groups and researchers in Liberia on this work. I have also co-founded the Consortium for Intercepting Emerging Diseases in Africa (CIEDA) with Dr. Kris Forbes (University of Arkansas) which brings together partners from North America, Europe and Africa to increase surveillance and identification of emerging infectious diseases that could impact global human and animal health. This work began through my research partnership with the Interdisciplinary Centre of Medical Research of

Franceville, Gabon, where I am a Visiting Scientist. I also have emerging infectious disease collaborations at the University of Nairobi Institute for Tropical Infectious Diseases, Kenya, where I have led emerging virus training programs for trainees and staff.

Covid-19 and SARS-CoV-2 Grants, Reports and Committee Appointments

My research group is currently examining the effects of respiratory virus co-infection on disease outcome during SARS-CoV-2 infection in hamsters. I was a co-applicant on a grant funded by the Canadian Institutes for Health Research (CIHR) entitled “Animal models for SARS-CoV-2: vaccines and immune enhancement” in Spring, 2020. I have also received funding as a co- or lead-applicant for two additional grants: i) Scalable, Customizable, Digital Health Communication Materials to Help Canada Address the COVID19 Pandemic (CIHR); and ii) Broad Spectrum CoV Therapeutic; rhACE2 Immunoadhesin to treat COVID19 (MITACS Accelerate).

My work on SARS-CoV-2 began in early January of 2020 following the identification of the emergent virus in Wuhan, China, as a novel coronavirus. Following the emergence of SARS-CoV-2, I have been involved in various research investigations that have included development of animal models of infection, characterization of biological variables on disease severity, novel drug development and behavioral assessments of Covid-19 infection prevention and control messaging. In addition, I am currently investigating the differences in molecular pathogenesis in respiratory cells from patients with no underlying respiratory complications and those with chronic obstructive pulmonary disorder. My work on SARS-CoV-2 began in early January of 2020 when I co-authored a publication with other Canadian emerging virus experts on the emergence of a new virus (then called 2019-nCoV).

I have published two peer reviewed manuscripts on SARS-CoV-2, including as a co-author on a peer-reviewed clinical review of Covid-19 (Cevik et al. 2020; Ralph et al. 2020) and two recently accepted data manuscripts describing Covid-19 pathogenesis in hamsters (Accepted in *PLoS Pathogens*) and ferrets (Accepted in *Scientific Reports*). Two additional manuscripts are currently in revision at *Clinical Microbiology Reviews* and *BMC Infect Dis*. I have also been involved in two publicly available reports from national committees on Covid-19 transmission as well as multiple national and international Covid-19 committees. These are outlined below.

Published Reports on Covid-19 Transmission:

- 1) CIHR-PHAC-CADTH – Best Brains Exchange – Transmission Routes for COVID-19: Implications for Public Health. Canadian Institutes of Health Research (CIHR); 2020 October. <https://cihr-irsc.gc.ca/e/52238.html>
- 2) Heating, Ventilation and Air Conditioning Systems in Public Spaces. Ottawa: Canadian Agency for Drugs and Technologies in Health (CADTH); 2020 June. (CADTH technology review). [Heating, Ventilation, and Air Conditioning Systems in Public Spaces \(cadth.ca\)](https://www.cadth.ca/heating-ventilation-and-air-conditioning-systems-in-public-spaces)

National and International Covid-19 Committees:

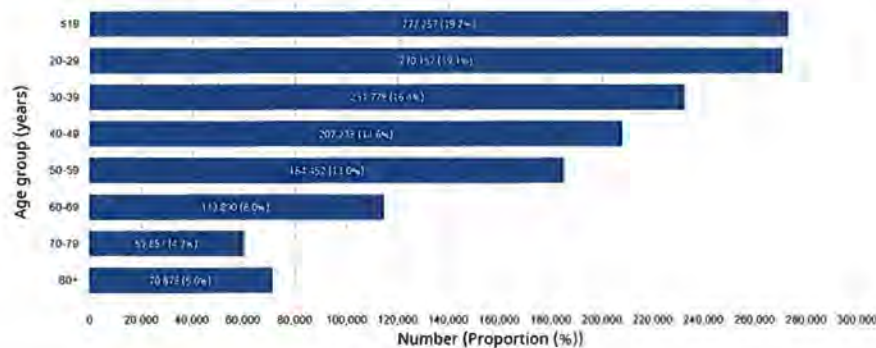

- 1) Panel Member – CIHR Institute of Infection and Immunity Consultation on Variant Strains of SARS-CoV-2
- 2) Panel Member – CIHR-PHAC-CADTH – Best Brains Exchange – Transmission Routes for COVID-19: Implications for Public Health. Canadian Institutes of Health Research (CIHR); 2020 October. <https://cihr-irsc.gc.ca/e/52238.html>
- 3) Panel Member – Heating, Ventilation and Air Conditioning Systems in Public Spaces. Ottawa: Canadian Agency for Drugs and Technologies in Health (CADTH); 2020 June. (CADTH technology review). [Heating, Ventilation, and Air Conditioning Systems in Public Spaces \(cadth.ca\)](https://www.cadth.ca/heating-ventilation-and-air-conditioning-systems-in-public-spaces)

- 4) Member – World Health Organization COVID-19 Solidarity Serology Study Group
- 5) Member – World Health Organization Ad Hoc Committee on COVID-19 Animal Models

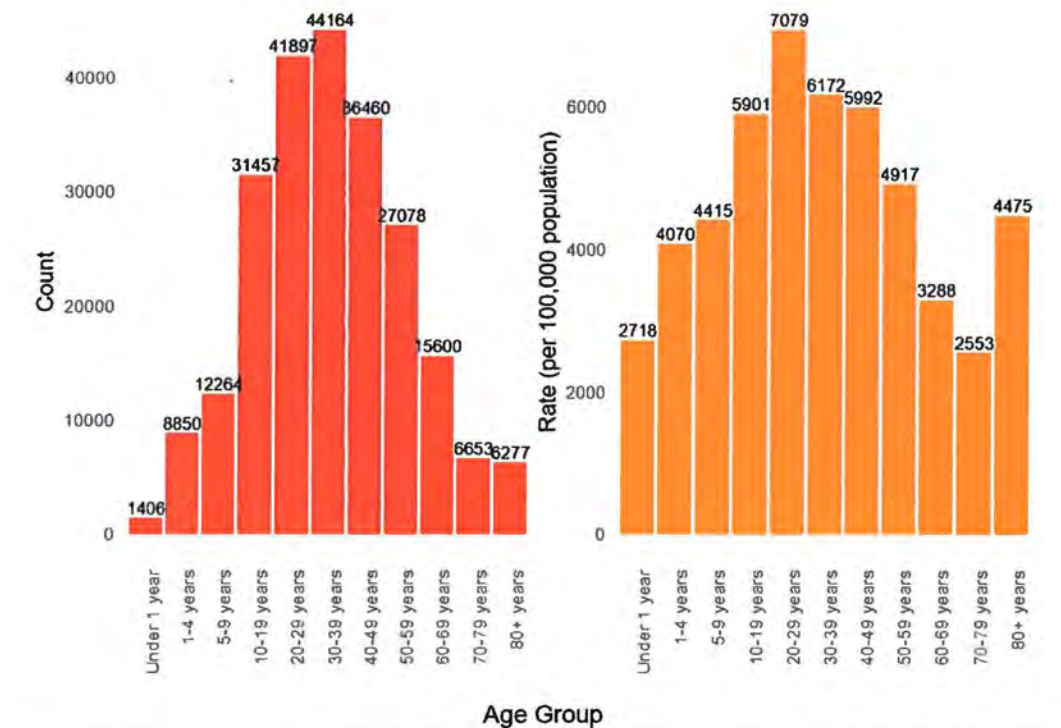

1. Current Knowledge of Covid-19 Cases and Disease Severity

There has been extensive investigation into the relation between biological risk factors and Covid-19 disease severity. Severe disease, including intensive care unit admission and fatal disease, are associated with older age, race/ethnicity, gender and socioeconomic status. The US Centers for Disease Control and Prevention outlined and ranked the risks for severe Covid-19 based on supportive published evidence including case series, cohort studies, cross-sectional studies, meta-analyses and systematic reviews (CDC 2021). While older age is convincingly linked to severe Covid-19, the outlined risks were not limited to those in high age groups. Factors strongly linked to severe disease in adults include cancer, chronic kidney disease, COPD, cardiovascular disease, obesity, pregnancy, sickle cell disease, smoking, organ transplantation and type 2 diabetes.

As of July 2, 2021, age distributions of Covid-19 cases in Canada show that both ≤ 19 years and 20-29 years represented the greatest proportion of all cases of infection and were nearly identical overall ([COVID-19 daily epidemiology update - Canada.ca](#)):

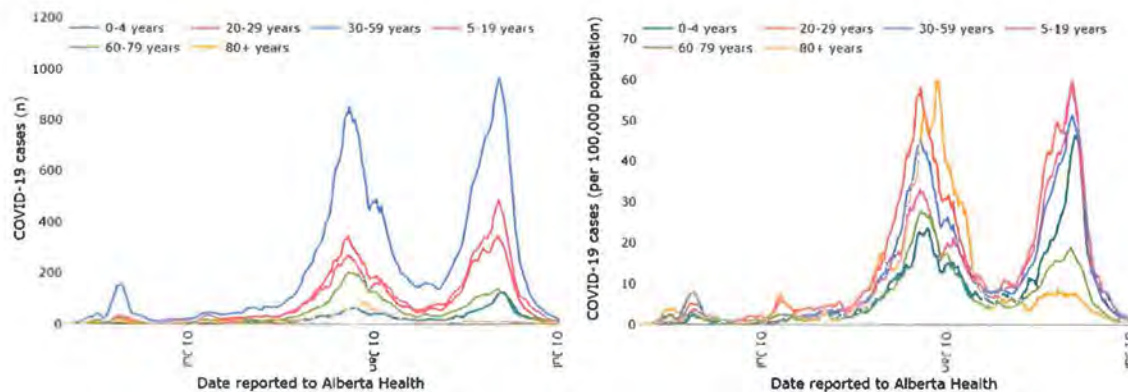

Alberta data is presented below ([COVID-19 Alberta statistics | alberta.ca](#)):

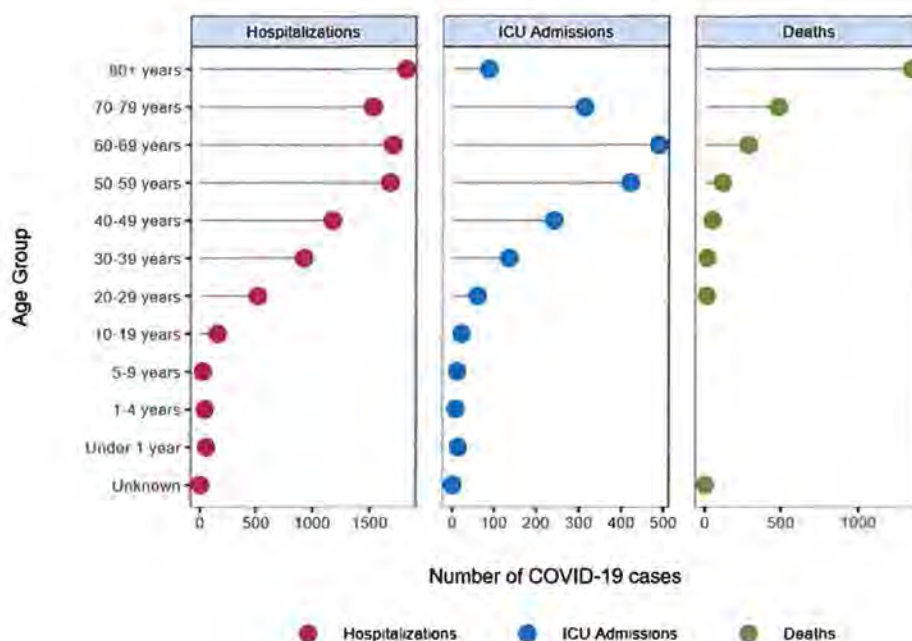

Temporal distribution of cases by age group in Alberta throughout the pandemic (A) and age distributions for severe outcomes (B):

A)

B)

In Alberta, total Covid-19 cases were highest in the ≤ 19 years age group with 53,977 cases (summation of all age groups from 0-19). This was followed by the 30-39, 20-29 and 40-49 year age groups, respectively. While hospitalizations were highest across all age groups ≥ 50 , ICU admissions highest in the 60-69 year age group followed by 50-59, 70-79 and 40-49 age groups, respectively. This data continues to demonstrate that younger age groups are susceptible to moderate or severe illness and at risk for hospitalization and intensive care unit admission.

Covid-19 clinical symptom onset and diversity

Covid-19 has a diverse range of clinical presentations that range from asymptomatic infections to severe and fatal disease. The presentation of symptoms is variable within increasing severity of illness associated with older age and/or underlying health complications. Symptom and wellness checks, including temperature screening, to identify have been employed to identify infected individuals. Malenfant and colleagues reported on the frequency of symptoms associated with Covid-19 in healthcare workers from March to April 2020 (Malenfant, Newhouse, and Kuo 2020). The authors demonstrated that Covid-19 presented with a broad spectrum of mild symptoms. While cough (51%), fever (41%), myalgia (38%) and headache (30%) were the most common initial symptoms reported, one-third of the respondents did not report fever or cough as one of their symptoms and nearly half (49%) continued to work while experiencing symptoms, some for several days. In an investigation of over 1,000 hospitalized patients, 44% of patients had fever upon admission though the half of these patients (22%) had very mild elevations in body temperature (37.6 to 38 °C) (Guan et al. 2020). Further, according to the Clinician Guide for Covid-19 signs, symptoms and severity of disease from the Government of Canada, clinical symptoms among older adults (≥ 65 years old) and those with underlying health conditions may be atypical or subtle (<https://www.canada.ca/en/public-health/services/diseases/2019-novel-coronavirus-infection/guidance-documents/signs-symptoms-severity.html>). Thus, it must be appreciated that symptoms are highly variable in regards to both type

and severity across infected individuals and thus screening alone as a measure of case identification would likely lead to many missed cases of infection.

Investigations of Covid-19 pathology suggest that there are similar pathologic findings and distribution of virus during infection. These reports suggest similarities across different geographic regions as well as similarities to prior observations from SARS and MERS patients. Deshmukh and colleagues published a systematic review demonstrating that SARS-CoV-2 infections in the lower respiratory tract correlated with more severe disease including pneumonia and organ failure (Deshmukh et al. 2021). The authors noted that many of the histopathological findings bore similarity to those described for severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS). It should be appreciated that 15-30% of those who recovered from either SARS or MERS developed long-term lung complications including pulmonary fibrosis (Hui et al. 2005; Ooi et al. 2004; Das et al. 2017). Therefore, though further research will be required to determine the full extent, it is likely that some who recover from Covid-19 will continue to experience long-term negative health effects.

2. SARS-CoV-2 Transmission and High Risk Activities

While three coronaviruses have emerged over the past two decades with drastic public health consequences, SARS-CoV-2 is distinguished by a high degree of community transmission. Thus, it has been important to establish the infectious period for those that have been infected. This has been driven by investigations of viral loads (amount of virus) within the respiratory tract of infected patients as well as the duration of infectiousness, including during the pre- and post-symptomatic periods of infection. Investigations from the SARS epidemic and MERS outbreaks demonstrated limited community transmission with either coronavirus with transmission largely concentrated in healthcare settings through close contacts. Scientific evidence strongly supports that SARS-CoV-2 transmission is driven by respiratory droplets and aerosols. Respiratory droplets ($>5\text{--}10\text{ }\mu\text{m}$ in diameter) remain suspended for short periods of time and are transmitted over short distances though this can be dependent on airflow. Small-particle aerosols ($<5\text{ }\mu\text{m}$) can disperse quickly and remain airborne while traveling longer distances. Epidemiological data suggests that close contact, defined as anyone who has shared an indoor space with a case for a cumulative total of 15 minutes over a 24 hour period (Canada 2020), or enclosed settings is a major driver for SARS-CoV-2 transmission (Leclerc et al. 2020; Qian et al. 2020). Recent animal model investigations (Richard et al. 2020; Kim, Kim, et al. 2020; Sia et al. 2020; Chan et al. 2020) and epidemiological studies (Lu and Yang 2020; Park, Kim, et al. 2020; Jang, Han, and Rhee 2020; Cai et al. 2020) suggest that aerosol transmission can occur during prolonged exposure in enclosed settings with reduced ventilation.

There has been considerable scientific investigation into the role of presymptomatic (prior to onset of symptoms) and asymptomatic (no symptom development though infected) transmission for Covid-19. Of central focus has been characterizing how the viral load (amount of virus) within the respiratory tract of an infected individual changes throughout the course of infection, both prior to symptom onset and following symptom resolution. The presence (viral load) and duration (kinetics) of virus within the respiratory tract are important determinants for the duration of infectiousness and thus transmission. Cevik and colleagues recently published a systematic review that incorporated data from 5,340 individuals across 79 studies (Cevik et al. 2021). Prior assessments of viral loads in the respiratory

tract through repeated sampling suggests that peak viral loads occurred either just prior to (presymptomatic phase), or coincident with, symptom onset (Wolfel et al. 2020; Zou et al. 2020; Kim, Chin, et al. 2020). In the systematic review by Cevik et al., the authors identified 12 reports that provided temporal viral load data for individuals with asymptomatic infections. Viral loads in the reports were found to be similar to (four reports) or lower than (two reports) those from symptomatic patients. However, viral clearance appeared faster in asymptomatic patients based on observations from six reports. This review provided temporal evidence for viral accumulation and clearance in asymptomatic patients. These observations are in good agreement with prior contact tracing studies where the highest risk of transmission fell from a few days prior to symptom onset to five days post-onset.

The contributions of asymptomatic and presymptomatic infections to SARS-CoV-2 transmission have been broadly investigated. An early study in April 2020 by Kimball and colleagues investigated an outbreak of Covid-19 in a long-term care facility in King County, Washington, US (Kimball et al. 2020). Following the initial identification of a Covid-19 case in the facility, broad testing was employed 16 days later and demonstrated that rapid spread of the virus had occurred with positive tests found in 30.3% of residents. Early adoption of infection prevention and control measures had been instituted following the identification of the first case. Nearly half of the residents that had positive test results were not symptomatic at the time of testing and the authors concluded that the evidence suggested transmission from asymptomatic and presymptomatic residents may have contributed to spread. Wang and colleagues performed a retrospective cohort study of 335 people in 124 families and with at least one laboratory confirmed Covid-19 case and provide strong evidence for the importance of the pre-symptomatic transmission of SARS-CoV-2 (Wang et al. 2020). Further, they found that face mask use by the primary case and family contacts prior to symptom onset in the primary case was 79% effective in reducing transmission. In a prospective study, Cheng and colleagues demonstrated that secondary transmission was higher among individuals with initial exposures to index cases within 5 days of symptom onset as compared to day 6 or later (Cheng et al. 2020). This study also found that transmission was similar whether contacts only had presymptomatic or postsymptomatic exposure to index cases. In the four clusters for which the date of exposure could be determined, presymptomatic transmission occurred 1-3 days before symptom onset in the presymptomatic source case. Clinical and epidemiological assessment of 243 Covid-19 cases between January 23, 2020 - March 26, 2020 were reviewed to identify potential cases of presymptomatic transmission of SARS-CoV-2. Out of 243 cases, 157 were locally acquired (Wei et al. 2020). The authors found seven epidemiologic clusters where presymptomatic transmission likely occurred and ten of the cases within these clusters were attributed to presymptomatic transmission, accounting for 6.4% of the 157 locally acquired cases. Katelaris and colleagues recently provided epidemiological evidence for airborne transmission of SARS-CoV-2 among attendees of a religious service in the absence of close physical contact (Katelaris et al. 2021). Here, 12 secondary case-patients were identified among 508 attendees across four services where the index patient had sung for 1 hour per service from a choir loft 3.5 metres above the congregation. The authors concluded that singing likely resulted in more dissemination of droplets and aerosols than talking, that limitations to ventilation may have allowed for the concentration of infectious virus in shared air, and lastly that the index patient was likely near the peak of infectiousness with symptom onset occurring around the exposure date. The index patient performed during his infectious period starting from 48 hours prior to symptom onset (initially malaise and headache).

There have been a growing number of investigations that have focused on separating asymptomatic and presymptomatic infections to facilitate increased understanding of transmission risks throughout the infectious period. Johansson and colleagues employed a decision analytical model to examine virus transmission from presymptomatic, symptomatic and asymptomatic individuals (Johansson et al. 2021). Model assumptions were that peak viral transmission occurred at the median of symptom onset, 30% of infected individuals were true asymptomatic infections and were 75% as infectious as symptomatic individuals. The model suggested that 59% of all infections occurred from those without symptoms of disease where 35% were patients that were in the presymptomatic stage of disease and 24% had asymptomatic infections. Buitrago-Garcia and colleagues recently examined asymptomatic and presymptomatic SARS-CoV-2 infections and transmission through a systematic review (Buitrago-Garcia et al. 2020). Using data from 94 studies, the authors calculated the overall estimate of true asymptomatic infection was 20% with the balance of 80% being those with presymptomatic infections. Thus, approximately 1 in 5 infected individuals will remain truly asymptomatic throughout the course of infection. However, the authors also stated that most studies included in the review were not designed to estimate asymptomatic infection proportions and thus combination nonpharmaceutical interventions will continue to be needed to help curb virus transmission. These sentiments were also echoed by Byambasuren and colleagues in their recent systematic review of asymptomatic Covid-19 (Byambasuren O 2020). The authors reviewed 13 studies and the asymptomatic proportion of described cases ranged from 4-41% with a corresponding overall proportion of asymptomatic infections as 17% exclusive of presymptomatic infections based on their meta-analysis. The authors stated that this remained sufficient to warrant policy attention. In the systematic review from Buitrago-Garcia et al., asymptomatic infections rose to 31% in seven of the studies with defined populations (Buitrago-Garcia et al. 2020). The secondary attack rate, and thus indication of transmission potential, was lower for asymptomatic infection as compared to symptomatic infection with a relative risk ratio of 0.35, suggesting that there is greater risk for transmission from those with symptomatic disease; however, risk of transmission remains from those with asymptomatic infections. Interestingly, the authors also found that the relative risk ratio of presymptomatic transmission as compared to symptomatic transmission was 0.63, further demonstrating that transmission in the absence of symptoms presents a risk. Moreover, the authors state that based on the contributions of asymptomatic and symptomatic infections in virus transmission, “combination prevention measures, with enhanced hand hygiene, masks, testing tracing, and isolation strategies and social distancing, will continue to be needed”. A recent investigation by Li et al assessed household transmission rates in Wuhan through a retrospective observational study (Li et al. 2021). The authors assessed 29,578 primary cases, 27,101 households and 57,581 household contacts in their analysis. The odds ratio for infection from asymptomatic individuals was lower than from symptomatic cases (0.21), similar to those reported by Liu et al (Liu et al. 2020). Importantly, the odds ratio for infection from presymptomatic cases was higher than from post-symptom onset cases (1.42). Thus, while true asymptomatic transmission may occur less frequently than during symptomatic transmission, there was a greater likelihood of transmission before symptom onset (presymptomatic) than post-symptom onset. The authors concluded that presymptomatic cases were more infectious than symptomatic cases and individuals with asymptomatic infection less infectious than their symptomatic counterparts.

Cevik and colleagues recently published a systematic review that included data from 79 studies and

5,340 individuals (Cevik et al. 2021). Prior assessments of respiratory tract viral loads have suggested that peak loads occurred either just prior to (presymptomatic phase), or coincident with, symptom onset (Wolfel et al. 2020; Zou et al. 2020; Kim, Chin, et al. 2020). Cevik et al. identified 12 reports that for individuals with asymptomatic infections where viral loads were assessed throughout the course of infection. Viral loads in asymptomatic patients were similar to, or lower than, those from symptomatic patients in four reports and two reports, respectively. Viral clearance appeared to be faster in asymptomatic patients (six reports). Overall, the accumulated data across all studies suggested that highest risk of transmission fell from a few days prior to symptom onset to five days post-onset. Chung et al. recently provided a comparison of SARS-CoV-2 viral loads from upper respiratory tract samples in children and adults in a respiratory surveillance study (Chung et al. 2021). Assessments were carried out across 555 virus-positive participants (mean age 33.7 years) that included 432 adults (≥ 18 years) and 123 children. Higher viral loads were found in those with symptomatic infections as compared to their asymptomatic counterparts; however, there were no statistical differences in viral loads between adults and children within either group.

While SARS-CoV-2 transmission is likely lower from individuals with asymptomatic infections as compared to symptomatic cases, those in the presymptomatic phase of disease appear to be able to transmit the virus similarly to symptomatic individuals. Dr. Nathalie Dean, corresponding author for this study, has provided additional context on the quantitative generalizations that can be drawn from her team's study, including the direct limitation noted in the paper recognizing that few studies were used in their analysis of asymptomatic transmission (four studies) as compared to symptomatic transmission (27 studies). Further, on December 29, 2020, Dr. Dean highlighted on social media that her study could not separate out asymptomatic and presymptomatic disease cases and instead directed those questions to the data presented from Qiu et al. which did directly assess this (<https://twitter.com/nataliexdean/status/1343989533050867712?s=20>). Dr. Zachary Madewell also provided additional context and commentary on the JAMA analysis on February 17, 2021:

February 17, 2021

Comment from the authors

Zachary Madewell, PhD, MPH | University of Florida

Thank you for your interest in our paper. In this sub-analysis of the household studies from our main analysis, we separated papers reporting index cases identified as symptomatic versus asymptomatic/pre-symptomatic. We noted lower transmission from this latter group, though we state that there was much less data. For this reason, we view the qualitative result as noteworthy but requiring further exploration. Since we relied upon other studies in the literature, we were unable to separate out fully asymptomatic index cases (who never develop symptoms) from pre-symptomatic index cases. A more recent meta-analysis has focused directly on separating these two groups (<https://pubmed.ncbi.nlm.nih.gov/33484843/>). The growing literature indicates that, while individuals can be similarly infectious during the pre-symptomatic and symptomatic phases, individuals who are fully asymptomatic are less infectious to others (summary secondary attack rate of 1% from Qiu et al. 2021). This may explain the low secondary attack rate we observed in our sub-analysis.

Qiu et al. assessed available secondary attack rate data from individuals with asymptomatic, pre-symptomatic and symptomatic SARS-CoV-2 infection. Eighty studies were included for their analysis and in agreement with other investigations, secondary attack rates (defined as the probability that an infected individual will transmit the disease to a susceptible individual) from asymptomatic cases were found to be lower than symptomatic cases (Qiu et al. 2021). Importantly, their analysis demonstrated that secondary attack rates were similar between presymptomatic and symptomatic cases.

More recently, Bi et al. assessed household transmission from asymptomatic patients as compared to those with symptoms (Bi Q 2021). Using serology testing, the authors used a population serosurvey of 4,534 individuals (≥ 5 years of age) in Geneva, Switzerland, across 2,267 households from April-June 2020. The risk of infection was three times higher for household exposures as compared to those outside of the household. Here, asymptomatic infections accounted for 14.5% (95% CI, 7.2-22.7%) of all household infections and had 0.31 times the odd ratio of infecting another household member compared to those with symptomatic infections. As stated directly by the authors, “While asymptomatic individuals appear to be less than a third as likely to transmit, they cannot be dismissed as inconsequential to disease spread, and are responsible for one in six within-household transmissions in this study”. The authors also commented on the fact that while their study did not assess asymptomatic spread in community settings, it is plausible that those with asymptomatic infections could play an even larger role there in regards to transmission as symptomatic individuals would be more likely to stay home or seek care.

It must be appreciated that while presymptomatic transmission likely plays a larger role in community transmission than asymptomatic transmission, there is also a reliance on the recognition of clinical symptom onset by individuals once they enter into the symptomatic phase of disease. As highlighted previously, given the mild and broad nature of clinical presentation in mild disease, it should be appreciated that there is no single indicator of infection outside of testing and many reports describing transmission events are related to index patients that attended events just prior to, or coincident with, the onset of clinical symptoms of disease.

There have been numerous investigations on the relation between viral load, transmission and biological characteristics including age, sex and disease severity. A recent systematic review by Koopmans et al. reviewed data from 26 studies to determine the relation between viral load dynamics and Covid-19 severity, age and sex (Chen PZ 2021). Higher viral loads were found in those with severe disease as compared to those with non-severe infections. Interestingly, viral load within those with symptomatic infections was not altered by age or sex as children had similar viral loads following symptom onset as their non-severe adult counterparts. While severe Covid-19 has largely been linked to age and underlying health comorbidities, there is growing appreciation that children can be infected and transmit SARS-CoV-2. Recent reports have suggested that transmission is efficient in children ≥ 10 years old (Szablewski et al. 2020; Park, Choe, et al. 2020). In the conclusion of the analysis of SARS-CoV-2 transmission at the summer camp in Georgia (Szablewski et al. 2020), Szablewski et al suggested that asymptomatic infection was common amongst the cases and could have contributed to undetected transmission as suggested in additional studies (Team 2020; Dong et al. 2020; Gotzinger et al. 2020; Huang et al. 2020). More recently, a case report from Lopez and colleagues investigated Covid-19 outbreaks at childcare facilities in Utah (Lopez et al. 2020). Twelve children (mean age 7 years; range 0.2-16 years) were found to have acquired SARS-CoV-2 in the facilities and transmitted the virus to 12

of 46 non-facility contacts that were assessed. Importantly, three of 12 children had asymptomatic infection (25%) and two transmitted the virus. It must also be appreciated that reduced incidence of severe disease in children is not equivalent to the absence of severe disease risk. The US Centers for Disease Control and Prevention estimate that the prevalence of obesity in US children is ~19%, a comorbidity linked to higher risk of severe Covid-19 ([Childhood Obesity Facts | Overweight & Obesity | CDC](#)), and higher amongst minority populations, which have been disproportionately affected by Covid-19 (Abedi et al. 2021). In Canada, children ≤ 19 years have thus far accounted for 1.8% of Covid-19-related hospitalizations, in line with US estimations from the American Academy of Pediatrics of 1.3-3.1% ([COVID-19 and Age \(aap.org\)](#)).

Taken together, there is strong scientific evidence for SARS-CoV-2 transmission to primarily occur from a few days prior to symptom onset up to ~5 days post-onset. Direct assessments of viral loads and the kinetics of viral shedding, when virus is released from infected cells in the respiratory tract, are in agreement with this and contact tracing studies in household cohort studies provide direct evidence for asymptomatic and presymptomatic transmission of SARS-CoV-2. Further, additional epidemiological studies of SARS-CoV-2 suggest that similar patterns of asymptomatic and presymptomatic transmission likely occur within children as with adults.

In sum, it is clear that people who have SARS-Cov-2 but are not displaying any symptoms still can and do transmit the disease and infect others. Accordingly, relying on symptom checks alone would not be an effective way to control the spread of COVID-19 in group settings.

Transmission Related to Activities

Exposure risk guidance is primarily based on the relation between exposure time and SARS-CoV-2 infection. By Health Canada guidelines, a high risk exposure (close contact) includes anyone that has shared an indoor space with a positive Covid-19 case for a prolonged period (a period of 15 cumulative minutes over 24 hours) without adhering to appropriate mitigation measures (Canada 2020). This also includes anyone with a close-range contact with a positive Covid-19 case or anyone that has been in settings where that person engaged in singing, shouting or heavy breathing (including exercise). Given the role of aerosol exposure in transmission, the accumulation of virus-laden aerosol particles in the air of an enclosed setting could result in continued exposure of individuals to virus over a prolonged period.

There have been multiple superspreader events during the Covid-19 pandemic that have been linked to close contacts in enclosed settings, including faith-based settings or places of worship. Most notably, infection of 53 of 61 attendees (33 confirmed and 20 probable cases) from a single symptomatic individual occurred during a 2.5-hour choir practice in Skagit County, Washington, USA (Hamner et al. 2020). Three of those infected during the practice were hospitalized and two succumbed to infection. A similar superspreader event occurred in Arkansas where 35 of 92 church attendees were infected, three fatally, during a five-day period (March 6-11) (James et al. 2020). Additionally, contact tracing found at least 26 additional Covid-19 cases among community members that had reported contacts with church attendees and had likely been infected during those contacts, including a fatal disease case. The index cases, a husband (pastor at the church) and his spouse, were likely infected during a two-day period

(March 6-8) with potential presymptomatic transmission from the pastor to others during a group event on March 11. Of the 61 total identified cases (35 church attendees and 26 contacts), eight were hospitalized and four had fatal infections. These observations have not been limited to North America. A superspreading event linked to a service at Shinchunji Church of Jesus, Daegu, South Korea is postulated to have resulted in >3,900 secondary Covid-19 cases (Shim et al. 2020) and choir-related outbreaks have been reported in Berlin and Amsterdam (Bahl et al. 2020).

Alsved et al. recently examined exhaled respiratory particle generation during breathing, talking and singing (Alsved M 2020). The generation of aerosol particles, as determined by particle number emission rates, were highest from those singing loudly with exaggerated diction followed by loud singing alone, normal singing, loud talking, normal talking and breathing. Addition of a face mask to those singing loudly reduced particle emission rates to levels found during normal talking. The authors examined SARS-CoV-2 release from those with confirmed Covid-19 during singing and talking. While virus was not detected, the authors identified several limitations in the study including variations in patient viral loads, test positivity versus infectious virus presence in the respiratory tract, and dilution steps in the sample preparation method.

These observations are in line with prior studies looking at respiratory viruses and aerosol particle emission. Previously, Lindsley and colleagues examined the release of influenza virus in aerosol particles during coughing and exhalation (Lindsley et al. 2016). The authors collected aerosol particles produced during coughing or exhalation from 61 patients with influenza-like illness. Aerosol particles with infectious virus were collected from 28 (53%) patients while coughing and 22 (42%) patients from exhalation. These results demonstrated that normal exhalation can generate virus-laden infectious particles which could potentially lead to virus accumulation over extended periods of exposure in an enclosed setting.

Previous investigations have also assessed droplet and aerosol emission during common vocal activities. An investigation by Bahl et al. examined the spread of droplet and aerosol generation during singing (Bahl et al. 2020). This was done using a detailed flow visualization of aerosols and droplets emitted during singing of a major scale using an image-based flow diagnostic system. The authors found that droplets generated by singing did not settle rapidly suggesting high aerosol generation which could saturate the indoor environment in the absence of adequate ventilation. Further, the direction of the generated droplets suggested that they could pose a potential infectious risk for other members arranged in multiple adjacent and distant rows. Recommendations from the authors to reduce droplet and aerosol exposure included reduction in group numbers, greater physical distancing between members, softer singing and shorter duration, and the implementation of face masks. Of interest, prior investigations of particle emission patterns during normal speech by Asadi and colleagues demonstrated that particle emission during normal speech is correlated with the loudness of vocalization, is highly heterogeneous and could amplify respiratory pathogen transmission (Asadi et al. 2019). A similar study from Mürbe and colleagues assessed the release of aerosol emissions from adolescents: four boys and four girls aged 13-15 (Murbe et al. 2021). Overall, while the emission spectrum reflected that found in adults (highest during shouting followed by singing and speaking) the emission of aerosol particles was lower during singing than adults. However, particle emission was within the same order of magnitude between the two groups during speaking. In a retrospective study, Wang and colleagues found that face mask use by

the primary case and family contacts prior to symptom onset in the primary case was 79% effective in reducing transmission (Wang et al. 2020).

Taken together, there is accumulating evidence and historical data demonstrating that SARS-CoV-2 emission from infected individuals is likely positively correlated with vocal activities and increases with the volume and exaggeration of vocalizations. Importantly, the emission of aerosol particles is of particular importance given that they can accumulate in the air of enclosed spaces over time based on their physical characteristics and increasing the potential for infection beyond proximal contacts (at 2 m or less in distance away). This highlights the importance of reducing emissions through nonpharmaceutical interventions including masking and social distancing.

3. Non-pharmaceutical interventions reduce SARS-CoV-2 transmission

Non-pharmaceutical interventions (NPIs) are actions, apart from getting vaccinated and taking medicine, that people and communities can take to help slow the spread of illnesses. These can include a variety of different actions, such as wearing face masks and other personal protective equipment, washing hands, social distancing, restricting gatherings, and, in more serious situations, stay-at-home orders or lockdowns. NPIs continue to play a central role in disrupting SARS-CoV-2 transmission chains. It must be appreciated that Covid-19 control is not a decision between unrestricted transmission and lockdowns. Lockdowns and stay-at-home restrictions should continue to be a decision of last resort when community transmission can no longer be either controlled or monitored via testing and contact tracing. NPIs, including face masks, have been utilized as a mechanism to reduce transmission of SARS-CoV-2, including those that are infected prior to symptom onset (pre-symptomatic infections) as well as those that may have asymptomatic infections (no development of disease symptoms).

Brooks and Butler recently outlined the increasing data demonstrating that face masks are associated with reduced SARS-CoV-2 infections (Brooks and Butler 2021). The authors also highlighted recent work from Ruba and Pollak that assessed the ability of 81 racially-diverse children (7-13 years of age) to make accurate inferences regarding emotions when faces were partially occluded (Ruba and Pollak 2020). The authors concluded that the social interactions of children may be minimally impacted by face masks. Interestingly, Ruba and Pollak also demonstrated that the accuracy of children in identifying masked facial configurations did not significantly differ from those identified in facial configurations that wore sunglasses.

A recent investigation by Fischer et al. assessed relationships between adherence to mask wearing and Covid-19 case rates in the United States (Fischer et al. 2021). In their analysis, the authors used state-level data for the study. This investigation demonstrated that out of 15 states with no mask wearing policy, 14 had high monthly Covid case rates (>200 per 100,000 residents). Further, states with the lowest levels of mask adherence were most likely to have high Covid-19 case rates in the subsequent month, independent of either mask policy or demographics. Monthly case rates did not meet the high criteria across all eight states with $\geq 75\%$ mask adherence where case rates were 109.26 per 100,000 in the prior month as compared to 249.99 per 100,000 with lower mask adherence. Importantly, the authors noted that while there was strong supportive evidence for mask wearing reducing Covid-19 case rates, the relationship between mask policy and case rates was less stable. Thus, it is important to also consider the adherence and adoption to NPI recommendations rather than relying solely on mandated policies.

Similarly, Trauer and colleagues recently assessed the roles of NPIs and mobility restrictions on the trajectory of Covid-19 in the state of Victoria, Australia. Note that this is a preprint article that was posted to *medRxiv* on April 7, 2021 (Trauer JM 2021). The authors assessed the impact of these recommendations and policies on local Covid-19 cases in the southern hemisphere in Winter 2020. Through the authors' transmission model, the authors demonstrated that both face coverings (masks) and behavioral changes were associated with a significant reduction in transmission risk per contact. Importantly, masks had a considerably greater effect on reversing the epidemic, as stated by the authors. Pratt and colleagues assessed the implementation of community mitigation measures, which included stay-at-home orders and masking, on Covid-19 transmission in the Blackfoot Reservation, Montana, USA, from June to December 2020 (Pratt et al. 2021). Following the implementation of both stay-at-home orders and mask use, the incidence of Covid-19 decreased from 6.40 cases per 1,000 residents on October 5 to 0.19 cases per 1,000 residents on November 7. Of note, the average daily incidence was 0.10 in July and local campgrounds were opened following the expiration of prior mandatory stay-at-home orders. Daily incidence began to rise in August and while a recommended stay-at-home order was issued, incidence peaked at 6.40 on October 5, one week after the implementation and strict enforcement of a new stay-at-home order. Incidence decreased to 0.19 one month later.

An investigation by Flaxman and colleagues from June 2020 that was published in *Nature*, one of the top scientific journals in the world (2019 impact factor 42.779), analyzed mortality data from 11 European countries estimated lockdowns reduced the R_t of SARS-CoV-2 transmission by 81% (Flaxman et al. 2020). Further, the authors stated that while the rapid deployment of multiple NPIs made it difficult to characterize the individual effects of each intervention separately, the sole effect of lockdowns was identifiable. Lai and colleagues examined the effect of combined NPIs in SARS-CoV-2 transmission in China from early 2020 in *Nature* (Lai et al. 2020). The authors suggested that their data supported that both population movement and close contact were important drivers of virus transmission and that early detection and isolation of cases in tandem with social distancing were important for virus containment. Further, they estimated that without NPIs, the cases of SARS-CoV-2 infection in mainland China would have been 67-fold higher by the end of February. Cowling and colleagues used an observational study of SARS-CoV-2 and influenza infections in Hong Kong in early 2020 to reach similar conclusions - transmission can be contained through a combination of NPIs that included test, trace and isolate approaches, quarantining close contacts and behavioral changes (including social distancing and personal protective measures) (Cowling et al. 2020).

In sum, NPIs are extremely effective in reducing the spread of SARS-CoV-2 in a population, especially when used in combination, and are indeed necessary to limit exponential spread which could otherwise overwhelm healthcare resources.

4. SARS-CoV-2 Variant of Concern

The emergence of SARS-CoV-2 variants of concern, where mutations have resulted in phenotypic changes within the virus (including increased transmission and disease severity, reduced vaccine effectiveness, detection failure) have had deleterious health consequences in Canada and abroad. While variants emerge frequently within RNA viruses due to error-prone genome replication, including coronaviruses, these mutations often have negligible effects on viral behaviors or activities. In contrast, variants of concern have emerged infrequently throughout the pandemic but have resulted in devastating waves of Covid-19. It has been suggested that the selection of variants at the population level is likely not driven by host immunity because there are not sufficient numbers of immune individuals to push

evolution of the virus in a given direction (Lauring and Hodcroft 2021). Rather, there is supporting evidence to suggest that variants of concern may have emerged in chronically infected Covid-19 patients. A preliminary characterization of the Alpha variant, formerly B.1.1.7, by Rambaut and colleagues highlighted that the accumulation of 14 amino-acid replacements found within B.1.1.7 prior to the initial detection of this variant was thus far unprecedented in the pandemic. In contrast to this, the authors noted that most branches in the global SARS-CoV-2 phylogenetic tree had shown relatively few mutations with a fairly rate of accumulation over time (~1-2 nucleotide changes per month) (Rambaut A 2020). However, prior studies of chronic SARS-CoV-2 infections in immunodeficient or immunocompromised patients have demonstrated high rates of mutation accumulation over short periods of time (Choi et al. 2020; Avanzato et al. 2020). Thus, the evolutionary dynamics and selective pressures exerted upon the virus population within such patients are likely very different from those found during a typical infection. Kemp and colleagues characterized the evolution of SARS-CoV-2 in a chronically-infected immunocompromised patient following multiple therapeutic treatments (Kemp et al. 2021). Remdesivir treatment during the first 57 days had negligible effects on the viral population; however, convalescent plasma therapy resulted in large population shifts and the emergence of a dominant variant. This demonstrated a strong selection for viral variants with reduced susceptibility to neutralizing antibodies following treatment of an immunosuppressed individual with a chronic SARS-CoV-2 infection. Generally, there is relatively limited within-host variation reported for SARS-CoV-2 over the course of infection (Jary et al. 2020; Shen et al. 2020; Capobianchi et al. 2020). However, factors such as prolonged infection and immunodeficiencies could result in selective pressures not encountered within those that are immune-competent. Thus, the strongest evidence to date suggests that prolonged infections and compromised immune system functions likely exert selective pressures on SARS-CoV-2 resulting in a more extensive genetic changes than found during typical infections. More recently, a pre-print study from Niesen and colleagues posted on July 5, 2021, suggests that viral genomic diversity was reduced in patients that were vaccinated as compared to unvaccinated individuals (Niesen MJM 2021). Through a longitudinal analysis of more than 1.8 million viral genomes spanning 183 countries, the authors showed that SARS-CoV-2 diversity decreases at the country-level with increasing vaccination status and that breakthrough infections harbored viruses with lower diversity in B cell epitopes as compared to those found in unvaccinated patients. The recent emergence of SARS-CoV-2 variants of concern, which includes Alpha (first identified in the UK), Beta (first identified in South Africa) Gamma (first identified in Brazil), and Delta (first identified in India) has resulted in new concerns regarding the global burden of Covid-19. Concerningly, Alpha has increased transmissibility ranging from 30-70% over circulating non-variants of concern and has been associated with increased risk of severe and fatal disease in hospitalized patients (Horby P 2021). The emergence of Alpha in the UK resulted in the overtaking of circulating SARS-CoV-2 strains within a few months, a trend echoed in additional countries including Canada, and currently being repeated with Delta. The enhanced transmissibility associated with these variants have resulted in renewed public messaging regarding the importance of infection prevention and control measures, including mask use and social distancing, to curb community transmission of these variants of concern and others that may emerge. There have also been concerns regarding the potential for re-infections by VOCs due to their adoption of mutations associated with immune evasion and decreased ability for antibodies from convalescent Covid-19 patients or vaccinees to neutralize these variants. Thus, decreased community transmission will reduce the potential for additional emergence of variants of concern that could have better immune escape mechanisms that could have detrimental impacts on global vaccination programs.

5. Herd Immunity and Vaccinations

In Canada, variants of concern had deleterious effects on health and healthcare systems across many regions during the third wave of Covid-19 in early 2021. While the high mortality associated with individuals living in long-term care facilities and personal care homes were drastically reduced during the third wave, hospitalizations and ICU admissions pushed healthcare systems beyond their capacity in numerous jurisdictions. Notably, Manitoba transferred Covid-19 patients out of province for care to Ontario, Alberta and Saskatchewan due to ICU capacity limits. The Ontario Covid-19 Science Table released a report on March 29, 2021, detailing increasing trends in hospitalizations and ICU admissions as compared to late December 2020, during the second pandemic wave

(<https://doi.org/10.47326/ocsat.2021.02.18.1.0>). The authors noted that patients ≤ 59 years comprised 46% of all new COVID-19 ICU admissions to ICUs, compared with 30% just prior to the start of the province-wide lockdown in December 2020. Similar trends in other regions of the country during the third wave demonstrated that the view of younger age groups as being refractory to severe disease were flawed. Mass vaccination rollouts coupled with restrictions in regions with high rates of community have coincided with decreased cases and test positivity rates. Test positivity rates in Ontario have subsequently fallen from +10% in late April to 1.1% on July 6, 2021.

There have been rampant discussions regarding the potential of natural herd immunity, dictated by broad infections in the community, as a mechanism to curb global transmission of SARS-CoV-2. While focused protection has been raised as a mechanism to protect those at highest risk for severe disease while allowing the virus to transmit in the absence of broad employment of nonpharmaceutical interventions, there are serious concerns regarding the public health outcome of such a strategy. In particular, the resurgence of Covid-19 in Manaus, Brazil, provides a cautionary tale for a natural infection-based herd immunity-style approach. Manaus was devastated by the first wave of the pandemic with 4.5-fold excess mortality (Orellana et al. 2020). A serological assessment of antibodies in Manaus suggested that between 44-66% of the population was infected with SARS-CoV-2 by July 2020, which followed the epidemic peak (Buss et al. 2021). This rate rose to 76% by October 2020, surpassing the theoretical herd immunity threshold for Covid-19 of 67%. However, virus transmission continued with a devastating second surge of SARS-CoV-2 infections by mid-January 2021 (Sabino et al. 2021). The authors provided four potential explanations for their observations. First, attack rates could have been overestimated during the first wave. However, as the authors suggest, even with an upwards bias there should have still been a larger effect of population immunity given the breadth of the first wave in 2020. Second, the authors raised concerns regarding the potential impacts of waning immunity in those that were previously infected. Could decreasing protective immunity in individuals infected during the first wave have resulted in a resurgence of Covid-19 due to reinfections in this population? Such a phenomenon would be devastating for an infection-based herd immunity strategy as the threshold for sustained herd immunity to curb virus transmission would be impeded. Third, the emergence of virus variants that might evade immunity generated from prior SARS-CoV-2 infection. Two virus variants, P.1 and P.2, have been identified in Brazil that possess a mutation in the spike protein that has been associated with immune evasion. Reinfections have been identified in Brazil for both P.1 and P.2 (Naveca F 2021; Vasques Nonaka 2021; Resende PC 2021). And fourth, new SARS-CoV-2 variants circulating in Manaus may have higher transmissibility than currently circulating strains. The emergence of the VOCs have served as a continuing reminder that ongoing transmission of the virus results in mutations within the viral genome that could lead to increased rates of infection.

India experienced a devastating second wave of Covid-19 in 2021, with 414,188 new cases reported on May 7, the most reported during a 24 hour period throughout the pandemic ([india-situation-report-72.pdf \(who.int\)](#)). By the end of May, India had recorded more than 300,000 deaths due to Covid-19 with ~100,000 occurring the prior 26 days, including 50,000 deaths the prior 12 days (<https://timesofindia.indiatimes.com/india/indias-covid-toll-tops-3-lakh-50000-deaths-in-12-days/articleshow/82892432.cms>). This contrasted with opinions provided in *The Print* (Agarwal S 2021) suggesting that mathematical modelling demonstrated that “more than 50% of the Indian population may have developed immunity” and were corroborated by serological tests by Thyrocare. However, this data contrasted with data released on March 30, 2021, where IgG antibodies against either the N or S1-RBD virus proteins were found in 26% of samples (Murhekar MV 2021). High seroprevalence levels ($\geq 50\%$) would have been expected to reduce the toll of subsequent pandemic waves. This is also the case for the high seroprevalence data suggested in Brazil from investigations in Manaus, Brazil, where the country was also enveloped in a devastating wave of infections starting in early 2021.

Over-estimations of seroprevalence could ultimately have far reaching consequences if used to guide Covid-19 public health responses if assumptions are made regarding levels of immune protection within communities. In addition, herd immunity thresholds are fluid given the reliance on R_0 and shifts in this value due to the emergence of the more transmissible variants of concern, including the newly identified Delta variant (B.1.617.2) that was first identified during the second pandemic wave in India. The herd immunity threshold (HIT) can be calculated using the formula: $HIT = 1 - 1/R_0$, where R_0 (the basic reproduction number) represents the transmissibility of a virus. For the ancestral strain of SARS-CoV-2, this was estimated to be 2-4, so $HIT = 50-75\%$. However, the increased transmissibility of Alpha (~50% more transmissible than the ancestral strain) and Delta (~50% more transmissible than the Alpha variant) variants will result in higher R_0 values that drive up the HIT. Randolph and Barreiro also discussed additional considerations that must be appreciated when estimating HIT, “It relies on several key assumptions, including homogeneous mixing of individuals within a population and that all individuals develop sterilizing immunity—immunity that confers lifelong protection against reinfection—upon vaccination or natural infection. In real-world situations, these epidemiological and immunological assumptions are often not met, and the magnitude of indirect protection attributed to herd immunity will depend on variations in these assumptions” (Randolph and Barreiro 2020).

In sum, reaching herd immunity without vaccines would require somewhere between 50-90% of the population to get infected. At Alberta’s population of 4.4 million, this would equate to roughly 2.2-4 million people infected. Using a conservative death rate of 1% this would equate to 22,000-40,000 deaths. However, if SARS-Cov-2 was allowed to spread exponentially without NPIs, the real death toll would actually be much higher, as the death rate would necessarily increase for patients who cannot access healthcare resources.

As Randolph and Barreiro noted, “Particularly in the context of attaining herd immunity to SARS-CoV-2, a regard for finite healthcare resources cannot be overstated, as this policy inherently relies on allowing a large fraction of the population to become infected. Unchecked, the spread of SARS-CoV-2 will rapidly overwhelm healthcare systems. A depletion in healthcare resources will lead not only to elevated COVID-19 mortality but also to increased all-cause mortality. This effect will be especially devastating for countries in which hospitals have limited surge capacity, where minimal public health infrastructure exists, and among vulnerable communities, including prison and homeless populations”.

Krammer and colleagues recently investigated the effect of vaccines on previously infected individuals (Krammer et al. 2021). Their study involved 110 participants with or without pre-existing SARS-CoV-2 immunity. Vaccinees with pre-existing immunity developed antibody titers 10-45 times as high as those without pre-existing immunity at the same time point following the first vaccine dose. A second dose of vaccine in the Covid-19 survivors had no further enhancement on antibody titers. While vaccinees with pre-existing immunity had higher frequencies of local and systemic side effects, no severe adverse events were reported.

Following the emergence and global spread of the SARS-CoV-2 Delta variant, now considered a VOC, there has been an expeditious effort to define the transmissibility and sensitivity to immune responses for this variant. Transmissibility is now generally regarded as to be ~50% greater than the Alpha variant. A recent publication from Planas and colleagues suggests that sera from long-term convalescent patients had reduced capacity to neutralize the Delta variant (Planas D 2021). In contrast, vaccination of resulted in a strong humoral immune response within these individuals resulting in elevation of neutralizing antibodies well above the threshold of neutralization. The authors stated that vaccination of previously infected individuals would likely result in protection against SARS-CoV-2 variants.

6. Ongoing and Future Research

There are many aspects of Covid-19 that will need to be continually researched in both the short- and long-term. Notably, research into the further understanding of the specific host and viral factors that underlie transmission needs to continue (including the minimum infectious dose, virus concentrations and viability in indoor and outdoor settings). Thus, adherence to established nonpharmaceutical interventions should remain the focus of the global response pending further research. In addition, the paucity of frontline antiviral therapeutics for those that have symptomatic infections or are hospitalized are desperately needed. Lastly, detailed understanding of the role of social determinants in Covid-19 disease severity and transmission are desperately needed.

Long-term complications in Covid-19 recoverees

There is a growing appreciation that Covid-19 can result in extended health complications and abnormalities, independent of disease severity and age (Rubin 2020). These include extended fatigue, shortness of breath, joint and chest pain, and neurological complications. A recent study from Italy suggested that 44% of recovered patients reported a worsened quality of life post-Covid-19 (Carfi et al. 2020). A US study by Tenforde et al. reported that 35% of surveyed patients had not returned to their normal state of health two to three weeks following a positive Covid-19 test result with 20% of those surveyed being 18-34 years of age with no underlying chronic medical conditions at the time of survey (Tenforde et al. 2020).

Reproductive health concerns

Recent data has suggested that severe Covid-19 can result in reproductive tissue damage in males. An investigation by Ma et al. assessed pathology in the testes from males with fatal disease and found strong signs of germ cell damage and may indicate the potential for reproductive health impairment in severe disease (Ma et al. 2021). Yang and colleagues had similar observations for reproductive tissue damage in deceased male Covid-19 patients including seminiferous tubular injury, reduced Leydig cell populations and mild lymphocytic inflammation (Yang, Chen, et al. 2020). There have also been recent

insights regarding the potential for Covid-19-related complications during pregnancy. Yang et al. provide evidence that SARS-CoV-2 infection during late pregnancy is associated with increased risks of adverse birth outcomes (Yang, Mei, et al. 2020). Kotlyar et al. also recently provided evidence for vertical transmission of SARS-CoV-2 in the third trimester (Kotlyar et al. 2021). These data suggest that SARS-CoV-2 infections may have impacts on both reproductive health and pregnancy that could have detrimental impacts on younger populations.

In conclusion, data overwhelmingly suggests that both asymptomatic transmission and presymptomatic transmission contribute to SARS-CoV-2 transmission with increasing reports suggesting that presymptomatic transmission in particular plays an important role in these events. Given this, there is an inherent need to utilize nonpharmaceutical interventions including, but not limited to face masks, to reduce transmission events from those in our communities that are unaware that they are infected and contagious. Primary points of consideration include:

- **Morbidity and mortality:** while much of the pandemic has centered around the increasing fatalities nationally and globally, there has been less discussion regarding the effects of Covid-19 associated morbidity. Hospitalization data demonstrates that this disease can have health impacts on individuals across multiple age groups and adds significant stress on national healthcare systems and capacity.
- **SARS-CoV-2 transmission routes:** there is growing appreciation for the role of aerosols in SARS-CoV-2 transmission in addition to respiratory droplets. Aerosols have the potential for broader transmission within enclosed settings in the absence of multiple nonpharmaceutical interventions (including face masks, distancing, ventilation) and data demonstrates that aerosols may be an important factor in presymptomatic transmission of the virus.
- **Nonpharmaceutical interventions:** while there is strong evidence that face masks provide a benefit for reducing SARS-CoV-2 transmission they are not a single failsafe intervention measure. This requires a multi-faceted approach that includes multiple interventions due the synergistic effects these measures.
- **VOCs and herd immunity:** the recent emergence of SARS-CoV-2 variants of concern that have increased transmissibility and the immune evasion characteristics supports the need to curb transmission in the global community quickly prior to further variant emergence. VOCs may be able to circulate even in populations that have exceeded the proposed herd immunity threshold with potentially devastating public health consequences. Thus, approaches that combine nonpharmaceutical interventions in addition to expanding vaccination campaigns will have the greatest opportunity to curb community transmission of the virus expediently.

Schedule B

Jason Kindrachuk, PhD

Laboratory of Emerging and Re-emerging Viruses
 Department of Medical Microbiology & Infectious Diseases
 University of Manitoba
 Winnipeg, MB, Canada
 Tel: (204) 789-3807
 Email: Jason.Kindrachuk@umanitoba.ca

EDUCATION

- 2002-2007 **Ph.D., Department of Biochemistry**
 University of Saskatchewan, Saskatoon, SK, Canada
 Supervisor: Dr. Scott Napper
 Thesis Title: *Host and Pathogen Sensory Systems as Targets for Therapeutic Intervention*
- 1996-2001 **B.Sc. (Honors), Department of Biochemistry**
 University of Saskatchewan, Saskatoon, SK, Canada

PROFESSIONAL EXPERIENCE

- 2017-present **Assistant Professor**
Canada Research Chair
 Laboratory of Emerging and Re-Emerging Viruses
 Department of Medical Microbiology and Infectious Diseases
 University of Manitoba
 Winnipeg, MB
- Associate Professor**
 Department of Biochemistry
 College of Medicine and Allied Health Sciences
 University of Sierra Leone
 Freetown, Sierra Leone
- 2014-2016 **Staff Scientist**
 Critical Care Medicine Department
 Clinical Center
 National Institutes of Health, Bethesda, MD, USA
- Sept 2014 **Scientific Lead – Field Diagnostics**
 Ebola Virus Disease Outbreak Response Efforts
 Centers for Disease Control/Department of Defense Joint Operations
 Monrovia, Liberia
- 2013-2014 **Principal Research Scientist**
 Battelle Memorial Institute
 Integrated Research Facility
 National Institutes of Allergy and Infectious Diseases
 National Institutes of Health, Frederick, MD, USA

- 2009-2013 **Visiting Fellow**
Emerging Viral Pathogens Section
National Institutes of Allergy and Infectious Diseases
National Institutes of Health, Bethesda, MD, USA
- 2007-2009 **Postdoctoral Fellow**
Centre for Microbial Diseases and Immunity Research
Department of Microbiology and Immunology
University of British Columbia, Vancouver, BC, Canada

SCIENTIFIC AFFILIATIONS & COMMITTEE ACTIVITIES

Affiliations

- 2020-present **Visiting Scientist** – Vaccine and Infectious Disease Organization-International Vaccine Centre
- 2020-present **Science Contributor** – Forbes Media, LLC
- 2020-present **Volunteer, Regional Leader** – COVID-19 Resources Canada
- 2020-present **Volunteer, Infection Control Lead** – Heart to Heart International COVID-19 Preparedness and Response Efforts
- 2019-present **Visiting Researcher** – The International Center for Medical Research in Franceville, Gabon (CIRMF)
- 2018-present **Visiting Scientist** – Public Health Agency of Canada, Special Pathogens Section
- 2018-present **Visiting Scientist** – Canadian Food Inspection Agency, Special Pathogens Unit
- 2017-present **Investigator** – Children's Health Research Institute of Manitoba

Committees and Review Panels

- 2020 **Panel Member** – CIHR Institute of Infection and Immunity Consultation on Variant Strains of SARS-CoV-2
- 2020 **Member** – World Health Organization COVID-19 Solidarity Serology Study Group
- 2020 **Member** – World Health Organization Ad Hoc Committee on COVID-19 Animal Models
- 2020 **Session chair** – Tuberculosis and other Infectious Diseases, University of Nairobi HIV/AIDS Collaborative Conference
- 2019-present **Member** – Community for Emerging and Zoonotic Diseases, Canadian Network for Public Health Intelligence (CNPHI)
- 2019 **Member** – CIHR Strategic Planning Meeting
- 2019 **Review Panel Member** – New Frontiers in Research Fund Exploration Grant
- 2018-present **Director** – Canadian Society for Virology Executive Council
- 2018-present **Member** – CIHR College of Reviewers
- 2018 **Co-Chair** – Emerging Viral Diseases and Global Preparedness Symposium
- 2018 **Organizing Committee Member** – Canada's Role in Global Public Health Conference
- 2017-present **Review Panel** – American Association for the Advancement of Science (AAAS) Research Competitiveness Program

- 2017-present **Reviewer** – Manitoba Poster Competition of the Canadian Student Health Research Forum
- 2017-present **Review Panel** – Research Manitoba PhD Scholarship Competition
- 2016 **External Reviewer** – National Science Centre, Poland (Narodowe Centrum Nauki – NCN) PRELUDIUM Funding scheme
- 2014 **Reviewer** – Alberta Livestock and Meat Agency (ALMA)
- 2012-2013 **Scientific Advisor** – World Health Organization Advisory Committee on Variola Virus Research (ACVVR): Provided updates and participated in critical discussions regarding ongoing variola virus research as a member of the US delegation

AWARDS & HONOURS

- 2021 Ken Hughes Young Investigator's Award in Medical Research
- 2021 Campbell Outreach Award
- 2018 Department of Medical Microbiology Faculty Educator Award
- 2018 National Institutes of Allergy and Infectious Diseases Merit Award
- 2017 Tier 2 Canada Research Chair Award
- 2015 National Institutes of Health Director's Award
- 2015 National Institutes of Health Clinical Center Summer Internship Program Best Mentor Award
- 2013 University of Maryland Integrated Life Sciences Honors College Mentor Award
- 2010-2013 National Institutes of Health Visiting Fellow Intramural Research Training Award

SCIENTIFIC JOURNAL ADVISORY BOARDS

- 2019-present **Guest Editor** – Viruses (Pathogenesis of Emerging Viruses Special Issue)
- 2019-present **Associate Editor** – Viruses
- 2019-present **Associate Editor** – Frontiers in Microbiology
- 2016-present **Associate Editor** – BMC Infectious Diseases
- 2014-present **Associated Review Editor** – Frontiers in Veterinary Science

PROFESSIONAL ASSOCIATIONS & MEMBERSHIPS

- 2019-present **Member** – Infectious Diseases Society of America
- 2017-present **Member** – Canadian Society for Virology
- 2017-present **Member** – Canadian Society of Microbiologists
- 2014-present **Member** – American Society for Microbiology
- 2014-present **Member** – American Society for Virology

FUNDING

1. Tier 2 Canada Research Chair in the molecular pathogenesis of emerging and re-emerging viruses.
Funding Sources:
 2017-2022 Canada Research Chairs Program
 Total Funding – 500,000 (Canadian dollar)
 Principal Investigator
2. Identification of the molecular determinants underlying asymptomatic Ebola virus testicular infections and long-term effects on reproductive health
Funding Sources:
 2021-2026 Canadian Institutes of Health Research Project Grant
 Total Funding – 726,500 (Canadian dollar)
 Principal Investigator
3. Cryo-electron microscopy (cryo-EM) to guide rapid development of novel therapeutic strategies and improved diagnostics for COVID-19
Funding Sources:
 Canadian Foundation for Innovation
 Total Funding – 950,000 (Canadian dollar)
 Co-Applicant
4. Animal models for SARS-CoV-2: vaccines and immune enhancement
Funding Sources:
 2020-2022 Canadian Institutes of Health 2019 Novel Coronavirus (COVID-19) Rapid Research Funding
 Total Funding – 999,793 (Canadian dollar)
 Co-Applicant
5. Scalable, Customizable, Digital Health Communication Materials to Help Canada Address the COVID19 Pandemic
Funding Sources:
 2020-2021 Canadian Institutes of Health COVID-19 Rapid Research - Social Policy and Public Health Responses
 Total Funding – 311,296 (Canadian dollar)
 Co-Applicant
6. Broad Spectrum CoV Therapeutic; rhACE2 Immunoadhesin to treat COVID19
Funding Sources:
 2020-2021 MITACS Accelerate
 Total Funding – 90,000 (Canadian dollar)
 Principal Applicant
7. Prairie Infectious Immunology Network 2020
Funding Sources:

2020-2021 Canadian Institutes of Health Research Planning and Dissemination Grant

Total Funding – 10,000 (Canadian dollar)

Co-Principal Investigator

8. Characterization of the molecular pathogenesis of severe influenza and influenza-bacterial infections at the alveolar-capillary barrier

Funding Sources:

2018-2020 Research Manitoba New Investigator Operating Grant

Total Funding – 130,000 (Canadian dollar)

Principal Investigator

9. Investigation of kinase-mediated cell signaling pathway modulation at the vector pathogen-livestock interface in vector-borne livestock diseases

Funding Sources:

2018/4 - 2023/3 Natural Sciences and Engineering Research Council of Canada (NSERC) Discovery Grant

Total Funding - 165,000 (Canadian dollar)

Principal Investigator

10. Establishment of a high-throughput molecular dynamics facility

Co-applicant: Denice Bay

Funding Sources:

2017/11 - 2022/11 Canada Foundation for Innovation (CFI) John R. Evans Leaders Fund

Total Funding - 609,191 (Canadian dollar)

Principal Investigator

11. Deciphering the bat kinome by immunometabolic peptide kinome arrays: critical insights for emerging viral diseases

Funding Sources:

2018/7 - 2019/6 University of Manitoba Dr. Paul H. T. Thorlakson Foundation Fund

Total Funding - 30,000 (Canadian dollar)

Principal Investigator

12. Characterizing the molecular mechanisms of Ebola virus persistence at the blood-testis barrier

Funding Sources:

2018/8 - 2019/4 University of Manitoba Tri-Agency Bridge Funding

Total Funding - 60,000 (Canadian dollar)

Principal Investigator

13. Characterizing the molecular mechanisms of Ebola virus persistence in a 3D co-culture model of the blood-testis barrier

Funding Sources:

2018/3 - 2019/3 Manitoba Medical Service Foundation (MMSF) Operating Grant

Total Funding - 19,219 (Canadian dollar)

Principal Investigator

14. Capacity Building Projects in an Institution of Higher Learning in the Developing World

Funding Sources:

2018/1 - 2019/10 University of Manitoba International Program and Partnership Seed

Total Funding – 5,000 (Canadian dollar)

Principal Investigator

INVITED PRESENTATIONS

1. Universal coronavirus vaccines: How close are we? **American Thoracic Society Annual Meeting**. Virtual. 2021

2. What virus goes there? Emerging virus research from the field to the lab. Molecular Biology & Biochemistry Department. **Simon Fraser University**. Virtual. 2021
3. Covid-19 and vaccine safety. Bisons Athletics. **University of Manitoba**. Virtual. 2021
4. Covid Q&A Part II with Raman Dhaliwal and Dr. Jason Kindrachuk. **University of Manitoba**. Virtual. 2021
5. Current perspectives on Covid-19. **British Columbia Dental Association**. Virtual. 2021
6. Covid-19: Current state of knowledge. **Wastewater Epidemiology Group**. Public Health Agency of Canada. Virtual. 2021
7. Covid-19: Current state of knowledge. **Covid-19 Genome Sequencing Group**. Public Health Agency of Canada. Virtual. 2021
8. Vaccines & therapeutics for COVID-19. **Café Scientifique**. Virtual. 2021
9. Balancing science and disinformation during Covid-19. Stem Skills for the 21st Century. **Bioscience Association of Manitoba**. Virtual. 2021
10. Eleven Covid months equals one decade - Emerging virus research during a pandemic. **Quebec Centre for Advanced Materials (QCAM)**. Virtual. 2020
11. Emerging Virus Research in the Time of Covid. Global Health Seminar Series. **Tel Aviv University**. Virtual. 2020
12. COVID-19 Transmission: Current state of virology knowledge. **Community-based aerosol transmission of Covid-19 and HVAC systems**. Canadian Agency for Drugs and Technologies in Health (CADTH). Virtual. 2020
13. Transmission Routes for COVID-19: Implications for Public Health. **CIHR-PHAC-CADTH – Best Brains Exchange**. Canadian Institutes of Health Research (CIHR). Virtual. 2020
14. Heating, Ventilation and Air Conditioning Systems in Public Spaces. Ottawa: **Canadian Agency for Drugs and Technologies in Health (CADTH)**. Virtual. 2020
15. 2020 Fall Member Forum: What's Next? The Aftermath of the COVID-19 Crisis. **Western Transportation Advisory Council (WESTAC)**. Virtual. 2020
16. Basic, Translational and Public Health Research During a Novel Pandemic. **School of Public Health, University of Saskatchewan**. Virtual. 2020
17. Characterizing tissue-barrier specific pathogenesis of epidemic and pandemic emerging viruses. **Infectious Disease, Microbiome, and Public Health Conference**. Virtual. 2020
18. COVID-19: Early Assessments of the First Coronavirus Pandemic. **Value Partners Annual General Meeting**. Virtual. 2020
19. COVID-19 and infection, prevention and control. **Canadian Dental Association**. Virtual. 2020

Abstract

Objectives There is preliminary evidence of racial and social economic disparities in the population infected by and dying from COVID-19. The goal of this study is to report the associations of COVID-19 with respect to race, health, and economic inequality in the United States.

Methods We performed an ecological study of the associations between infection and mortality rate of COVID-19 and demographic, socioeconomic, and mobility variables from 369 counties (total population, 102,178,117 [median, 73,447; IQR, 30,761–256,098]) from the seven most affected states (Michigan, New York, New Jersey, Pennsylvania, California, Louisiana, Massachusetts).

Results The risk factors for infection and mortality are different. Our analysis shows that counties with more diverse demographics, higher population, education, income levels, and lower disability rates were at a higher risk of COVID-19 infection. However, counties with higher proportion with disability and poverty rates had a higher death rate. African Americans were more vulnerable to COVID-19 than other ethnic groups (1981 African American infected cases versus 658 Whites per million). Data on mobility changes corroborate the impact of social distancing.

Conclusion Our study provides evidence of racial, economic, and health inequality in the population infected by and dying from COVID-19. These observations might be due to the workforce of essential services, poverty, and access to care. Counties in more urban areas are probably better equipped at providing care. The lower rate of infection, but a higher death rate in counties with higher poverty and disability could be due to lower levels of mobility, but a higher rate of comorbidities and health care access.

Keywords Healthcare disparities · Health status disparities · Socioeconomic factors · COVID-19 · Economic inequality · Racial disparity · United States · Population-based analysis · Ecological-based study

Introduction

The complexity of managing patients with the coronavirus disease 2019 (COVID-19), a global pandemic [1] originated in China [2], has led to the widespread implementation of preventative measures such as social distancing and mask use [3] in many countries including the United States (US). As of April 14, 2020, there were over 1.9 million confirmed cases around the world with 601,000 cases and 24,129 deaths in the US alone [4]. It has been reported that age 65 and older, body mass index ≥ 40 , diabetes [5] immunosuppression, smoking, hypertension, and cardiovascular diseases are underlying conditions that increase the risk of death from COVID-19 [6, 7].

The most recent conundrum of this disease is ascribed to the preliminary evidence of racial disparities in the population infected and dying from COVID-19 [3]. In a recent study, the Centers for Disease Control and Prevention (CDC) reported

data from fourteen states and suggested that the US Black population may be disproportionately affected by COVID-19 [3]. This observation is consistent with the influenza A (H1N1) pandemic where other studies showed evidence of racial and ethnic disparities in the population affected both in exposure, severity, and mortality of the disease [8, 9]. As states release the racial and ethnic demographic data of COVID-19 cases, in addition to the increased spread of this disease to the central states, it is imperative that we understand the patterns of infection and death to reduce the risks, especially for high-risk population, and resolve issues that impede the provision of optimal care.

In this study, we conducted an ecological-based analysis to explore racial and economic inequality associated with the infection rate and risk of mortality due to COVID-19 in the US. The goal of the study was to provide evidence on the association of COVID-19 with respect to race, income level, poverty, education, and the impact of preventative measures such as social distancing. We trust that the decision making by the states' officials will be driven by data and based on their unique needs and population characteristics to help in combating this disease.

Methodology

The study was conducted at two levels: (1) analysis of population characteristics (44 variables) for 369 counties in seven states which had the highest rate of COVID-19 infection as of April 9, 2020, along with COVID-19 infection and mortality rates. The included states were California, Michigan, New York, New Jersey, Louisiana, Pennsylvania, and Massachusetts; (2) analysis of COVID-19-related infection and death rate across all the states in the US with race/ethnicity information on the affected subject when available.

Data Source, Outcomes, and Independent Variables: Data sources in this study include (1) publicly available data from USAfacts and the US Census Bureau for COVID-19 cases and county-level demographic data [10, 11], (2) COVID-19 data reported by each state on their department of health websites [10], (3) State Population by race/ethnicity data [12, 13], and (4) mobility data extracted from Google [14].

The variables used in this study include county-level information on total population, mobility, race, poverty level, median income, education, disability, and rate of the insured population. Mobility data were extracted from Google as reported on April 05, 2020. The state-level data were extracted on April 16, 2020. The outcome variables include the rate of COVID-19 infection and all COVID-19-related death as provided by each state's department of health as of April 09, 2020. The infection rate is based on the reported results from all the laboratories testing samples in each county/state. The

mortality data are reported by hospitals, nursing homes, and other health facilities. Table 1 summarizes the data elements used in this study. Only data provided by the states on their official websites were included in this study. Additionally, to compare the rate of COVID-19 cases and death, the population data for each ethnic/racial group affected were extracted from health department websites.

Statistical Analysis We summarized all continuous variables as mean \pm standard deviation or median with inter-quartile range [IQR] and categorical variables as percentages. Data from different sources were extracted and analyzed for outliers. Values not within three inter-quartiles were removed as part of the data pre-processing. Each continuous variable was centralized and z score transformed. Thus, the transformed variables passed the normality test and the correlation matrix was created. Bivariate, partial correlation, and regression were used to test hypotheses of association. The correlation coefficients between "death rate" and "infection rate" with independent variables were calculated by Pearson's correlation (R corr package). Partial correlation was further evaluated by Pearson's correlation (R ppcor package) to determine if the existing correlation was still valid after controlling the second independent variable. The Bonferroni correction for multiple testing of controlling variables was considered to adjust the p value of the correlation. Bivariate linear regression adjusted for "State" variables was utilized to test the association between "death rate" or "infection rate" with independent variables. The raw p value was present in the forest plot. False discovery rate (FDR) corrections for multiple testing were calculated using the Benjamin and Hochberg procedure. Statistical analyses were performed using R version 3.6.2 [16]. and IBM SPSS Statistics 26 [17].

Results

Population, Mobility, and Socioeconomic Determinants

We extracted data from four different sources on 369 counties from seven states, including five states from the East Coast (Michigan, New York, New Jersey, Pennsylvania, and Massachusetts), one state from the West Coast (California), and one state from the South (Louisiana) with the total population of 102,178,117 (median, 73,447; IQR, 30,761–256,098). The information on race, income, education level, insurance, poverty, and disability including the description of abbreviated variables is summarized in Table 1, (Supplemental Table S1 includes additional summary statistics of the dataset).

Our data show a significant association among different socioeconomic determinants, such as poverty level, education,

and income (see Table S2). In particular, counties with a higher percentage of people below the poverty level had a significantly lower percentage of the population with higher education (Pearson correlation, -0.52 , $p < 0.005$ for Bachelor's degree; Pearson correlation, -0.61 , $p < 0.005$ for high school), as well as a lower percentage of people insured, but a higher percentage of people on Medicaid (Pearson correlation, 0.77 , $p < 0.005$) or on disability (Pearson correlation, 0.41 , $p < 0.005$; see Table S2 for more details). Counties with a higher percentage of residents below the poverty level had a higher percentage of Blacks (Pearson correlation, 0.52 , $p < 0.005$ for men; Pearson correlation, 0.50 , $p < 0.005$ for women) and a lower percentage of non-Hispanic Whites (Pearson correlation, -0.30 , $p < 0.005$ for men; Pearson correlation, -0.33 , $p < 0.005$ for women).

Counties with a Higher Total Population, More Diverse Demographics, Higher Education, and Income Level Are at a Higher Risk of COVID-19 Infection

The COVID-19 infection rate per one million (mean, 912.20 ± 1034.26) ranged from 15.36 to 5093.99 in different counties (Table 1 and S1). Figure 1 shows the map of Pennsylvania with total population for each county, rate of infection and death due to COVID-19 infection, as well as, median income in the counties and percentage of the population who are

identified as non-Hispanic Whites. The map of the other six states is provided as Supplemental Fig. S1-S6 for reference. The outliers were not removed in these figures.

The results of the bivariate linear regression (Fig. 2, Table S3) estimate effect sizes (regression coefficients) of a number of variables contributed to COVID-19 infection when controlled for states in the model. Counties with a higher population (est. 0.34 , 95% CI 0.24 , 0.44 , $q < 1.1E-08$), a higher median income (est. 0.36 , 95% CI 0.25 , 0.48 , $q < 2.3E-08$), and a more diverse population (higher percentage of Hispanics, Asians, and Blacks) have a higher rate of infection. More specifically, a higher percentage of Asians (est. 0.32 , 95% CI 0.20 , 0.44 , $q < 6.3E-07$, women; est. 0.32 , 95% CI 0.20 , 0.43 , $q < 4.5E-07$, men), Blacks (est. 0.47 , 95% CI 0.32 , 0.62 , $q < 2.3E-08$, women; est. 0.35 , 95% CI 0.20 , 0.51 , $q < 1.7E-05$, men), and Hispanics (est. 0.49 , 95% CI 0.34 , 0.64 , $q < 1.2E-08$, women; est. 0.46 , CI 0.31 , 0.62 , $q < 8.1E-08$, men) are associated with a higher rate of infection while a higher percentage of non-Hispanic Whites (est. -0.41 , 95% CI -0.55 , -0.26 , $q < 2.9E-07$, women; est. -0.44 , 95% CI -0.58 , -0.30 , $q < 4.2E-08$, men) is associated with a lower rate of COVID-19. Change in grocery mobility (est. -0.24 , 95% CI -0.36 , -0.13 , $q < 5.5E-05$), retail mobility (est. -0.26 , 95% CI -0.38 , -0.14 , $q < 4.5E-05$), and work mobility (est. -0.31 , 95% CI -0.43 , -0.20 , $q < 9.0E-07$) were associated with a lower rate of infection. Another protective factor in

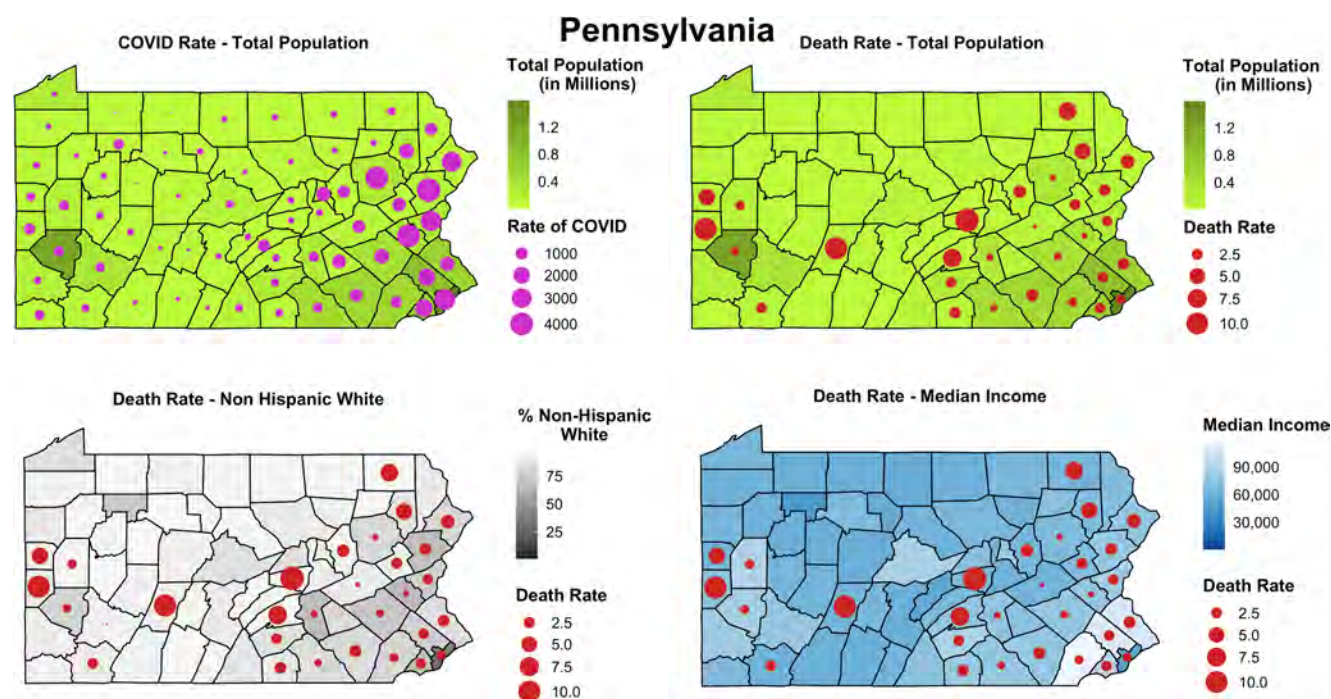

Fig. 1 Population count, non-Hispanic White, and Median Income and the rate of COVID-19 and related death in the counties of the state of Pennsylvania, as of April 9, 2020

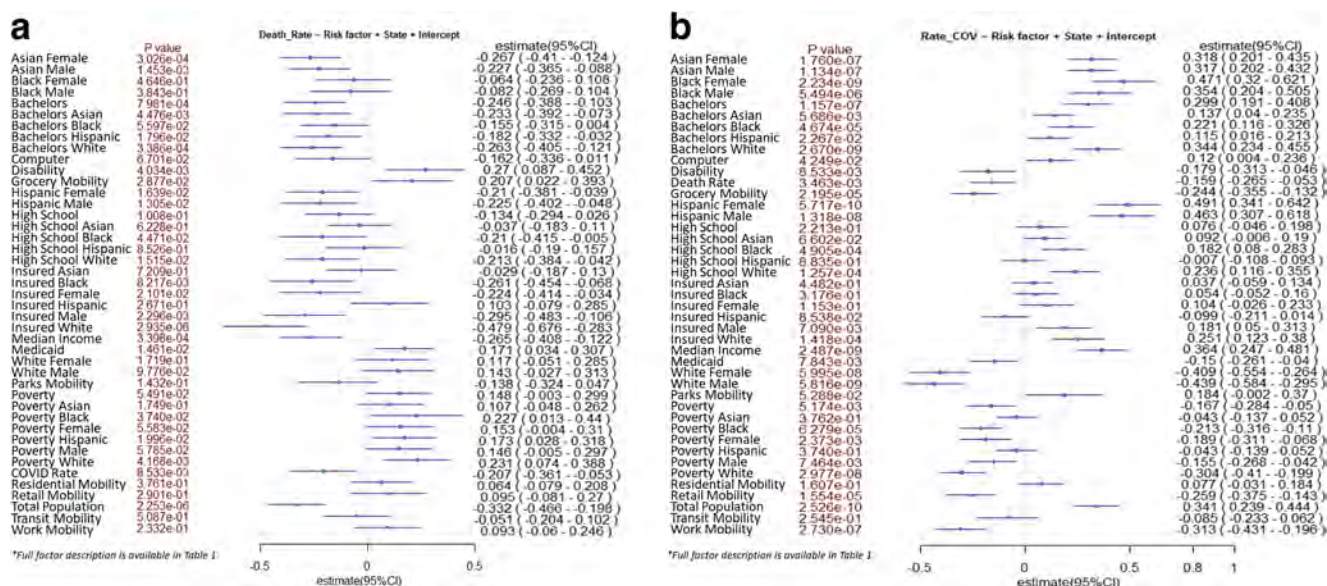

Fig. 2 a Bivariate analysis of factors for mortality due to COVID-19. b Bivariate analysis of factors for infection by COVID-19

terms of rate of infection for the counties analyzed was a higher percentage of disability (est. -0.159 , 95% CI $-0.265, -0.053$, $q < 0.006$). We also analyzed the rate of infection for counties with respect to their percentage of uninsured and found no significant association other than among men (est. 0.181 , 95% CI $0.05, 0.313$, $q < 1.2E-02$) and non-Hispanic Whites (est. 0.251 , 95% CI $0.123, 0.380$, $q < 3.1E-04$). Furthermore, in our stepwise regression model, minorities specifically Black and Hispanic women, poverty, and level of education among non-Hispanic Whites, disability, the total county population, and level of mobility are predictors of the rate of COVID-19 infection (Table S4).

Counties with a Smaller Population, Higher Poverty Levels, and Higher Disability Have a Higher Rate of Mortality

The COVID-19-related death (mean, $4.13\% \pm 2.70\%$; median, 3.40 ; IQR, $2.22-5.61$) varied among different counties (Table 1 and S1). Figure 2 and Table S5 show the results of the bivariate regression analysis estimating the odds of mortality due to COVID-19 infection (model corrected for states). Protective factors for the counties are a higher percentage of Asians (est. -0.27 , 95% CI $-0.41, -0.12$, $q < 0.003$, women; est. -0.23 , 95% CI $-0.37, -0.09$, $q < 0.009$, men) and education level with a bachelor's degree or higher with an odds ratio ranging from -0.41 to -0.03 across the various ethnicities (see Fig. 2). Other protective factors for counties include having a higher percentage of people insured (strongest indicator being for non-Hispanic White people with an estimate of

-0.48 , 95% CI $-0.68, -0.28$, $q < 6.0E-05$) and median income (est. -0.27 , 95% CI $-0.41, -0.12$, $q < 0.003$). The total population in the counties is also a major indicator (est. -0.33 , 95% CI $-0.43, -0.20$, $q < 6.0E-05$) of lower COVID-related death. We have also explored the association between total population and various confounding factors, such as mobility data when analyzing the death rate and found that the total population is still an important protective factor (see Table S6, Fig. S7 and S8). Factors significantly associated with higher mortality in the counties analyzed include a higher percentage of people under the poverty level (for all the races analyzed in this study), a higher percentage of people on Medicaid (est. 0.17 , 95% CI $0.03, 0.30$, $q < 0.04$), and a higher rate of people with disability in the county (est. 0.27 , 95% CI $0.09, 0.45$, $q < 0.02$). Grocery mobility was also highly associated with mortality (est. 0.21 , 95% CI $0.02, 0.39$, $q < 0.06$).

To better understand the characteristics of counties with higher or lower death rates, we performed a comparative analysis using ANOVA and found that, similar to the above, counties with more population diversity, higher income and education, a lower rate of disability, and a higher rate at the insured population have a significantly lower than the median death rate. Table 2 and Table S7 summarizes the population characteristics when counties are compared with death rate lower and higher than the median (median death rate is 3.4% across the counties in the seven states, Table S1). Park and retail mobility changes are significantly different between the two groups. The average number of Asians (both man and woman), as well as Hispanics (both man and woman), is significantly higher ($p < 0.05$) in group 1 (death rate ≤ 3.4). The

Full risk factor description is available in Table 1

**Denotes statistically significant

counties with higher death rates have lower median income and higher poverty levels across all the races. The group with a lower death rate has also a higher rate of the insured population and a lower rate of disability. The percentage of Medicaid is significantly higher in the group with a higher death rate.

COVID-19 Infection and Mortality Are Higher Among African Americans

We have also extracted data on all the states with respect to race distribution (see Table S8). As of April 16, 2020, we have observed that African Americans, as defined in the reports, have a higher rate of COVID-19 infection and a higher death rate. The number of African Americans infected by COVID-19 is 64,605 (1981 cases per million) with the number of deaths reaching 6181 (211 deaths per million), while the number of Whites, as defined in the reports, is 104,914 (658 cases per million) infected and 9806 (76 deaths per million) dead leading to a disproportional percentage of African Americans infected ($p < 0.0001$) by COVID-19 and dead ($p < 0.0001$) as the result. The number of infected Latinos and Asians per million, as defined in the reports, is 947 and 390, while the rate of mortality (per million) is 82 and 52 respectively.

Discussion

Our analysis highlights that counties with a higher total population, more diverse demographics, higher education, and income level are at a higher risk of COVID-19 infection; however, counties with a smaller population, higher disability rates, and higher poverty levels have a higher rate of mortality. The conflicting results for counties' population could be related to the population density, easier access to the high quality of healthcare, and more experience managing the COVID-19 infection due to the higher number of patients. One can argue that counties with fewer residents have a higher rural population. Studies have shown that there are significant differences in the overall healthcare assessment of rural populations as compared with urban populations [18]. Our observation is also aligned with a recent analysis of health differences in 3053 US counties, showing that rural areas are more likely to have poorer health outcomes [19]. The association of poverty and disability makes the conclusion of this study more complex and beyond the analysis of social determinants. By adding the interaction terms in the linear regression model (death rate~poverty + disability + poverty:disability) of death rate, we do not observe a significant interaction ($p = 0.469$), suggesting these two variables could be independent in their contribution to the risk of mortality. Populations with a higher disability [20] and lower median income [21] might be less mobile, have more comorbidities [22, 23], and also less likely

benefit from timely high-quality care [24] and high-quality nutrition; all of these factors could be equally important to combating this pandemic [25, 26]. Furthermore, our analysis of the preliminary data on mobility, given the recent social distancing guidelines, corroborate the impact of this intervention on lowering the infection rate and death.

Our findings highlight that race (especially Black) is a risk factor for the infection. To further our understanding of the impact of race, we performed an additional comparative analysis using ANOVA and found that counties with fewer than median non-Hispanic Whites (group 1: percentage of non-Hispanic Whites $\leq 39.7\%$) had a significantly lower total population ($p < 5.2\text{E-}15$) than counties with more than median non-Hispanic Whites (group 2: percentage of non-Hispanic Whites $> 39.7\%$); however, the rate of mortality is significantly higher ($p < 0.003$) while the rate of infection is significantly lower ($p < 4.4\text{E-}13$) in this group; Table S9 includes additional details. Finally, access to insurance was a protective factor in terms of mortality from COVID-19, but access to insurance did not significantly associate with the rate of infection. Comparison of counties with higher or lower than median death rates provided further evidence of the association of lower median income and higher poverty levels across all the races with mortality. The counties with a higher death rate also had a higher percentage of people on Medicaid. The latter is expected since Medicaid is significantly associated with the rate of poverty (Pearson correlation, 0.769, $p < 0.005$) as well as the rate of disability (Pearson correlation, 0.428, $p < 0.005$). Descriptive statistics of data from all the states also corroborates that African Americans might be disproportionally affected by this pandemic as of April 16, 2020. This observation is consistent with the H1N1 pandemic, where studies have shown evidence of racial and ethnic disparities in the population affected in terms of exposure, severity, and mortality of the disease [8, 9]. Finally, historical data have taught us that minorities and people of color tend to be more affected by different diseases [27–30].

This is the first systematic study on the racial, health, and economic disparity, as well as education, mobility, and COVID-19 infection in the US with the available data from the most severely impacted states. Our study had several limitations; the data was not granular, and we had missingness, especially for smaller and less populated counties. Access to the infected patient information and mortality data was not possible, and only aggregated data were used. Furthermore, many states claimed difficulties in reporting racial/ethnic demographic data due to patients opting out of providing their racial identification. The lack of clarity resulted in partially reported data for the death and case rate per million reported in this article, due to some states reporting on racial data for one, two, or all the racial variables specified in this study. The infection rate estimate may be underrepresented, as some individuals may have mild symptoms but lacked clinical validation of the infection. Finally, our in-depth analysis was

based on only seven states, leading to conclusions that may not be generalizable to other regions.

Conclusion

Implications of the results from this study highlight the value of the targeted interventions, as different counties, even within the same state, may have different characteristics and different needs. Furthermore, as the association between COVID-19-related fatality and infection is different among different race and health status, it is important to further study the impact of the immune system and immune-boosting strategies in the at-risk population (such as people with certain disabilities or those residing in elderly community centers), as preventive measure along with other measures based on social distancing guidelines and the ability to work from home.

Author's Contribution V.A. and R.Z. designed the study. O.O. and V.A. extracted and prepared the data for analysis. A.K. and D.C. performed data validation. J.L., R.Z., O.O., and V.A. performed the analysis. J.L., R.Z., O.O., S.S., and V.A. contributed to the interpretation of the results. V.A. and O.O. wrote the initial draft. All authors provided critical feedback and contributed to different sections of the manuscript. All authors reviewed and approved the final version of the manuscript. Authors would like to extend their thanks to Drs. Annemarie G. Hirsch, Melissa Poulsen, and Lester H. Kirchner for insightful comments.

Funding Information R.Z. and V.A. have funding support from the Geisinger Health Plan Quality Fund as well as the National Institute of Health R56HL116832 (sub-award) during the study period. The funders had no role in study design, data collection, and interpretation, or the decision to submit the work for publication.

Majority Indians have natural immunity. Vaccinating entire population can cause great harm

For recovered Covid patients, the vaccines provide no benefit and some harm. It is thus unethical to vaccinate them.

Text Size: A- A+

As we start 2021, the Covid-19 epidemic in India has progressed to a point where a near majority of the population has **developed immunity** to the virus. Though too many have died, India's Covid death rate is, fortunately, lower than many other countries. With the vaccine roll-out imminent, there are reasons for optimism after a challenging year.

The primary question at hand for Indian Covid response policy planners is how best to use the vaccine — roll-out for which in India begins from **16 January** and will target three crore health staff — to minimise the harm from the disease until the end of the epidemic. Given the size of the population and the rate of production of the vaccine, it may take a considerable amount of time to vaccinate the entire population. So it will be necessary to choose who receives priority.

Despite the deployment of the vaccine, many countries – including the US and UK – continue to impose lockdowns as the primary means of controlling the virus's spread. The results have not been good, with both cases and deaths rising despite the shuttered businesses, schools, and places of worship. Indian policy planners should take full advantage of these bad examples and continue to avoid **lockdowns**

that have devastated the lives and livelihoods of millions of poor people throughout the country.

We know from the mortality statistics that the Covid infection poses the greatest risk to older populations. Worldwide, the **infection survival rate** for people under 70 is 99.95 per cent, while the analogous number for those aged 70 and over is 95 per cent. So, the only ethical choice requires offering the vaccine to people aged 70 and older first, as well as to the frontline health workers who care for Covid patients.

The problem is that, with 88 million elderly citizens in India, there will not be enough doses in the immediate future to vaccinate them all for months to come. We argue that inoculating only people who have not been previously infected provides an efficient way to target the vaccine at those who will benefit from it most.

Also read: *Russia's Sputnik V vaccine has no peer-reviewed data yet. Question is — would you take it*

Immunity after recovery from Covid

The scientific evidence is overwhelming that natural immunity attained after recovery from Covid infection **is effective and long lasting**. The immune system responds to infection by various mechanisms, including the production of specific antibodies, T-cells, and B-cells to protect nearly every recovered Covid patient from reinfection. After almost a year of pandemic, globally, only **34 cases and two deaths** have been definitively identified as reinfections at the time of writing, out of the **90 million** Covid cases and likely hundreds of millions of infections worldwide.

Vaccines cause the immune system of those inoculated to mimic the immune response that natural infection induces. While the immunity conferred by the Covid vaccines documented in the clinical trials is excellent, it is not as effective as the immunity conferred by natural infection.

Furthermore, those who have already developed immunity to Covid through natural infection are extremely unlikely to develop additional immunity from vaccination. For instance, in the **Pfizer randomised trial**, the vaccine was tested in previously infected patients to check for its safety in that group. But those same patients were excluded from the analysis of efficacy, presumably because the scientists understood that the vaccine would confer no additional benefit to them.

Every vaccine has some side effects, and though the approved Covid vaccines are safe, they are no exception. Most of the side effects are mild – soreness at the injection site, aches and pains from the immunological reaction – but very rarely, severe adverse events do occur. For recovered Covid patients, then, the vaccines provide no benefit and some harm. It is thus unethical to vaccinate them.

Also read: *How India's regulatory pitfalls helped Covishield and Covaxin get rapid approval*

India is reaching very high level of natural immunity

These considerations are not merely of theoretical interest because an enormous proportion of the Indian population has already been infected and recovered. While the officially reported figure of Covid cases in India is around **1.4 crore**, mathematical models imply that more than 50 per cent of the Indian population may have developed natural immunity to the virus.

This fact is corroborated by serological **tests for Covid antibodies carried out commercially on a large scale by Thyrocare**. The founder of Thyrocare, **Dr A. Velumani**, says that “nature... already has immunised, freely, silently 70% Indians”.

Though this may sound like bad news, since it implies that nearly a billion Indians have already been infected, the silver lining is that the vast majority have recovered from infection and have lasting immunity to reinfection. They will likely be better protected from Covid over a longer period of time than those who achieve immunity via vaccination since it is not clear **how long the vaccination-induced immunity lasts**.

Checking for previous infection is simple. Before vaccination, patients should be asked if they have been previously infected, and if the answer is no, an inexpensive test for antibodies should be administered. Only if that test is negative should the vaccine be administered. This procedure will not capture all previous infections **since antibodies fade after a few months**, and many infected people were never identified as cases. Still, this procedure will nevertheless spare a large number of people from unnecessary vaccination.

Thus, reserving vaccine doses for people who have not been previously infected could solve the problem of excess demand for the vaccine by the vulnerable in the early months of the vaccine roll out when not enough doses will be available for all.

Also read: *Vaccine maker IIL, other companies in touch with Moderna to bring its Covid vaccine to India*

Prioritise the vulnerable for vaccination

In a disease with high asymptomatic cases and low morbidity or infection fatality rate, the first goal of vaccination is to reach **herd immunity** and not 100 per cent eradication through universal vaccination — that would be simply impossible. The only human virus that has been entirely eradicated from the face of the earth is smallpox, and that effort took decades despite the availability of an excellent vaccine. Chasing this impossible goal would impose great harm to India.

By contrast, a swift, focused protection strategy of vaccine administration, which prioritises the most vulnerable who have not been previously been infected, would reduce death rates from Covid infection to nearly zero and is a far better strategy.

Once the vulnerable are protected, even while the vaccine is administered to the less vulnerable younger populations, the Disaster Management Act's lockdown restrictions should be lifted fully and forever. The economic, physical, and emotional harms from the lockdown far exceed the mortality and morbidity risks from Covid infection for less vulnerable people. Since either vaccine-induced or natural immunity would already protect the vulnerable, there would be no ethical reason for the remaining lockdown restrictions to be in place.

ARTICLE HISTORY Received 12 July 2020; Accepted 15 August 2020

EDITOR Tiina Reponen

Introduction

Choir singing has been suspended in many countries during the Covid-19 pandemic due to incidental reports of disease transmission (Hamner et al. 2020). The mode of transmission has been attributed to exhaled droplets, but with the exception of a study on tuberculosis from 1968, there is presently almost no scientific evidence of increased particle emissions from singing (Loudon and Roberts 1968). A substantial number of studies have, however, investigated aerosols emitted from breathing, talking, coughing and sneezing (e.g., Asadi et al. 2019; Johnson et al. 2011). It has also been shown that just normal breathing over time can generate more viable virus aerosol than coughing, since the latter is a less frequent activity (Lindsley et al. 2016).

Compared to talking, singing often involves continuous voicing, higher sound pressure, higher frequencies, deeper breaths, higher peak airflows and more articulated consonants. All these factors are likely to increase exhaled emissions.

The aim of this study was to investigate aerosol and droplet emissions during singing, as compared to talking and breathing. We also examined the presence of SARS-CoV-2 in the air from breathing, talking and singing, and the efficacy of face masks to reduce emissions. In this study we defined aerosol particles as having a dry size in the range 0.5–10 µm. Although debatable from an aerosol physics point of view, a cutoff diameter between 5 and 10 µm is normally used in medicine for classification of aerosol versus droplet route of transmission. Droplets are here defined as exhaled particles, from micron size with no upper size limit, and measured directly at the mouth before complete evaporation, thus partly in liquid phase.

Methods

Twelve volunteer singers were included in the study: 7 professional opera singers (2 basses, 1 baritone, 2 altos and 2 sopranos) and 5 amateurs (3 tenors, 2 altos). The singers were sitting or standing in an upright position. Measurements on the 12 singers were carried out in a 22 m³ airtight experimental chamber at room temperature around 22 °C and maximum 40% relative humidity. The chamber was ventilated by particle-free air with an air exchange rate of 3 h⁻¹. Both singers and researches were wearing clean air suits to minimize background particle concentrations. In addition, we analyzed SARS-CoV-2 in air samples collected close to two persons confirmed positive for Covid-19 while talking and singing.

A short consonant-rich text was repeated during eight exercises: talking normal (no set tone, 50–60 dBA measured at 1 m distance), talking loud (no set tone, 65–80 dBA), singing normal (A natural, man/woman: A3/A4, <70 dBA), singing loud (A natural, 70–90 dBA), singing loud with exaggerated diction (A natural, 70–90 dBA), singing loud at high pitch (man/woman: E4/E5) and singing loud wearing a surgical face mask (A natural). The singers had varied voice strength at the chosen pitches, and sound pressure values are thus approximate. Singing was carried out at a single pitch with a metronome set at 92 bpm to provide constant rhythm. Each exercise was performed for 2 min, which corresponded to 12 repetitions of the spoken or sung text. Particle concentrations reached a steady state after 10–15 s, after which the data were analyzed. For reference, we also detected particle emissions during normal breathing.

The size and concentration of aerosol particles in the range 0.5–10 µm were measured by an aerodynamic particle sizer (APS, Model 3321, TSI Inc.) at 5 s scan time.

Figure 1. Aerosol particle mass emission rates during different exercises (dark blue, left y-axis), and the average number of droplets per frame (from image analysis, see Figure 3) in the exhaled air during the same exercises (red, right y-axis). Particle mass was measured in the range 0.5–10 μm . Each blue box represent data for 12 singers for aerosol particles and 5 singers for droplets. Two high values for loud singing not shown.

The aerosol was sampled from a 50 cm long horizontal anti-static metal funnel (volume 4.4 L) fitted around the face of the singers. A vacuum pump pulled a constant airflow of 15 L/min through the funnel in order to introduce fresh air for the singers, reduce deposition by limiting particle residence time, and decrease relative humidity to ensure measurement at particle dry size. It was not possible to achieve isokinetic and vertical sampling due to the varying flow rates from breathing and the preferable upright positioning of the singers. Emission rates were calculated with the assumption of zero particle losses in the funnel, and thus aerosol emissions may be somewhat underestimated. Between exercises, the aerosol particle concentration was left to decrease to background levels below 0.5 cm^{-3} .

For five of the singers, droplet emissions (non-evaporated particles with no upper size limit) were imaged with a high-speed camera (Photron FastCAM SA-X2) with an acquisition frequency of 125 frames per second and exposure time of 250 μs . A Nikon 50 mm prime lens was used with the aperture set at $f/2.8$ to balance adequate depth-of-field and low-light sensitivity. Particles were visualized by means of elastic light scattering, with light provided by ten 50 W narrow spread-angle reflector halogen lamps in a configuration of two overlapping racks of five lamps, resulting in a homogenous illumination profile with a rectangular cross section of 10x50 cm. This light profile was aimed in front of the participants, directed toward the camera at an angle

Figure 2. Median number of emitted particles in the size range 0.54–10 μm per second for the 12 singers.

approximately 30° off the detection axis, in order to utilize the forward scattering properties of micrometer sized particles. The detection limit of the setup was evaluated using glass beads with a MMAD of 4 μm ($\rho = 2 \text{ g/cm}^3$), which yielded high signals and clearly resolved particles. The images were analyzed with an in-house developed algorithm in Matlab to obtain the number of particles and visualize the temporal variation.

The SARS-CoV-2 virus in aerosols was investigated with a method previously validated for detection of airborne virus (Alsvéd et al. 2020). Samples were collected at a distance of 0.8 m in front of two persons with confirmed Covid-19 that were talking or singing (sitting position). Both were within two days of symptom onset. No precise quantitative information about viral loads in the airways could be obtained, but combined nasal/throat swabs analyzed for SARS-CoV-2 within 24 h of measurement had qPCR Ct values of 22–25, as reported by the hospital laboratory. Aerosols were collected into phosphate buffered saline by a cyclone (Coriolis μ , Bertin Technologies, flow rate 200 L/min) and on gelatin filters (MD8 airscan, Sartorius GmbH, flow rate 100 L/min). Sampling was performed for 10 min each for: (1) normal silent breathing, (2) reading a book loud, (3) singing, and (4) singing with a face mask. The samples were stored at 4°C . RNA was extracted with the viral RNA mini kit (QIAGEN) according to the protocol of the manufacturer and quantitative reverse transcription polymerase chain reaction (qRT-PCR) was performed using the SuperScriptTM III PlatinumTM One-Step qRT-PCR Kit (ThermoFisher Scientific) with primer and probes as described (Corman et al. 2020). Both positive (patient samples) and negative controls (blanks and sampling in virus-free environments) were made to validate the virus analysis. Approval was granted by the ethical review board in Sweden (2020-01396) for collecting air

Figure 3. The number of droplets per picture frame generated during loud singing with exaggerated consonants by the professional opera singers. During the 20 s the same phrase is repeated twice. Videos are available in the [online supplementary information](#).

samples close to Covid-19 infected patients and for retrieving personal data about patient samples.

The Friedman test was used to evaluate if there were differences between all types of exercises and post hoc analysis with the Wilcoxon signed rank test was conducted for pairs of samples (SPSS version 26, IBM Inc.).

Results and discussion

As illustrated in [Figures 1](#) and [2](#), there were significant differences in particle emissions between breathing, talking and singing (Friedman test for emitted aerosol particle mass, $p < 0.0001$). Normal singing generated significantly more aerosol particles than normal talking ($p = 0.002$). Loud singing produced more particles than normal singing ($p = 0.002$). [Figure 1](#) illustrates mass emission rates. Median (range) aerosol particle number emission rates were ([Figure 2](#)): 135 (85–691) particles/s for breathing, 270 (120–1380) particles/s for normal talking, 570 (180–1760) particles/s for loud talking, 690 (320–2870) particles/s for normal singing, 980 (390–2870) particles/s for loud singing, and 1480 (500–2820) particles/s for loud singing with exaggerated diction. For loud singing with a face mask, the emission rate was 410 (200–1150) particles/s. Hence, a simple face mask reduced the amount of generated aerosol particles from singing to a level similar to normal talking (no significant difference, $p = 0.08$).

There was a trend toward increased aerosol emissions with higher pitched singing, but this could also be an effect of increased sound pressures achieved at especially high pitches. The professional singers in this study generated 2–3 times more aerosol particle mass when singing loud at high E compared to A natural. The professional singers produced about a factor two more aerosol particles than the amateur singers at perceived normal sound pressure (Mann-Whitney, $p = 0.03$).

From the high-speed camera droplet analysis we found that some consonants, for example ‘p’, ‘b’, ‘r’ and ‘t’, generated a high number of small to large droplets ([Figure 3](#), see also the videos provided in the [online supplementary information](#)). The singing of vowels does not provide high airflows for the dispersal of particles, but as shown in the video files, the articulation of consonants expels droplets with considerable forward velocity. Nevertheless, many of the largest droplets travel a limited distance (< 0.5 m) before their movement become vertical due to sedimentation.

There were substantial differences in emissions of droplets between singing and talking, but statistical significance could not be verified due to the limited group size for the video recordings ([Figures 1](#) and [3](#)). Mean (\pm SEM) droplet numbers per frame were 12 ± 3 for normal talking, 29 ± 14 for loud talking, 16 ± 7 for normal singing, 38 ± 16 for loud singing, and 5 ± 1 for loud singing with a face mask. Thus, for the droplet analysis a common face mask also appears to be very efficient in reducing emissions. Although not measured systematically, we noted that subject-reported sense of accumulation of saliva in the mouth coincided with increased droplet generation from articulation, which resulted in high variation also within the data from the same singer ([Figure 3](#), top diagram). When singing loud with a surgical mask, almost no droplets were detected with the camera. A warm-up exercise where one lets the lips vibrate during exhalation (without activating the vocal cords) generated immense amounts of droplets (data not shown).

SARS-CoV-2 could not be detected in the air samples collected while confirmed Covid-19 patients were singing and talking. This can be due to the low concentrations of viruses in the air, but could also be attributed to individual differences in viral loads in the parts of the respiratory tract where the droplets are produced, as well as dilution steps in the sample preparation method.

Singing generated more respiratory aerosol particles and droplets than talking. Exhaled aerosol particles and droplets increased with song loudness. The data also indicated that emissions might increase at high pitch. Wearing an ordinary surgical face mask reduced the amount of measured exhaled aerosol particles and droplets to levels comparable with normal talking. However, as surgical masks have a loose fit, some particles may have exited on the sides where we did not measure. Based on these results, singing in groups is likely to be an activity at risk of transmitting infection if not appropriate control and prevention measures are applied, such as distancing, hygiene, ventilation and shielding.

Acknowledgments

We want to express our gratitude to the singers who kindly and enthusiastically contributed with song for the aerosol detectors: foremost from Malmö Opera Choir but also from Malmö Limelight Chorus, Svanholm Singers, Lunds Student Singers and last, but not least, the two people who sang while having Covid-19.

SCIENTIFIC REPORTS

OPEN

Aerosol emission and superemission during human speech increase with voice loudness

Sima Asadi¹, Anthony S. Wexler^{2,3,4,5}, Christopher D. Cappa⁴, Santiago Barreda⁶, Nicole M. Bouvier^{7,8} & William D. Ristenpart¹

Mechanistic hypotheses about airborne infectious disease transmission have traditionally emphasized the role of coughing and sneezing, which are dramatic expiratory events that yield both easily visible droplets and large quantities of particles too small to see by eye. Nonetheless, it has long been known that normal speech also yields large quantities of particles that are too small to see by eye, but are large enough to carry a variety of communicable respiratory pathogens. Here we show that the rate of particle emission during normal human speech is positively correlated with the loudness (amplitude) of vocalization, ranging from approximately 1 to 50 particles per second (0.06 to 3 particles per cm³) for low to high amplitudes, regardless of the language spoken (English, Spanish, Mandarin, or Arabic). Furthermore, a small fraction of individuals behaves as “speech superemitters,” consistently releasing an order of magnitude more particles than their peers. Our data demonstrate that the phenomenon of speech superemission cannot be fully explained either by the phonic structures or the amplitude of the speech. These results suggest that other unknown physiological factors, varying dramatically among individuals, could affect the probability of respiratory infectious disease transmission, and also help explain the existence of superspreaders who are disproportionately responsible for outbreaks of airborne infectious disease.

It has long been recognized that particles expelled during human expiratory events, such as sneezing, coughing, talking, and breathing, serve as vehicles for respiratory pathogen transmission^{1–6}. The relative contribution of each expiratory activity in transmitting infectious microorganisms, however, remains unclear⁴. Much previous research has focused on coughing^{7–12} and sneezing^{11,13,14} activities that yield relatively large droplets (approximately 50 µm or larger) easily visible to the naked eye. Less noticeable, but arguably more infectious for some diseases, are the smaller particles emitted during sneezing and coughing as well as during breathing^{15–17} and talking^{16,18,19}. These small particles are believed to be generated during breathing and talking from the mucosal layers coating the respiratory tract via a combination of a “fluid-film burst” mechanism within the bronchioles and from vocal folds adduction and vibration within the larynx^{6,20,21}. The particles emitted during breathing and typical speech predominantly average only 1 µm in diameter^{15–17} and are thus too small to see without specialized equipment; most people outside of the community of bioaerosol researchers are less aware of them.

Despite their small size, however, these micron-scale particles are sufficiently large to carry a variety of respiratory pathogens such as measles virus (50–500 nm)²², influenza virus (100 nm–1 µm)²³, and *Mycobacterium tuberculosis* (1–3 µm)²⁴. Indeed, recent work by Yan *et al.* has confirmed that significant amounts of influenza viral RNA are present in small particles (<5 µm) emitted by influenza-infected individuals during natural breathing, without coughing or sneezing²⁵. These small particles are potentially more infectious than larger sneeze- or

cough-generated droplets for several reasons. First, smaller particles persist in the air for longer time periods before settling by gravity, thus increasing the probability of inhalation by susceptible individuals²⁶. Second, smaller particles have a larger probability of penetrating further into the respiratory tract of a susceptible individual to initiate a lower respiratory tract infection⁴. Third, and perhaps most importantly, speech can release dramatically larger numbers of particles compared to coughing. Early work by Papineni and Rosenthal¹⁶ and Loudon and Roberts¹⁹ reported that speaking (as exemplified by counting aloud) releases about 2–10 times as many total particles as a single cough. Similarly, Loudon and Roberts investigated the role of singing in the spread of tuberculosis and showed that the percentage of airborne droplet nuclei generated by singing is 6 times more than that emitted during normal talking and approximately equivalent to that released by coughing²⁷. More recent work using advanced particle characterization techniques have yielded similar results^{21,28–30}. Chao *et al.*²⁸ used an interferometric imaging technique to obtain the size distribution of particles larger than 2 μm and found that counting aloud from 1 to 100 releases at least 6 times as many particles as an individual cough. Likewise, Morawska and coworkers^{21,29} reported that counting aloud for 10 seconds followed by 10 seconds of breathing, repeated over two minutes, releases half as many particles as 30 seconds of continual coughing, which in turn releases half as many particles as saying “aah” for 30 seconds. They also reported that more particles are released when speech is voiced, which involves vocal folds vibration, rather than whispered, which does not.

Despite the clear evidence that speech emits large quantities of potentially infectious particles, to date little is known about how particle emission is modulated by different types of speech. Notably, the above work measured neither the total duration nor the loudness of the vocalizations; it is also unclear whether counting aloud will have a distribution of phones (phonemes) that is representative of typical conversational speech. Many important questions remain unanswered. For example, does raising your voice cause an increase in particle emission, or alter the particle size distribution? Does it matter what language you speak? Do all individuals emit particles at similar rates?

To address these questions, we used an aerodynamic particle sizer (APS) placed in a laminar flow hood to characterize the number and size distribution of particles emitted by individual human volunteers while they performed various vocalizations and breathing activities. Using this approach, we found three key results:

- (1) The particle emission rate during speech is linearly correlated with the amplitude (loudness) of vocalization, for four different languages tested.
- (2) The particle size distribution is independent of vocalization loudness or language spoken.
- (3) Some individuals emit particles at a rate more than an order of magnitude larger than their peers, i.e., they behave as “speech superemitters.”

Taken together, the results strongly suggest that individual human speech patterns and speech-associated particle emissions are highly heterogeneous and thus might play a role in the transmission of some respiratory pathogens. Furthermore, the results suggest a new hypothesis: that speech superemitters might contribute to the phenomenon of superspreading, in which a relative few contagious individuals infect a disproportionately large number of secondary cases during infectious disease outbreaks³¹.

Results

Four separate types of experiments were performed. In the first experiment, participants said /a/ (the vowel sound in ‘saw’) for five seconds, followed by 15 seconds of nose breathing, repeated six times in succession. This procedure mimics previous experimental measurements of particle emission during vocalization²¹, but here the participants also systematically repeated the experiment at different voice amplitudes. Representative raw data for a single participant performing a series of six successive /a/ vocalizations, at approximately the same loudness, are shown in Fig. 1. The simultaneous microphone recording (Fig. 1A) and APS measurements (Fig. 1B) demonstrate that the dynamics of particle release are highly correlated with the vocalization. Prior to and between vocalizations, during nose breathing in which exhaled air is directed away from the APS, the particle count is negligible, as is expected for the HEPA filtered air inside the laminar flow hood. Shortly after the vocalization commences, the number of particles rapidly increases and peaks, then decreases back to zero as the participant resumes nose breathing; the process then repeats at the next five-second vocalization. The approximately two-second lag between onset of vocalization and the observed increase in particle count is due to the time necessary for the released particles to reach the sensor in the APS. We emphasize that by design an APS does not measure 100% of the particles drawn into it, so the particle emission rates reported here do not represent the absolute number of particles emitted by the participant; the emission rates are best understood in relative terms, or in terms of the equivalent instantaneous concentrations of particles sampled from the funnel. As shown in the secondary axis of Fig. 1B, the instantaneous concentration of particles for this particular experiment was approximately 2 per cm^3 of sampled air.

The six vocalizations shown in Fig. 1A were made, to the best of the participant’s ability, at the same loudness. Each participant then repeated a similar series of /a/ vocalizations at different self-regulated voice amplitudes. Representative results for a single participant (F4) show that the particle emission rate (N), defined as the total number of particles emitted during a single vocalization divided by the measured duration (in seconds) of that vocalization, also correlates with the root mean square amplitude (A_{rms}) of the vocalization (Fig. 2A). In our set-up $A_{\text{rms}} = 0.45$ corresponds to an extremely loud conversational voice, as loud as comfortable without yelling (~98 decibels measured 6.5 cm from the participant’s mouth, measured over background noise of approximately 65 decibels), while $A_{\text{rms}} = 0.02$ corresponds to a quiet vocalization just above whispering (~70 decibels; cf. Supplementary Fig. S1). As shown in Fig. 2A, the particle emission rate is linearly correlated with A_{rms} over this entire range of vocalization amplitudes, with the particle emission rate increasing from 6 to 53 particles per second at the quietest and loudest vocalizations respectively.

Figure 1. Representative raw data in which a participant (F4) said /a/ for 5 seconds, followed by 15 seconds of nose breathing, repeated 6 times at approximately the same loudness. (A) The amplitude (arb. units) recorded by the microphone versus time. Magnification shows 13 ms of the waveform with fundamental frequency of F_0 . (B) The corresponding number/concentration of particles measured by the APS versus time.

Although the particle emission rate increased with amplitude, the size distribution of the particles was not affected significantly (Fig. 2B), with the geometric mean particle diameter remaining near $1\ \mu\text{m}$ regardless of voice amplitude (Supplementary Fig. S2A). Because the particle size remains similar regardless of amplitude, the increased particle counts shown in Fig. 2 indicate that the total volume of emitted respiratory fluid (i.e., the proteinaceous liquid droplets aerosolized from the serous and mucoid layers lining the respiratory tract) increases considerably with the vocalization loudness. Note that the characteristic time scale for evaporative drying of 1-micron diameter droplets is on the order of 100 milliseconds²⁶, which is much less than the time required for the particles to move from the participant's mouth into the detection module within the APS, suggesting that the particles measured here had fully dried into droplet nuclei prior to measurement (see methods and Supplementary Fig. S3).

Experiments with multiple participants indicated that these trends are conserved over a larger sample size (Fig. 2C). The particle emission rate increased approximately linearly with A_{rms} for each of the study participants, although the absolute magnitude varied between individuals. One participant (F3) released as many as 200 particles per second at higher amplitudes; another (F2) released as few as 1 particle per second at lower amplitudes. Notably, the data with this cohort of non-elderly adults reveal no obvious trends with gender or age (Supplementary Figs S4A, B). Similarly, no clear correlation was observed with the body mass index (BMI) of the participants (Supplementary Figs S4C, D).

To more closely represent normal conversational speech, the participants read aloud a short passage of text in English at varied loudness (quiet, intermediate, or loud). Representative raw data for a single participant (F4) indicate that the particle emission rate also correlates with voice amplitude for normal speech (Fig. 3A,B). To quantify the loudness, we take A_{rms} here as the average over the entire approximately two-minute duration of the vocalization, excluding pauses between words. Aggregated data for 10 participants confirms that the particle emission rate for normal English speech correlates linearly with A_{rms} (Fig. 3C); speaking loudly yielded on average a 10-fold increase in the emission rate compared to speaking the same series of words quietly. Again, the size distributions (Fig. 3D) and geometric mean diameter of particles (Supplementary Fig. S2B) were insensitive to voice amplitude. The reading experiment also was repeated in different languages to test whether choice of language matters; the results (Supplementary Fig. S5) confirmed the increasing trend between particle emission rate and amplitude, but exhibited no significant difference in the particle emission rate among the languages tested (Supplementary Fig. S6). Likewise, we measured the temperature and humidity during the experiments, and found no significant impact of temperature or humidity on either the particle emission rate or the mean particle size (Supplementary Figs S7 and S8).

A key recurring feature of the data is that some individual participants emitted many more particles than others. Because all participants spoke at slightly different amplitudes, we used linear regressions of the particle emission rate versus amplitude for each individual (cf. Fig. 2A) to calculate a normalized particle emission rate at the loudness amplitude of 0.1 (approximately 85 dB). Using this approach, the results for 40 people show that the particle emission rate for different individuals follows a long-tailed distribution for both vocalization of /a/ (Fig. 4A) and reading of English text aloud (Fig. 4B). At this loudness, the normalized particle emission rates ranged from approximately 1 to 14 particles per second between different individuals, with an average of approximately 4 particles per second. Notably, the rates have a sizeable standard deviation well approximated by a lognormal fit (red curves in Fig. 4). In other words, although half of the participants emitted fewer than 3 particles per second, a small fraction of individuals (8 out of 40) emitted considerably more. These “speech superemitters,”

Figure 2. Particle emission rate/concentration while saying /a/ at 8 different amplitudes, repeated 6 times at each amplitude. (A) Particle emission rate/concentration versus root mean square amplitude, A_{rms} (arb. units) for a representative participant (F4). Solid line is the best linear fit, with correlation coefficient $r = 0.932$ and Pearson's p value $= 5.9 \times 10^{-22}$. (B) Corresponding particle size distribution for the data presented in (A). (C) Aggregated particle emission rate/concentration versus root mean square amplitude, A_{rms} (arb. units) for 10 participants, 5 males (denoted as M1 to M5) and 5 females (denoted as F1 to F5). There are 8 data points for each participant, each representing the average of repeating /a/ six times at approximately the same voice amplitude (cf. Fig. 1). Solid line is a power law fit with exponent 1.004, correlation coefficient $r = 0.774$ and Pearson's p value $= 3.8 \times 10^{-17}$.

Figure 3. Particle emission rate/concentration while reading a passage of text aloud (the “Rainbow” passage), at three different loudness levels. (A) Superimposed representative recordings of amplitude (arb. units) for an individual (F4) reading the passage at three different voice amplitudes, and (B) the corresponding number/concentration of particles measured by the APS versus time. Color code same as in (A). (C) Particle emission rate/concentration as a function of root mean square amplitude, A_{rms} , for 10 participants. There are 3 points for each person, representing 3 voice amplitudes, color code same as Fig. 2C. Solid line is a power law fit with exponent 0.96, correlation coefficient $r = 0.865$ and Pearson's p value $= 6.8 \times 10^{-10}$. (D) Representative particle size distribution for the one individual (F4).

whose individual particle emission rate exceeded the group mean by one standard deviation or more, consistently released an order of magnitude more particles than their peers. For vocalizing /a/, Fig. 4A shows that 15% of the participants emitted 32% of the total particles, while Fig. 4B shows that, for reading aloud in English, 12.5% of the participants emitted 40% of the total particles. Supplementary Fig. S9A shows that 4 out of these 8 individuals are superemitters for both saying /a/ and passage reading activities, while 2 of them are only superemitters while saying /a/, and 2 of them are superemitters while reading a text passage. We repeated the passage reading experiment for two of the participants (M5 and F4) on three different days separated by several months (Supplementary Fig. S9B), and the results show that the particle emission rates remained almost unchanged for at least these two individuals (F4, a superemitter, and M5, a non-superemitter) despite the long time period between measurements.

To help interpret our findings we also compared the particle emission rates of four different types of breathing with speech at three levels of loudness using the same experimental set-up. The breathing experiments included nose breathing, mouth breathing, a “deep-fast” mode, and a “fast-deep” mode (see methods for details). The results show that the particle emission rate for speech is significantly higher than all types of breathing tested here (Fig. 5A). Furthermore, the corresponding geometric mean diameters of the particles generated during speech are slightly larger on average than those generated during breathing (Fig. 5B), consistent with prior work and the hypothesis that vocalization activates laryngeal particle generation²¹. Note that in Fig. 5A the speech outliers correspond to a single participant who is a speech superemitter (F4), but this individual was not also responsible

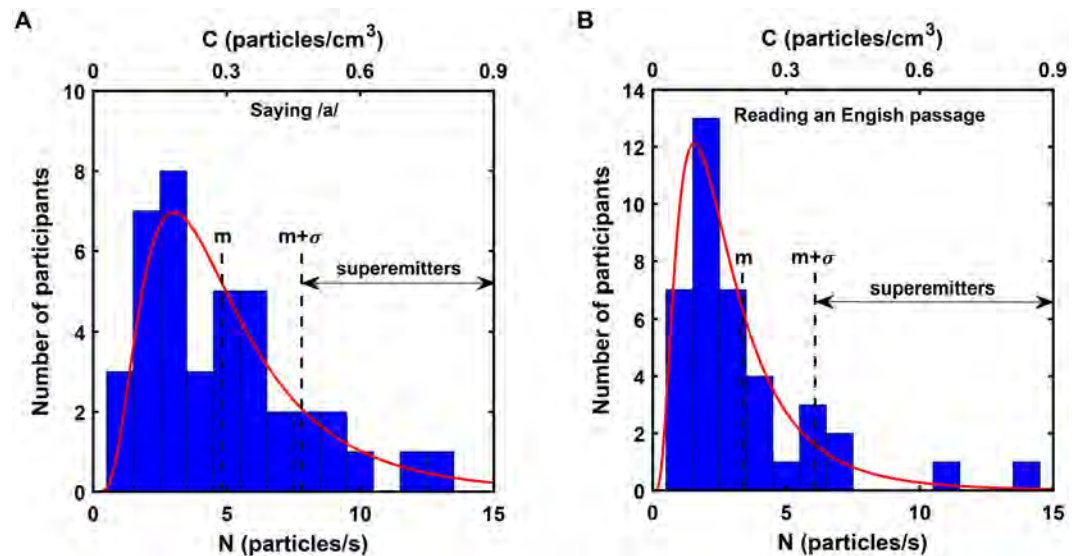

Figure 4. Histogram of particle emission rate/concentration at voice amplitude of 0.1 (approximately 85 dB). (A) For saying /a/, with median of $M = 4.3$ particles/s, mean of $m = 4.8$ particles/s and standard deviation of $\sigma = 3.0$ particles/s. (B) For reading an English passage (10 people read the “Rainbow” passage and 30 people read chapter 24 of “The Little Prince”) with median of $M = 2.5$ particles/s, mean of $m = 3.4$ particles/s and standard deviation of $\sigma = 2.7$ particles/s. Particle emission rates larger than $m + \sigma$ are labeled superemitters. Red curves are lognormal fits found via nonlinear regression.

for the observed outliers of “fast-deep” and “nose” breathing activities. In other words, the “breathing high producers” as defined by Edwards *et al.*¹⁵ are not necessarily also speech superemitters.

Discussion

Given that the results clearly indicate that particle emission rate is correlated with vocalization amplitude, a natural question is: why? The particles emitted during breathing and speech are hypothesized to be formed primarily by a “fluid-film burst” mechanism inside the small airways of the lungs and/or via vocal folds vibration and adduction at the larynx^{6,20,21}. During exhalation the elastic walls of the respiratory bronchioles contract, and the mucosal fluid on the lumen surface forms a continuous film that can completely fill the airway. During the subsequent inhalation, the bronchioles expand and the film ruptures, yielding particles that are drawn into the alveoli and subsequently exhaled. A similar mechanism is believed to occur in the larynx, as the vocal folds repeatedly close and open during vocalization²¹; when the vocal folds come into contact during adduction, fluid films that form between them can then rupture during their subsequent abduction. Our direct comparison of particles emitted during various types of breathing versus speech demonstrates that even quiet speech yields significantly more particles than normal breathing (Fig. 5A). Coupled with the observation that the particles generated during speech on average are slightly larger (Fig. 5B), the results suggest that laryngeal particle generation, which presumably does not occur during normal breathing, is at least partially responsible for the observed larger rates of particle emission. Indeed, the fundamental frequency or “pitch” of vocalization (i.e., the frequency at which the vocal folds open and close) increases slightly with amplitude (cf. Supplementary Fig. S11 and Gramming *et al.*³²), so the increased amplitude could reflect an increased opportunity for particles to form at the larynx.

Complicating matters, however, vocalization at a larger voice amplitude requires a larger exhalation flow rate^{33,34}. A possible interpretation of our observations is that the underlying physical mechanism of particle release hinges on the combination of laryngeal particle generation rate and the time integral of the exhalation flow rate during vocalization³⁵. If the volume of exhaled air is larger when the voice amplitude is higher, a larger fraction of particles formed in bronchiolar film rupture may escape from the lungs, with consequently more emitted particles, thus increasing the particle concentration in the exhaled air. Since our measurements only gauge the particle emission rate (and equivalent concentration), it is difficult to decouple the relative contributions of these two mechanisms. Fitting our particle size distributions to constrained bimodal lognormal distributions provides some evidence consistent with the interpretation presented by Johnson *et al.*²¹ that there are two modes, presumably due to bronchiolar versus laryngeal generation, but we do not find any significant difference in particle emission rates for the two modes as a function of vocalization amplitude (Supplementary Fig. S10 and cf. Fig. 5B). Furthermore, it is less understood how particles originating in the respiratory tract might deposit in more proximal regions instead of being emitted during exhalation. Particle deposition efficiency during nasal exhalation is known to depend on exhalation flow rate in a convoluted fashion, with Brownian diffusion, sedimentation, and inertial impaction all playing roles at different length and time scales within the respiratory tract³⁶. Nonetheless, our results strongly suggest that, in general, more particles escape the respiratory tract if the vocalization is louder.

Our results also clearly show that some participants release many more particles than others, for as-yet unclear reasons. It is known that the Rayleigh-Plateau instability that gives rise to small droplets during the “film burst” is

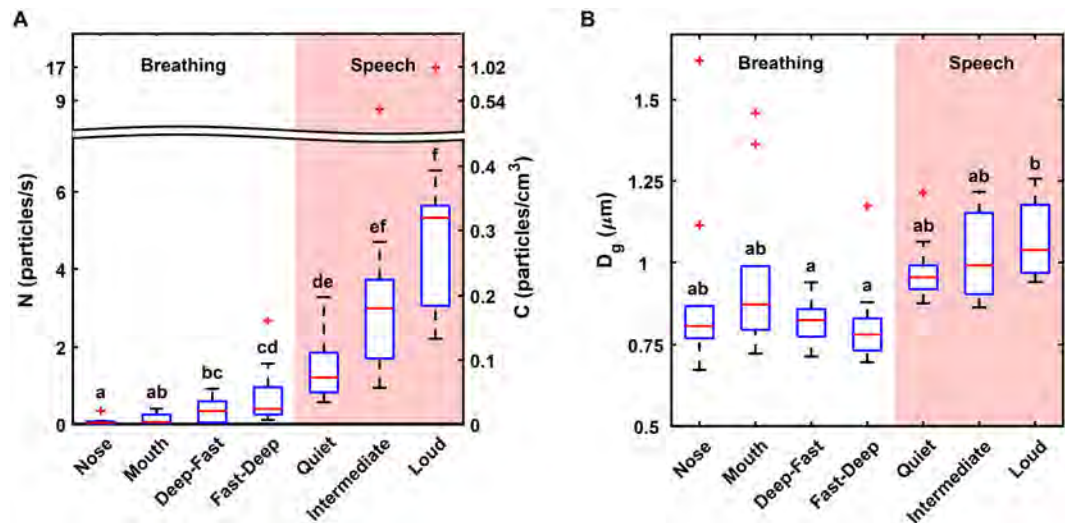

Figure 5. Comparison of (A) emission rate/concentration and (B) corresponding geometric mean diameters of particles emitted during various modes of breathing versus speech at different loudness levels. “Nose” denotes normal nasal breathing; “Mouth” denotes normal mouth breathing; “Deep-Fast” denotes deep, slow nasal inhalation followed by fast mouth exhalation; “Fast-Deep” denotes fast nasal inhalation followed by deep (i.e., slow and prolonged) mouth exhalation. “Quiet”, “Intermediate”, and “Loud” denote loudness levels while reading aloud a passage of text (“Rainbow” passage) at respective amplitudes. Red lines indicate medians, while bottom and top of blue boxes indicate the 25th and 75th percentiles respectively; sample size is $n = 10$. Outliers (defined as values that exceed 2.7 standard deviations) are indicated with red plus signs. Note that the 2 outliers for speech in (A) are a different individual (F4) than the two outliers observed for nose and fast-deep breathing (M24 and M5 respectively). Scheffé groups are indicated with letters; groups with no common letter are considered significantly different with $p < 0.05$, cf. Supplementary Table S1. Note that (A) has different scales above and below the break.

sensitive to the interfacial tension, density, and viscosity of the fluid³⁷, so one possible explanation is that the mucosal fluids in different people have different material properties and correspondingly generate more or fewer drops. Notably, different disease states are known to alter the physicochemical properties of the mucosal fluid lining the respiratory tract³⁸, so it is possible that infected individuals might generate markedly different quantities of particles than those emitted by the healthy individuals tested here. Intriguingly, Edwards *et al.*¹⁵ found that delivering nebulized isotonic saline to individuals decreased the number of particles exhaled during normal breathing for a few hours after inhalation of the saline; further tests are warranted with speech. Alternatively, it is possible that individual manners of articulation affect the amount of internal deposition of the particles before they manage to escape the mouth. Our tests of different languages yielded no significant differences, at odds with previous speculation that language spoken might have played a role in the epidemiology of SARS coronavirus transmission³⁹, and suggesting that some as yet unknown physiological factor causes the dramatic variation among individuals.

Regardless of the underlying physical mechanism, from an epidemiological perspective the existence of speech superemitters motivates consideration of a new hypothesis: that speech superemitters contribute to “superspreading” of infectious diseases transmitted by emitted airborne particles. A superspreader is a contagious individual who infects a disproportionately large number of susceptible contacts^{31,40,41}. To date, several airborne superspreading events have been documented, such as the MERS-CoV outbreak in South Korea in 2015 and the SARS-CoV outbreak in 2003, the latter being initiated in Hong Kong and spreading to Canada, Vietnam, and Singapore through travel^{40–43}. In the case of respiratory infectious diseases in particular, the underlying physiological and immunological factors that contribute to heterogeneity in individual infectiousness remain poorly understood, despite the epidemiological importance of respiratory superspreaders. Quantifying infectious pathogen loads in exhaled air is technically challenging, relative to other contagious substances like blood, urine, and feces. Many factors presumably affect the secondary attack rate attributable to any infectious individual, including the herd immunity status of others in proximity. Nonetheless, our results suggest that, for respiratory infections transmitted from person to person via airborne particles, the existence of speech superemitters might help explain the existence of superspreaders. A similar hypothesis was advanced by Edwards *et al.*¹⁵ in response to their observation of variability between individuals in the number of particles emitted during mouth breathing. Interestingly, our data show that speech superemitters are not necessarily breathing superemitters as well (Fig. 5A), suggesting that respiratory superemission during vocalized speech has a different underlying physiology than superemission during tidal breathing.

Our results indicate that speech is potentially of much greater concern than breathing for two reasons: the particles on average are larger, and thus could potentially carry a larger number of pathogens, and much greater quantities of particles are emitted compared to breathing, thus increasing the odds of infecting nearby susceptible individuals. Laryngeal particle generation during speech is also potentially important since some studies suggest that human influenza viruses attach more abundantly to the large airways of the upper respiratory tract than to

the bronchiolar and alveolar cells in the lower respiratory tract, while MERS-CoV and avian influenza viruses mainly cause lower respiratory tract infections due to the greater presence of these virus receptors deeper within the lung^{44–47}; likewise there is evidence that laryngeal tuberculosis is potentially more contagious than typical pulmonary tuberculosis⁴⁸.

A second key epidemiological implication of our results is that simply talking in a loud voice would increase the rate at which an infected individual releases pathogen-laden particles into the air, which in turn would increase the probability of transmission to susceptible individuals nearby⁴⁹. For example, an airborne infectious disease might spread more efficiently in a school cafeteria than a library, or in a noisy hospital waiting room than a quiet ward. Moreover, our data suggest a related hypothesis, that infected individuals could be transmitting significant numbers of respiratory pathogens via speech in the absence of overt clinical signs of illness like coughing or sneezing. More research is needed; however, the presence of asymptomatic or paucisymptomatic superspreaders would have important public health implications in the surveillance for and mitigation of infectious disease epidemics that are spread by airborne respiratory particles. The data presented here strongly suggest that further efforts to test these hypotheses are warranted.

Methods

Human subjects. The University of California Davis Institutional Review Board approved this study and all research was performed in accordance with relevant guidelines and regulations of the Institutional Review Board. We recruited 48 healthy volunteers (26 males and 22 females, ranging in age from 18 to 45 years old) by posting flyers at the University of California Davis campus over the time period May 2016 to March 2018. Informed consent was obtained from all participants prior to study participation. All participants completed a brief questionnaire including age, gender, weight, height, general health status, and smoking history. Only participants who self-reported as healthy non-smokers were included in the study. The subject in Supplementary Fig. S12 provided her written informed consent for the publication of identifying information/images in an online open-access publication.

Experimental set-up. A photograph of the experimental set-up is provided as Supplementary Fig. S12. An aerodynamic particle sizer (APS, TSI model 3321) operating at a total flow rate of 5 L/min (sheath flow rate \cong 4 L/min, sample flow rate \cong 1 L/min) was placed inside a HEPA filtered laminar flow hood that provided class 10 air. A plastic funnel (diameter = 10 cm) was connected to the APS sampling inlet via a conductive silicon tube (distance between funnel hole to APS inlet = 7.5 cm, tube inner diameter = 1.2 cm). During each experiment, participants sat at the laminar flow hood, in front of the APS, and spoke into the funnel. For the majority of speaking and breathing experiments, a nose rest across the funnel opening was used to position participants' mouths approximately 7.5 cm away from the funnel inlet (hole) and also to divert nasal exhalations away from the APS. During "nose-breathing" experiments, the nose rest was removed to allow nasal exhalations to be drawn into the APS. Note that participants' faces did not touch the funnel, so that air was free to move around the side of their faces; in this sense the cone was a semi-confined environment and not all expired particles were necessarily sampled by the APS. Also note that the sheath flow inside of an APS is filtered, so the particle emission rates sampled by the APS automatically remove 80% of the particles sampled from the funnel. Equivalent concentrations reported on the secondary axes in Figs 1 through 5 are determined from the raw particle counts using the sample flow rate, i.e., $C = \frac{\text{particles}}{\text{cm}^3} \times \frac{s}{\text{cm}^3} = \frac{\text{particles}}{\text{cm}^3}$. Also note that the APS measures the size distribution of particles larger than 0.5 μm , but only detects the presence of particles between 0.37 μm and 0.5 μm without providing precise size measurements. For this reason Figs 1–5 exclude the counts of particles smaller than 0.5 μm ; including them has little impact on the results since the vast majority of particles were larger than 0.5 microns.

A microphone (audio-technica PRO 37) and a decibel meter (Extech, 407760) were placed immediately on either side of the funnel to record the vocalizations. A computer screen with word prompts and a timer was placed behind the APS to guide participants in making requested vocalizations for the specified duration. The timing, duration, repetition, and order of vocalization and breathing experiments were coordinated by customized code written in LabVIEW (National Instruments). A digital hygrometer was used to measure the ambient temperature and relative humidity inside the laminar flow hood during all experiments. The participants were not allowed to drink or eat during the experiment, but they were free to rest between experiments for a few minutes as needed; data from each individual participant was gathered over an approximately 1-hour time period. We performed the experiments in an indoor (controlled) environment, so the ambient temperature varied only from approximately 20 to 25 °C, while the ambient relative humidity measured inside the laminar flow hood varied from a low of approximately 45% to a high of 80%. Control experiments indicate that the particle size distribution was independent of whether the particles were expired early or late during a sustained vocalization (Supplementary Fig. S3), indicating that transient fluctuations in the humidity inside the funnel due to exhalation had no impact on the final measured size distribution. Particles with initial diameter of less than 20 μm dry to approximately half of their initial diameter in less than 1 second^{49,50}. Different correction factors have been suggested in the literature that one can use to estimate the initial size of the particles^{49,51}; here we focus on the final size distribution because epidemiologically it is the final size distribution governs the deposition efficiency of the particles in the respiratory tract of nearby susceptible individuals⁵².

Vocalization experiments. *“/a/” experiments.* Participants (n = 10, 5 males, M1 to M5, and 5 females, F1 to F5) voiced /a/ (the vowel sound in ‘saw’) for five seconds, followed by 15 seconds of nose breathing, repeated six times in succession. The participant repeated the series of six /a/ vocalizations, to the best of the participant's ability, at the same amplitude. Each participant completed eight sets of /a/ experiments, each set performed at different, self-regulated voice amplitude. Timed prompts with directions for the requested vocalization appeared on the computer screen, which displayed a timer and an amplitude (loudness) gauge to help the participants regulate their voice amplitude. The requested amplitudes were presented to participants in a random order.

“Rainbow passage” experiments. Participants ($n = 10$, 5 males, M1 to M5, and 5 females, F1 to F5) read aloud a 330-word excerpt of text in English, known in linguistics research as the Rainbow passage⁵³. Participants were asked to read the Rainbow passage aloud three times, at a comfortable pace, over approximately 2 minutes per reading. Each of the three readings was performed at a different self-regulated amplitude: quiet, intermediate, and loud. Quiet was defined for participants as “just louder than a whisper,” intermediate as a “normal conversational voice,” and loud as “giving a loud lecture”.

“The Little Prince” experiments. Bilingual participants ($n = 30$) fluent in both English and either Spanish ($n = 10$, 5 males, M6 to M10, and 5 females, F6 to F10), Mandarin ($n = 10$, 5 males, M11 to M15, and 5 females, F11 to F15), or Arabic ($n = 10$, 6 males, M16 to M21, and 4 females, F16 to F19) read Chapter 24 of “The Little Prince”⁵⁴ aloud six times, three times in English translation, each time at a different amplitude (quiet, intermediate, and loud) and three times in their respective language, again at three loudness levels.

Breathing/speaking experiments. Participants ($n = 10$, 6 males, M5 and M22 to M26, and 4 females, F4 and F20 to F22) alternated four silent breathing patterns with vocalized speech at three amplitudes. For breathing measurements, the breathing patterns were designated as “nose” (both inhalation and exhalation through the nose), “mouth” (both inhalation and exhalation through the mouth), “deep-fast” (deep, slow inhalation for ~3 seconds through the nose, holding it for ~1 second, followed by fast exhalation through the mouth (~1 second)), and “fast-deep” (rapid inhalation through the nose (~1 second), holding it for ~1 second, followed by slow exhalation through the mouth for ~3 seconds). Each breathing experiment was performed over 2 minutes, and at a comfortable pace for the participants. Between performing different breathing patterns, participants were asked to read the Rainbow passage in a “quiet,” “intermediate,” or “loud” voice, as prompted by the computer in random order.

Statistical analysis. Data analysis was performed in MATLAB (MathWorks), with data fits performed as noted in figure legends. Pearson’s linear correlation coefficients and p values were calculated for linear fits. Lognormal fits were made via nonlinear regression, and median, mean, and standard deviation were calculated. Box-and-whisker plots show the median (red line), interquartile range (blue box), and range (black whiskers). To analyze the breathing/speaking experiments data presented in Fig. 5, Stata/SE 15.1 was used to perform general linear mixed model (GLMM) analysis to account for person-level correlations, and post hoc pairwise comparisons were performed and adjusted for multiple comparisons using Scheffe’s method.

In Brief

This case study describes a female immunocompromised individual with chronic lymphocytic leukemia and acquired hypogammaglobulinemia who became persistently infected with SARS-CoV-2. Although asymptomatic throughout the course of infection, she demonstrated prolonged shedding of infectious SARS-CoV-2 virus and RNA. This study demonstrates that certain individuals may remain infectious for prolonged periods of time and highlights the need for further studies to understand risk factors for prolonged infectious SARS-CoV-2 shedding.

Highlights

- Persistent SARS-CoV-2 infection and shedding in immunocompromised individual
- Infectious SARS-CoV-2 isolated up to 70 days after diagnosis
- Observed within-host genetic variation with continuous turnover of viral variants
- SARS-CoV-2 isolates from the individual do not display altered replication

SUMMARY

Long-term severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) shedding was observed from the upper respiratory tract of a female immunocompromised individual with chronic lymphocytic leukemia and acquired hypogammaglobulinemia. Shedding of infectious SARS-CoV-2 was observed up to 70 days, and of genomic and subgenomic RNA up to 105 days, after initial diagnosis. The infection was not cleared after the first treatment with convalescent plasma, suggesting a limited effect on SARS-CoV-2 in the upper respiratory tract of this individual. Several weeks after a second convalescent plasma transfusion, SARS-CoV-2 RNA was no longer detected. We observed marked within-host genomic evolution of SARS-CoV-2 with continuous turnover of dominant viral variants. However, replication kinetics in Vero E6 cells and primary human alveolar epithelial tissues were not affected. Our data indicate that certain immunocompromised individuals may shed infectious virus longer than previously recognized. Detection of subgenomic RNA is recommended in persistently SARS-CoV-2-positive individuals as a proxy for shedding of infectious virus.

INTRODUCTION

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) RNA can be detected at various sites, including samples obtained from the nares, nasopharynx, pharynx, bronchoalveolar lavage (BAL) fluid, feces, and blood (Wang et al., 2020a; Sun et al., 2020; Judson and Munster, 2020). The duration of SARS-CoV-2 RNA shedding is generally between 3 and 46 days after symptom onset (Fu et al., 2020; Qian et al., 2020; Liu et al., 2020c). Asymptomatic individuals shed SARS-CoV-2 RNA comparably with symptomatic individuals regarding duration and viral load (Lee et al., 2020; Long et al., 2020; Zou et al., 2020). Persistent SARS-CoV-2 RNA shedding has been documented, with patients remaining qRT-PCR-positive for up to 63 days (Li et al., 2020; Liu et al., 2020b). In addition, there are reports of symptomatic and asymptomatic individuals testing positive again after a period of negative testing (Lan et al., 2020; Hu et al., 2020). Because qRT-PCR detects viral RNA but does not confirm the presence of infectious SARS-

CoV-2, these observations raise questions about the duration of infectious SARS-CoV-2 shedding and transmission potential for symptomatic and asymptomatic individuals.

Estimates suggest that infectiousness begins 2.3 days prior to symptom onset and declines within 7 days of symptom onset (He et al., 2020b). Consistent with this, infectious SARS-CoV-2 has been isolated from patient samples taken up to 8 days after symptom onset but typically not thereafter (Wölfel et al., 2020; Bullard et al., 2020). In contrast to prolonged shedding of SARS-CoV-2 RNA, the longest detected shedding of infectious SARS-CoV-2 virus is up to 20 days after the initial positive test result (van Kampen et al., 2020; Liu et al., 2020b). The probability of isolating SARS-CoV-2 decreases with a lower viral load, when the duration of symptoms exceeds 15 days, and upon generation of detectable neutralizing antibodies (van Kampen et al., 2020).

On January 19, 2020, the first case of coronavirus disease 2019 (COVID-19) was identified in the United States, in Snohomish County, Washington, in a traveler returning from Wuhan,

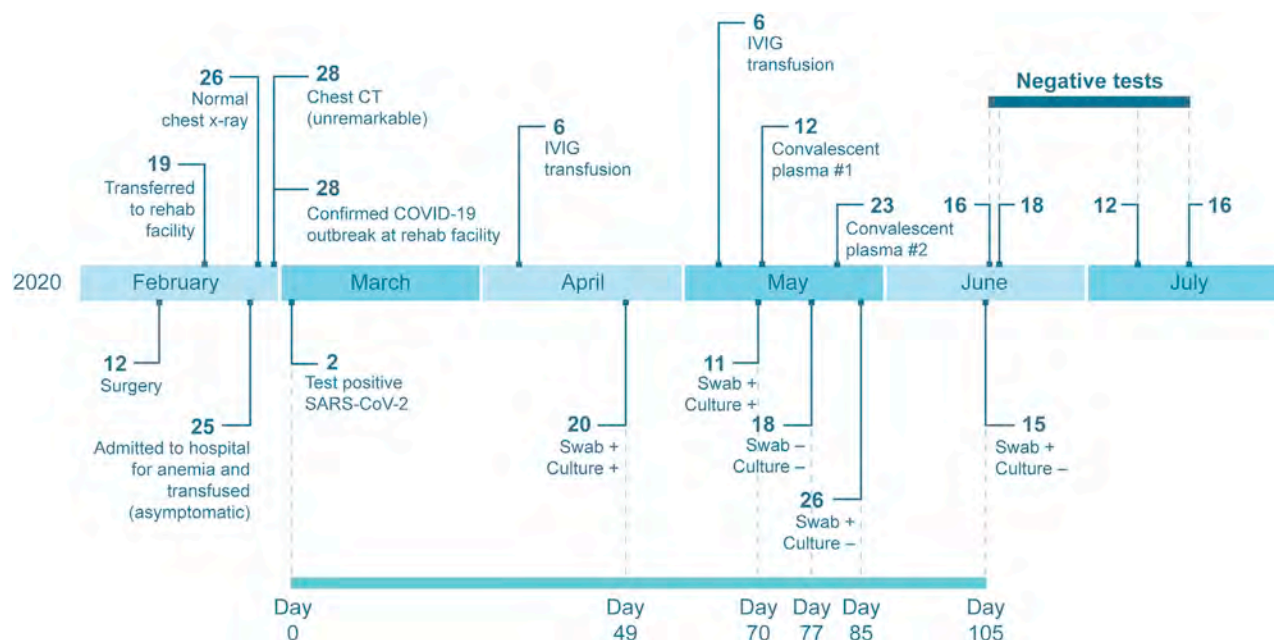

Figure 1. Timeline of Clinical Presentation, Diagnostic Tests, and Treatments of an Immunocompromised Individual with Long-Term Shedding of SARS-CoV-2

Dates of relevant clinical events, such as surgeries, therapies, and outcome of diagnostic tests, are shown. Diagnostic qRT-PCR-positive nasopharyngeal and oropharyngeal swabs taken 49, 70, 77, 85, and 105 days after the initial positive sample were sent to Rocky Mountain Laboratories, NIH, for further analysis. Serum and plasma samples pre- and post-transfusion as well as a sample from the donor plasma were also provided. See also [Tables S1–S3](#) for additional laboratory values and clinical information.

China. Community spread in the Seattle region became evident in late February of 2020 ([Bhatraju et al., 2020](#)), with extensive spread in a long-term care facility ([McMichael et al., 2020a](#)). Here we describe an asymptomatic, immunocompromised individual persistently testing positive for SARS-CoV-2 by qRT-PCR who was infected during the early phase of SARS-CoV-2 spread in the United States. Infectious SARS-CoV-2 was successfully isolated from nasopharyngeal swabs 49 days and 70 days after the initial positive qRT-PCR test. Convalescent plasma treatment was not immediately successful in clearing the infection, but evidence of SARS-CoV-2 RNA was eventually cleared after 105 days.

RESULTS

Clinical Presentation of an Immunocompromised Individual Persistently Infected with SARS-CoV-2

On February 12, 2020, a 71-year-old woman with a 10-year history of chronic lymphocytic leukemia (CLL), acquired hypogammaglobulinemia, anemia, and chronic leukocytosis presented to the emergency department with low back and lower extremity pain. She underwent surgery for a spinal fracture and stenosis related to her cancer on February 14, 2020 (biopsy results in [Table S1](#)) and was subsequently transferred to a rehabilitation facility on February 19, 2020. On February 25, 2020, she was re-hospitalized for anemia and underwent a chest X-ray the following day, which was normal. She could not return to her rehabilitation center because of a confirmed outbreak of COVID-19 at the facility ([McMichael et al., 2020a, 2020b](#)). Chest computed tomog-

raphy (CT), performed on February 28, 2020, was unremarkable. The patient had no respiratory or systemic symptoms during this time. Because she was residing in the rehabilitation facility around the time of the COVID-19 outbreak, she was tested and found positive for SARS-CoV-2 on March 2, 2020 ([Figure 1](#)). After the initial SARS-CoV-2 diagnosis, she was kept in an isolation ward in a single room with negative airflow. Attending medical staff were using full personal protective equipment comprised of powered air-purifying respirators (PAPR) or N95 respirators with goggles, gowns, and gloves. Over the course of the next 15 weeks, she was tested for SARS-CoV-2 another 14 times by several diagnostic companies and remained positive through June 15, 2020, 105 days since the initial positive test. Subsequently, she tested negative on four consecutive swabs from June 16 to July 16, indicating that her infection had cleared.

Because of acquired hypogammaglobulinemia caused by her CLL, the individual received intravenous immunoglobulin (IVIG) every 4–6 weeks as part of her treatment regimen. She received IVIG treatment on April 6 and May 6, 2020. The manufacture date of her specific lot of IVIG preceded January 1, 2020, the beginning of the COVID-19 pandemic, and therefore did not contribute to any SARS-CoV-2 serology results ([Table S2](#)). Because of the persistence of her SARS-CoV-2 infection, serum samples were tested for antibodies against the spike glycoprotein through a study at the NIH Clinical Center, and no spike-specific antibodies were detected ([Burbelo et al., 2020](#)). On May 12, 2020, she was transfused with 200 mL of SARS-CoV-2 convalescent plasma provided by Bloodworks Northwest under a US Food and Drug Administration (FDA) emergency investigational new drug

Table 1. Virus Neutralization Titers in Pre- and Post-transfusion Sera from the Individual and Convalescent Plasma Used for Transfusion

Serum	USA/WA1/2020	Day 49 Isolate	Day 70 Isolate
Day 49	<10	<10	<10
Day 71	<10	<10	<10
Day 71 after transfusion	<10	<10	<10
Day 77	<10	<10	<10
Day 82	< 10	10	<10
Day 82 after transfusion	10	10	15
Day 105	10	<10	<10
Convalescent plasma 1	60	40	40
Convalescent plasma 2	160	160	60

Virus neutralization assays were performed for all serum and plasma samples with SARS-CoV-2 strains USA/WA1/2020 and the day 49 and day 70 isolates from the individual. Each serum/plasma sample was tested in duplicate.

(eIND) protocol with a virus-neutralizing (VN) titer of 60 (Table 1). Her infection persisted, and on May 23, 2020, she received another 200-mL dose of convalescent plasma from a different donor with a VN titer of 160 under the same protocol (Table 1). Additional laboratory values are available in Table S3.

Long-Term Shedding of Genomic RNA, Subgenomic RNA, and Infectious SARS-CoV-2

SARS-CoV-2 shedding kinetics in the individual were monitored using detection of genomic RNA (gRNA), subgenomic RNA (sgRNA), and infectious SARS-CoV-2. RNA was extracted from nasopharyngeal and oropharyngeal swabs collected 49, 70, 77, 85, 105, and 136 days after the initial diagnosis and evaluated for the presence of viral gRNA (Corman et al., 2020) and sgRNA (Wölfel et al., 2020). gRNA and sgRNA were detected in nasopharyngeal swabs out to day 105, except for the swab taken on day 77 (Figure 2A), although the test through EvergreenHealth was positive at this time. None of the oropharyngeal swabs were positive for gRNA or sgRNA, suggesting that the infection was confined to the nasopharynx. Absolute quantification of gRNA and sgRNA on positive swabs was performed by droplet digital PCR (ddPCR) (Figure 2A). The highest viral load was detected in the day 70 swab, at 2.2×10^6 gRNA copies/mL (cycle threshold [Ct] 22.44) and 1.1×10^5 sgRNA copies/mL (Ct 29.05). Detection of sgRNA in swabs is indicative of active SARS-CoV-2 replication because only actively replicating SARS-CoV-2 initiates RNA synthesis, resulting in replication and transcription of sgRNAs (Wang et al., 2020b; Kim et al., 2020), and sgRNA, unlike gRNA, does not persist in the nasal cavity in the absence of virus replication (Speranza et al., 2020). Virus isolation was attempted on all qRT-PCR-positive samples. Infectious SARS-CoV-2 was successfully cultured from the nasopharyngeal swabs collected on day 49 and day 70. Scanning and transmission electron microscopy on SARS-CoV-2 cultured from the nasopharyngeal swabs collected on days 49 and 70 showed viral particles consistent with coronavirus morphology, supporting persistent SARS-CoV-2 infection with shedding of infectious virus in this individual (Figure 3).

Convalescent Plasma Treatment Did Not Clear SARS-CoV-2 from the Upper Respiratory Tract

In an attempt to treat the persistent SARS-CoV-2 infection, the individual received two doses of convalescent plasma therapy on days 71 and 82. Pre- and post-transfusion serum samples and the transfusion convalescent plasma samples were analyzed for the presence of full-length spike and spike receptor binding domain (RBD) antibodies by ELISA assay and of SARS-CoV-2-neutralizing antibodies in a VN assay (Figures 2B and 2C; Figures S1A and S1B; Table 1; Amanat et al., 2020; Wrapp et al., 2020). The first dose of convalescent plasma (convalescent plasma 1) had an immunoglobulin G (IgG) spike titer of 2,560, RBD titer of 3,840, and VN titer of 60. The second dose of convalescent plasma (convalescent plasma 2) had an IgG spike titer of 5,120, RBD titer of 5,120, and VN titer of 160 (Figure 2B; Figure S1A; Table 1). Prior to the first dose of plasma given on day 71, detectable spike and RBD IgG antibody titers were very low in serum collected from the individual, with IgG titers between 1:10 and 1:40 on days 49 and 71 pre transfusion; no VN titers were detected in these samples. Immediately after the first transfusion on day 71, the spike and RBD IgG antibody titers rose to 1:320 and then decreased to 1:80 and 1:160, respectively, on day 77. No VN titers were detected on days 71 and 77 (Figure 2C; Figure S1B; Table 1). Immediately after the second transfusion on day 82, the spike and RBD IgG titers increased to 1:320 and 1:640, respectively, and remained elevated by day 105 (Figure 2C; Figure S1B). Low neutralizing titers of 1:10 were observed on day 82 and 105 (Table 1).

Despite two transfusions of convalescent plasma, nasopharyngeal swabs on days 85 and 105 remained positive for gRNA and sgRNA, suggesting that the convalescent plasma therapy was not successful in rapidly clearing the infection from the upper respiratory tract in this individual. Although the presence of sgRNA at these time points suggests active viral replication, infectious SARS-CoV-2 could not be cultured after day 70.

Genetic Analysis of Patient Swab Samples Links Infection to the Primary Washington State Outbreak

SARS-CoV-2 full genome sequences were obtained from nasopharyngeal swabs collected on days 49, 70, 85, and 105 (Table S4). Full genomes were obtained by sequencing using the ARTIC primer set (<https://artic.network/>) and assembling reads to MN985325.1 (USA/WA1/2020) as the reference genome (Harcourt et al., 2020). The SARS-CoV-2 lineage was determined using Pangolin software (<https://pangolin.cog-uk.io/>), which placed the individual's viral genomes in lineage A.1, which consists of genomes originating from the primary outbreak in Washington state (Rambaut et al., 2020). A maximum-likelihood tree was generated using representative SARS-CoV-2 genomes from previously described lineages (Rambaut et al., 2020) obtained from the GISAID database (<https://www.gisaid.org/>; Shu and McCauley, 2017). The individual's SARS-CoV-2 full-length genomes cluster together within lineage A.1 (Figure 4A). This suggests that she was infected with a virus from the SARS-CoV-2 A.1 lineage, which circulated after the initial import from China, followed by exponential growth and local transmission in Washington state.

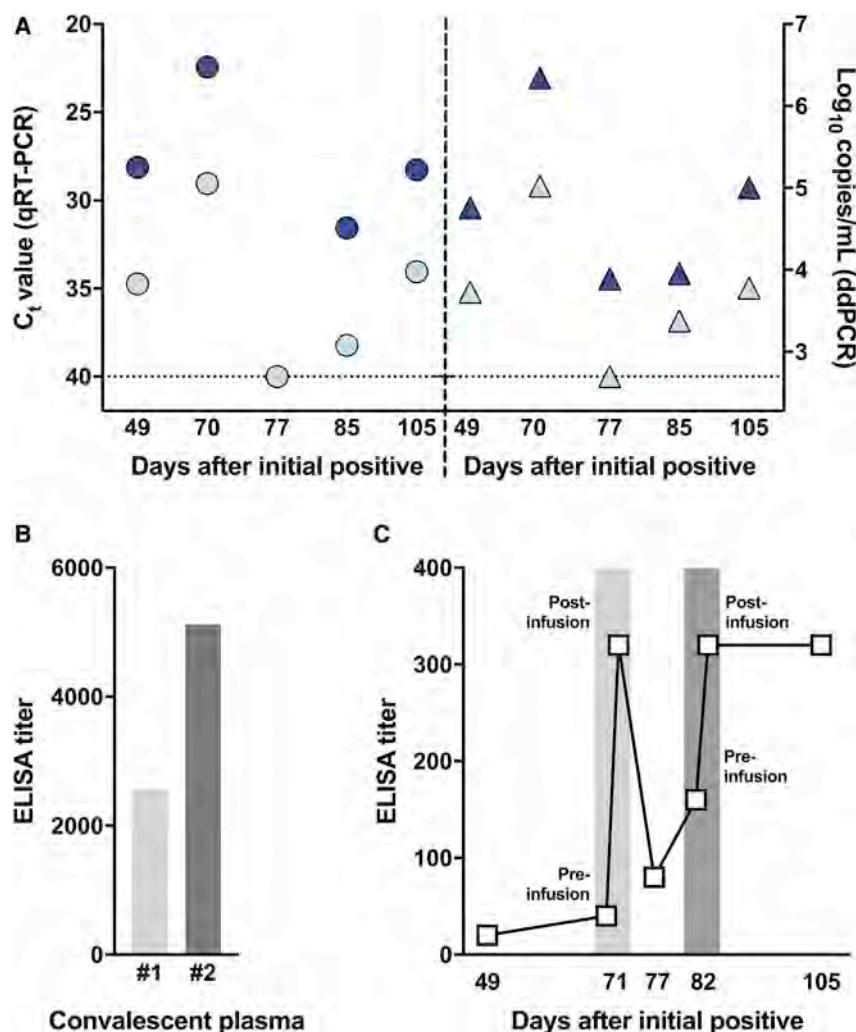

Figure 2. Assessment of Viral Load and Seroconversion in an Individual Persistently Infected with SARS-CoV-2 and Treated with Convalescent Plasma

(A) Viral loads were in nasopharyngeal swabs collected at different time points after the initial SARS-CoV-2 diagnosis. Viral RNA extracted from a nasopharyngeal swab was analyzed for the presence of genomic RNA (gRNA; dark blue) and sub-genomic RNA (sgRNA; light blue symbols) by qRT-PCR and reported as a cycle threshold (Ct) value (circles, left panel) and in ddPCR and reported as copy numbers (triangles, right panel).

(B) IgG titers against the full-length recombinant SARS-CoV-2 spike ectodomain were determined by ELISA in convalescent plasma used for transfusion. The light gray bar represents the IgG titer of the first donor (convalescent plasma 1), and the dark gray bar represents the second donor (convalescent plasma 2).

(C) IgG titers against the full-length recombinant SARS-CoV-2 spike ectodomain were determined by ELISA in patient serum collected at several time points, including immediately before and after transfusion with convalescent plasma on days 71 (light gray) and 82 (dark gray). Each serum/plasma sample was tested in duplicate.

See also Figure S1 for IgG titers against the SARS-CoV-2 receptor binding domain (RBD).

tween February 27 and March 31, 2020, within 90% of the marginal probability distribution. This is consistent with the timing of the individual's first positive test on March 2, 2020. To further evaluate the relationship between the SARS-CoV-2 genomes recovered from the patient swabs and other SARS-CoV-2 genomes circulating in Washington state at the times of sampling (April 20, May 11, May 26, and

To visualize the temporal relationships of the patient isolates, 44 full SARS-CoV-2 genome sequences from Washington state belonging to NextStrain clade 19B (<http://clades.nextstrain.org/>) were subsampled from the GISAID database (<https://www.gisaid.org/>; Shu and McCauley, 2017) representing strains collected in Washington state from February to May 2020. A full genome alignment was performed with four of the full genome sequences recovered from the persistently infected individual, the USA/WA1/2020 genome sequence, and the Wuhan-Hu-1/2019 genome sequence with MAFFT v.1.4 (Katoh and Standley, 2013; Katoh et al., 2002) implemented in Geneious Prime v.2020.1.2 (<https://www.geneious.com/>). A maximum-likelihood tree was reconstructed with PhyML v.3.1 (Guindon et al., 2010), and a tree showing temporal divergence (Figure 4B) was inferred in TreeTime v.0.7.6 (Sagulenko et al., 2018; Hadfield et al., 2018) using the HKY85 model of nucleotide substitution and a fixed molecular clock at 8×10^{-4} with a standard deviation of 4×10^{-4} , as implemented in the NextStrain pipeline (<https://nextstrain.org/sars-cov-2/>). Divergence dating estimates place the patient isolates sharing a most recent common ancestor be-

June 15, 2020), Washington SARS-CoV-2 genomes were downloaded from the GISAID database (Shu and McCauley, 2017). The quality of the sequences was determined by Nextclade v.0.7.5 (<https://nextstrain.org/ncov/global>), and 1,789 sequences on April 20, 385 sequences between April 20 and May 11, 268 sequences between May 11 and May 26, and 709 sequences between May 26 and June 15 were kept for further phylogenetic analysis. Maximum likelihood trees using the curated sets of sequences, the four patient genomes, and the USA/WA1/2020 genome were inferred using ModelFinder (Kalyaanamoorthy et al., 2017) and ultrafast bootstrap (Hoang et al., 2018) implemented in IQ-TREE v.1.6.12 (Nguyen et al., 2015). The phylogenetic trees show that the patient genomes in this study cluster as a monophyletic clade consistent with infection in late February/early March, followed by virus persistence (Figure S2).

Next, full genome sequences from the two SARS-CoV-2 isolates were obtained (Table S4), and the consensus level variants in the sequences obtained from nasopharyngeal swabs and SARS-CoV-2 isolates cultured from those swabs were

Figure 3. Electron Microscopy Confirms Isolation of Coronavirus from the Individual's Nasopharyngeal Swabs

SEM scale bars, 1 μ m; TEM scale bars, 0.5 μ m.

compared with the reference strain USA/WA1/2020 (MN985325.1) (Harcourt et al., 2020). Several single-nucleotide (nt) substitutions were observed within the ORF1ab, spike, M, and ORF8 coding sequence in the full-genome sequences obtained directly from the individual's swabs and the SARS-CoV-2 isolates. In addition, a 3-nt deletion leading to loss of a methionine residue was observed in nsp1 in day 49 and day 70 samples (Table 2). Within the genomes of the two SARS-CoV-2 isolates, two in-frame deletions were observed in the spike glycoprotein coding region. A 21-nt in-frame deletion (residues 21,975–21,995) was found in the N-terminal domain (NTD) of S1, leading to a 7-amino-acid deletion (amino acids [aa] 139–145) in the spike glycoprotein of the SARS-CoV-2 day 49 isolate. A smaller, 12-nt deletion (residues 21,982–21,993) was detected in the day 70 isolate, leading to a 4-aa deletion (aa 141–144) in the NTD, which falls within the 7-aa deletion found in the day 49 isolate (Figure 5A). These observed deletions in the spike glycoprotein map to a region in the NTD that is partially solvent exposed and forms a β strand in a compact conformation of the spike (Wrobel et al., 2020; Figures 5B and 5C). This region is unmodelled in other structures representing additional conformational states of the spike and, thus, is likely flexible (Wrapp et al., 2020; Walls et al., 2020). It is possible that the apparent plasticity in this region of the molecule may contribute to the structural permissibility of the identified deletions. The position of these deletions is distinct from those observed in other SARS-CoV-2 isolates, which locate to the S1/S2 and S2' cleavage sites (Andrés et al., 2020; Lau et al., 2020; Liu et al., 2020d).

Comparison of the full genome sequences obtained directly from the individual's samples with the genome data obtained from the two SARS-CoV-2 isolates showed that the 21-nt deletion was present in a minority of sequencing reads (1%) in the genome obtained from the individual's sample from day 49 (Table 2) and was selected for upon passage in cell culture. The 12-nt deletion on day 70 was present in 100% of the reads in the

clinical sample and tissue culture isolate. Notably, neither spike deletion was detected in the genome sequences from the day 85 and day 105 swabs (Table 2). It is possible that other minor variants exist at low levels that were undetected by the depth of sequencing coverage or were not reflected in the sampling at that time point. The variation observed

between the different full-length genomes obtained at various time points during the course of infection points to a quasispecies complex with continuous turnover of dominant viral species.

Growth Kinetics of SARS-CoV-2 Patient Isolates

The replication kinetics of the day 49 isolate SARS-CoV-2 were compared with those of the reference strain USA/WA1/2020 in Vero E6 cells. Despite the observed mutations in the day 49 isolate, no difference in replication kinetics were observed between the day 49 isolate and the reference strain (Figure 6A). To determine growth kinetics in a more functionally relevant cell type, growth curves were also performed on primary human alveolar epithelial tissues (EpiAlveolar; MatTek, Ashland, MA, USA). No significant differences were observed between the individual's isolate and the reference strain in these cells (Figure 6B).

DISCUSSION

In this report, we describe long-term SARS-CoV-2 shedding in an immunocompromised individual with CLL and acquired hypogammaglobulinemia out to 105 days after the initial positive test. Although the exact time point when the individual acquired SARS-CoV-2 is unknown, it is likely that the exposure occurred in the long-term care facility where she resided between February 19–25, 2020, shortly before a large COVID-19 outbreak was identified in that facility on February 28, 2020. The individual remained asymptomatic throughout the course of infection despite isolation of infectious SARS-CoV-2 49 and 70 days after the initial diagnosis, much longer than shedding of infectious virus up to day 20, as reported previously (van Kampen et al., 2020). The information available to date about SARS-CoV-2 infection in immunocompromised individuals, including those with cancers such as CLL, is limited and mostly focuses on disease severity and outcome (He et al., 2020a; Paneesha et al.,

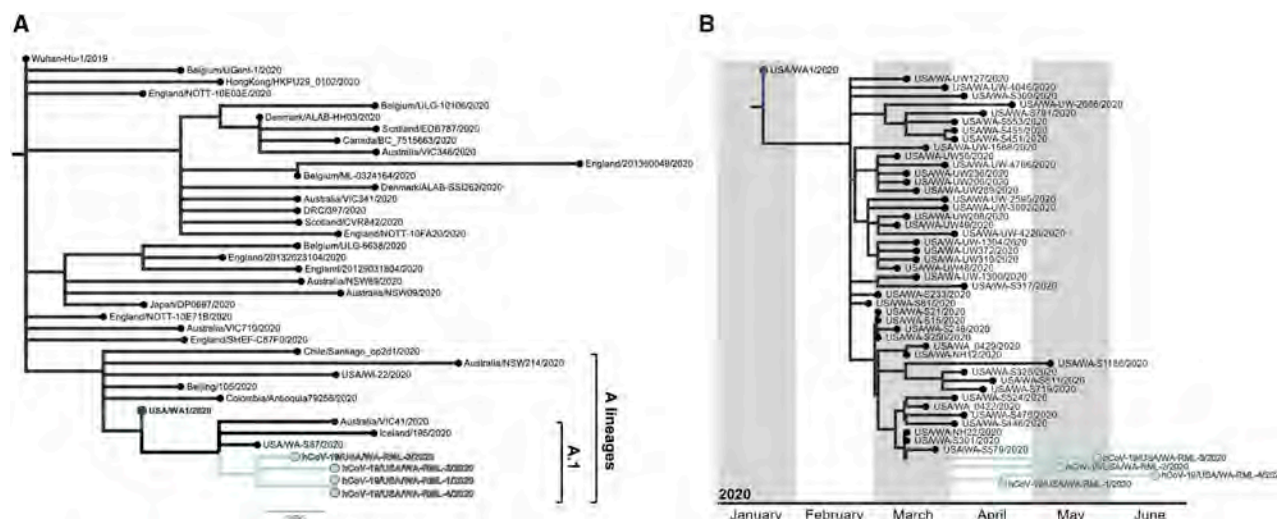

Figure 4. Phylogenomic Analyses of Described SARS-CoV-2 Strains in a Persistently Infected Individual

(A) Full-genome SARS-CoV-2 sequences representing previously described lineages (Rambaut et al., 2020) were downloaded from GISAID (Shu and McCauley, 2017). Lineages were then assigned using Pangolin v.2.0.3 (<https://pangolin.cog-uk.io/>). Using a representative genome from the assigned lineages and the four SARS-CoV-2 sequences from the individual, a maximum-likelihood tree was inferred using PhyML v.3.3.20180621 (Guindon et al., 2010) implemented in Geneious Prime v.2020.1.2 (<https://www.geneious.com/>) with a general time-reversible model of nucleotide substitution and rooted at the Wuhan-Hu-1/2019 SARS-CoV-2 strain. Sequences from the A and A.1 lineages are labeled, and the individual's SARS-CoV-2 sequences are shown in cyan. hCoV-19/USA/WA-RML-1, -2, -3, and -4 are the genome sequences derived from the individual from day 49, 70, 85, and 105 nasopharyngeal swabs, respectively.

(B) Full SARS-CoV-2 genomes were subsampled from Washington state, representing NextStrain clade 19B, including the four full-genome sequences recovered from the individual and the Wuhan-Hu-1/2019 sequence and aligned using MAFFT v.1.4 (Katoh and Standley, 2013; Katoh et al., 2002) implemented in Geneious Prime v.2020.1.2 (<https://www.geneious.com/>). A maximum-likelihood tree was then reconstructed with PhyML v.3.1 (Guindon et al., 2010), and a tree showing temporal divergence was inferred in TreeTime v.0.7.6 (Hadfield et al., 2018). The individual's SARS-CoV-2 sequences are shown in cyan, and hCoV-19/USA/WA-RML-1, -2, -3, and -4 are the genome sequences derived from the individual from day 49, 70, 85, and 105 nasopharyngeal swabs, respectively.

See also Figure S2.

2020; Baumann et al., 2020; Fürstenau et al., 2020; Jin et al., 2020; Soresina et al., 2020; Zhu et al., 2020; Fill et al., 2020). Although it is difficult to extrapolate from a single individual, our data suggest that long-term shedding of infectious virus may be a concern in certain immunocompromised people. Given that immunocompromised individuals could have prolonged shedding and may not have typical symptoms of COVID-19, symptom-based strategies for testing and discontinuing transmission-based precautions, as recommended by the Centers for Disease Control and Prevention (CDC) (CDC, 2020b), may fail to detect whether certain individuals are shedding infectious virus.

The individual eventually cleared the SARS-CoV-2 infection from the upper respiratory tract after developing low neutralizing antibody titers. How the virus was cleared and the effect of convalescent plasma on clearance of the virus is unknown. The initial administration of convalescent plasma was followed by a decreased viral load in nasal swabs, but viral loads subsequently increased, despite administration of a second dose of convalescent plasma comprising higher antibody titers. Therapeutic administration of convalescent plasma is focused on treatment of severe or life-threatening COVID-19. Several clinical trials are investigating the efficacy of convalescent plasma, but currently the effect of convalescent plasma therapy on COVID-19 outcome remains equivocal (Mira et al., 2020; Salazar et al., 2020). The limited effect of convalescent plasma treatment on

clearance of SARS-CoV-2 could be due to the fact that intravenously (i.v.) administered antibodies do not distribute well to the nasal epithelium (Ikegami et al., 2020) compared with the lower respiratory tract (Mira et al., 2020).

Throughout the course of infection, there was marked within-host genomic evolution of SARS-CoV-2. Deep sequencing revealed a continuously changing virus population structure with turnover in the relative frequency of the observed genotypes over the course of infection. With SARS-CoV-2, there is generally relatively limited within-host variation reported, and over the course of infection, the major SARS-CoV-2 population remains identical (Jary et al., 2020; Shen et al., 2020; Capobianchi et al., 2020). Potential factors contributing to the observed within-host evolution is prolonged infection and the compromised immune status of the host, possibly resulting in a different set of selective pressures compared with an immune-competent host. These differential selective pressures may have allowed a larger genetic diversity with continuous turnover of dominant viral species throughout the course of infection. Although some sequence variants remain consistent throughout the duration of infection, we also observed variants unique to individual time points, such as the spike deletions observed on day 49 and day 70. Previously reported spike deletions, distinct from those reported here, were observed at relatively low frequency in clinical samples but were enriched upon virus isolation (Andrés et al., 2020; Liu et al., 2020d). Similar to these reports, the spike

deletion in the isolate on day 49 was observed as a minor variant in the individual's sample but was also selected for during passage upon virus isolation.

In contrast to the previously reported deletions at the cleavage sites, both spike deletions observed on day 49 and 70 in the individual are located in the NTD of S1, a region distal from the receptor binding site. These deleted residues are not modeled in a number of spike structures (Wrapp et al., 2020; Walls et al., 2020), suggesting that this region is conformationally labile. Although the NTD has been identified as an antigenic target (Brouwer et al., 2020; Chi et al., 2020; Liu et al., 2020a), no clear difference in virus neutralization was observed between the two patient isolates and the prototype USA/WA1/2020 SARS-CoV-2 isolate.

Despite genetic changes in the SARS-CoV-2 isolated from the individual, the replication kinetics did not change significantly compared with the USA/WA1/2020 virus in Vero E6 cells and primary human alveolar epithelial tissues. This indicates that, most likely, the infectious virus shed by the individual would still be able to establish productive infection in contacts upon transmission, assuming that viral growth kinetics *in vitro* are a suitable surrogate for virus fitness *in vivo*. Moreover, despite prolonged replication exclusively in the upper respiratory tract, the virus was still able to replicate in epithelial cells derived from the lower respiratory tract, suggesting that it could still cause pneumonia.

Many current infection control guidelines assume that persistently PCR-positive individuals are shedding residual RNA and not infectious virus, with immunocompromised people thought to remain infectious for no longer than 20 days after symptom onset (CDC, 2020a). Here we show that certain individuals may shed infectious, replication-competent virus for much longer

than previously recognized (van Kampen et al., 2020). Although infectious virus could be detected up to day 70, sgRNA, a molecular marker for active SARS-CoV-2 replication (Speranza et al., 2020), could be detected up until day 105. An immunocompromised state has been identified as a risk factor for development of severe disease and complications from COVID-19 (CDC, 2020b). A wide variety of conditions and treatments can alter the immune system and cause immunodeficiency, creating opportunities for prolonged viral replication and shedding of infectious SARS-CoV-2. Although this report focuses on long-term shedding of one immunocompromised individual, an estimated 3 million people in the United States have some form of immunocompromising condition, including individuals with HIV infection, solid organ transplant recipients, hematopoietic stem cell transplant recipients, and individuals receiving chemotherapy and corticosteroids (Kunisaki and Janoff, 2009). This transient or chronic immunocompromised population is at higher risk of respiratory disease complications with respiratory infections such as influenza A virus and SARS-CoV-2 (Kunisaki and Janoff, 2009). Prolonged shedding of pH1N1 was observed in immunocompromised individuals with a variety of immunocompromising conditions during the previous pandemic in 2009, such as people with cancer on chemotherapy and solid organ transplant recipients (van der Vries et al., 2013). For the SARS-CoV-2 related Middle East respiratory syndrome CoV (MERS-CoV), prolonged shedding up to 38 days was observed in individuals with myelodysplastic syndrome, autologous peripheral blood stem cell transplantation for treatment of large B cell lymphoma, and an individual with peripheral T cell lymphoma (Kim et al., 2017). MERS-CoV shedding was higher and longer in experimentally

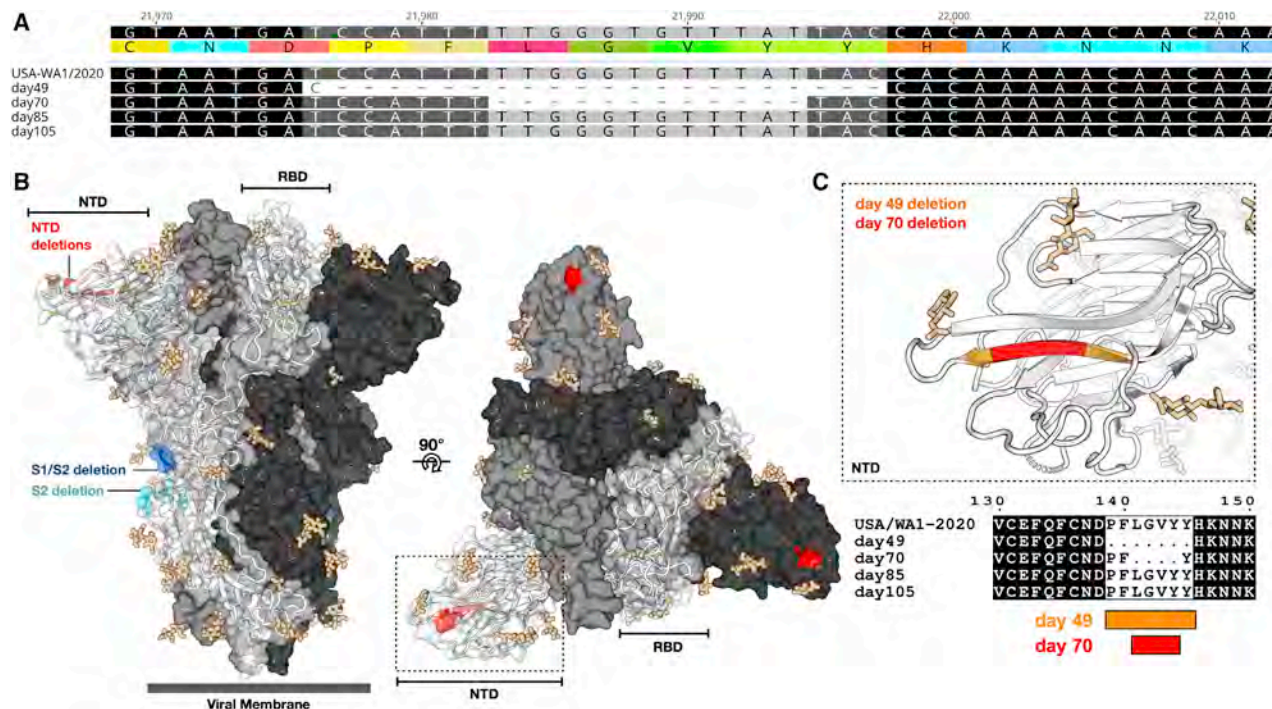

Figure 5. Deletions in the NTD of S1 of the Spike Protein

(A) Nucleotide and amino acid sequence alignment of the region of the spike gene of the four sequences from the individual and the reference USA/WA1/2020 genome sequence containing the deletions observed in the day 49 and day 70 samples. Alignment was generated with MAFFT v.1.4 (Kato and Standley, 2013; Kato et al., 2002) implemented in Geneious Prime 2020.1.2 (<https://www.geneious.com>).

(B) Amino acid residues removed by the day 49 (orange) and day 70 (red) spike deletions are highlighted on a SARS-CoV-2 spike trimer (PDB: 6zge; Wrobel et al., 2020). Each protomer of the trimer is shown in surface representation, colored in shades of gray. A single protomer is annotated, and its secondary structure is shown in cartoon representation. Glycans are shown as beige sticks. Previously reported spike deletions observed at the S1/S2 and S2' cleavage sites (Andrés et al., 2020; Lau et al., 2020; Liu et al., 2020d) are colored blue and cyan, respectively.

(C) Close-up view of the indicated region of (B) (dotted box) with the protein surface removed for clarity and accompanying amino acid sequence alignment, generated using Multalin (Corpet, 1988) and plotted with ESPrpt (Robert and Gouet, 2014).

infected non-human primates immunosuppressed with cyclophosphamide and dexamethasone, providing experimental support for the effect of immunosuppression on virus-host dynamics observed here (Prescott et al., 2018).

Limitations of Study

A limitation of the present study is that it comprises only a single case, making it difficult to draw general conclusions regarding use of convalescent plasma for clearance of the virus, potential alternative mechanisms involved in virus clearance, and the frequency of persistent SARS-CoV-2 infection and shedding in individuals with other immunocompromising conditions. Identification of additional cases of persistent infection and long-term shedding of infectious virus are needed so the infection dynamics can be studied in more detail in this diverse population. Understanding the mechanism of virus persistence and eventual clearance will be essential for providing appropriate treatment and preventing transmission of SARS-CoV-2 because persistent infection and prolonged shedding of infectious SARS-CoV-2 might occur more frequently. Because immunocompromised individuals are often cohorted in hospital settings, a more nuanced approach to testing these individuals is warranted, and the presence of persistently positive people by performing SARS-CoV-2

gRNA and sgRNA analyses on clinical samples should be investigated.

STAR★METHODS

Detailed methods are provided in the online version of this paper and include the following:

- **KEY RESOURCES TABLE**
- **RESOURCE AVAILABILITY**
 - Lead Contact
 - Materials Availability
 - Data Availability
- **EXPERIMENTAL MODEL AND SUBJECT DETAILS**
 - Human Patient
 - Cells
 - SARS-CoV-2 Virus
- **METHOD DETAILS**

STAR★METHODS

KEY RESOURCES TABLE

REAGENT or RESOURCE	SOURCE	IDENTIFIER
Antibodies		
Rabbit anti-Human IgG Fc fragment Secondary Antibody (HRP)	Novus biologicals	Cat# NBP1-73529; Lot 34900
Bacterial and Virus Strains		
hCoV-19/USA/WA1/2020	CDC, Atlanta, USA (Harcourt et al., 2020)	GenBank: MN985325.1
hCoV-19/USA/WA-RML-5/2020 (SARS-CoV-2 patient genome d49 isolate)	This paper	GenBank: MT982401
hCoV-19/USA/WA-RML-6/2020 (SARS-CoV-2 patient genome d70 isolate)	This paper	GenBank: MT982404
Biological Samples		
Patient nasopharyngeal swabs	This paper	EvergreenHealth
Patient oropharyngeal swabs	This paper	EvergreenHealth
Patient serum and plasma	This paper	EvergreenHealth
Donor convalescent plasma	This paper	EvergreenHealth
Chemicals, Peptides, and Recombinant Proteins		
SARS-CoV-2 spike protein	This paper (Wrapp et al., 2020)	N/A
SARS-CoV-2 receptor binding domain protein	This paper (Amanat et al., 2020)	N/A
PEI transfection reagent	Polysciences	Cat# 23966-1
Blocker Casein in PBS	ThermoFisher	Cat# 37528
TMB 2-Component Microwell Peroxidase Substrate Kit	SeraCare	Cat# 5120-0047
KPL TMB Stop Solution	SeraCare	Cat# 5150-0020
Trizol Reagent	Invitrogen	Cat# 15596026
Karnovsky's EM fixative	Electron Microscopy Sciences	Cat#15720
Sodium Cacodylate	Sigma	Cat#C4945-10G; CAS#6131-99-3
Osmium Tetroxide	Electron Microscopy Sciences	Cat#19190; CAS#20816-12-0
Potassium Ferrocyanide	Sigma	Cat#P-3289; CAS#14459-95-1
Uranyl Acetate	Ted Pella	Cat#19481; CAS#6159-44-0
Critical Commercial Assays		
PureLink RNA Mini Kit	Invitrogen	Cat# 12183018A
SuperScript IV First-Strand Synthesis System	Invitrogen	Cat# 18091050
Quantifast Probe RT-PCR Kit (for Rotorgene)	QIAGEN	Cat# 204556
ddPCR Supermix for Probes (no dUTP)	Biorad	Cat# 1863024
Q5 Hot Start High-Fidelity DNA Polymerase – 100U	New England Biolabs	Cat#M0493S
ARTIC nCoV-2019 V3 Panel, 500rxn	Integrated DNA Technologies	Cat#10006788
TruSeq DNA PCR-Free LT Library Prep	Illumina	Cat#20015962
TruSeq DNA Idx Kit Set A	Illumina	Cat#20015960
MiSeq Reagent Nano Kit, v2 (500 cycles) (1M)	Illumina	Cat#MS-103-1003
Deposited Data		
Data used to generate figures	This paper	Mendeley Data at https://dx.doi.org/10.17632/3n377gv8kb .
hCoV-19/USA/WA-RML-1/2020 (SARS-CoV-2 patient genome d49 NP swab)	This paper	GenBank: MT982403

RESOURCE AVAILABILITY**Lead Contact**

Further information and requests for resources and reagents should be directed to and will be fulfilled by the Lead Contact, Vincent Munster (Vincent.munster@nih.gov).

Materials Availability

This study did not generate new reagents.

Data Availability

The data and the Supplementary Tables from this study have been deposited to Mendeley Data at <https://dx.doi.org/10.17632/3n377gv8kb>.

Genome sequences have been deposited to GenBank: MT982403, MT982402, MT982405, MT982406, MT982401 and MT982404.

EXPERIMENTAL MODEL AND SUBJECT DETAILS**Human Patient**

The patient described in this case study is a 71 year old female with a 10 year history of chronic lymphocytic leukemia (CLL), acquired hypogammaglobulinemia, anemia, and chronic leukocytosis. The patient tested positive for SARS-CoV-2 on March 2, 2020, and

remained positive through June 15, 2020. During the course of the study, the patient was transfused with intravenous immunoglobulin (IVIG, 25 g) on April 6 and May 6, 2020, and convalescent plasma against SARS-CoV-2 on May 12 and May 23, 2020. After the initial SARS-CoV-2 diagnosis, the patient was kept in isolation in an isolation ward in a single room with negative airflow. Anonymized plasma, serum and swabs from a patient at EvergreenHealth, Kirkland, Washington were obtained under an NIH Institutional Review Board exemption. Verbal and signed consent were obtained from the patient to allow analyses of the samples.

Cells

Vero E6 is a female African green monkey kidney epithelial cell line. Vero E6 cells were maintained at 37°C and 5% CO₂ in DMEM supplemented with 10% fetal bovine serum, 1 mM L-glutamine, 50 U/mL penicillin and 50 µg/mL streptomycin. Vero E6 cells were provided by Dr. Ralph Baric. Cells were authenticated by cytochrome B sequencing. Mycoplasma testing was performed monthly, and no mycoplasma was detected.

FreeStyle 293-F (RRID: CVCL_D603) is a female human embryonic cell line adapted for growth in suspension culture. FreeStyle 293-F cells were grown in Freestyle 293 Expression Medium (GIBCO) at 37°C and 8% CO₂, shaking at 130 rpm. Cells were not authenticated in house. Mycoplasma testing was performed monthly, and no mycoplasma was detected.

MatTek EpiAlveolar is a 3D co-culture model of the air-blood barrier produced from primary human alveolar epithelial cells, pulmonary endothelial cells and fibroblasts, and maintained according to manufactures instructions (<https://www.mattek.com/products/epialveolar/>). Cells were not authenticated in house. Mycoplasma testing was performed monthly, and no mycoplasma was detected.

SARS-CoV-2 Virus

SARS-CoV-2 strain nCoV-WA1-2020 (MN985325.1) (Harcourt et al., 2020) was provided by CDC, Atlanta, USA. SARS-CoV-2 isolates were propagated on Vero E6 cells grown in DMEM supplemented with 2% fetal bovine serum (GIBCO), 1 mM L-glutamine (GIBCO), 50 U/mL penicillin and 50 µg/mL streptomycin (GIBCO) (virus isolation medium), at 37°C and 5% CO₂.

Infectious titer of SARS-CoV-2 virus stocks was determined by end-point titration and is reported as log₁₀ 50% tissue culture infective dose (TCID₅₀/mL). 1.5 × 10⁴ Vero E6 cells were seeded into each well in 96-well plates in DMEM supplemented with 10% fetal bovine serum, 1 mM L-glutamine, 50 U/mL penicillin and 50 µg/mL streptomycin and incubated overnight at 37°C and 5% CO₂. The following morning, when the cells were at approximately 90% confluency, the wells were inoculated with ten-fold serial dilutions of virus stock diluted in virus isolation medium (100 µL per well, with 10 replicate wells for each dilution). The plates were incubated at 37°C and 5% CO₂, and the cytopathic effect (CPE) was assessed for each well after 5 days. Wells that demonstrated CPE were counted, and the titer was determined by the method of Spearman and Kärber using 10 replicates as follows:

$$\text{Log}_{10}\text{TCID}_{50}/\text{mL} = (X - d/2 + [d \bullet S])$$

where X is log₁₀ of the lowest dilution with all wells positive for CPE, d is log₁₀ of the dilution factor (10 in these titrations), and S is the sum of the fraction of wells positive for CPE at all tested dilutions.

METHOD DETAILS

Clinical Sample RNA Extraction and qRT-PCR

Clinical samples were deidentified as part of their analyses. Nasopharyngeal and oropharyngeal swabs were shipped on wet ice in viral transport medium (VTM) to Rocky Mountain Laboratories (NIH). RNA was extracted using Trizol (Invitrogen), Phasemaker tubes (Invitrogen) and the PureLink RNA Mini Kit (Invitrogen) according to manufacturer's instructions and eluted in 100 µL RNase-free H₂O. First strand cDNA synthesis was performed with the SuperScript IV First Strand Synthesis System (Invitrogen), using 11 µL input RNA and random hexamers. qRT-PCR was performed using 5 µL of cDNA using the QuantiFast Probe kit (QIAGEN) using E gRNA (Corman et al., 2020) and sgRNA specific assays (Wölfel et al., 2020). To quantify viral load within the patient samples, 5 µL of cDNA was analyzed using droplet digital PCR (Biorad) using the same E gRNA and sgRNA assays. The SARS-CoV-2 testing through EvergreenHealth were performed by University of Washington, LabCrop, Cepheid, and GenMark. Kashi clinical laboratories and Magnolia diagnostics performed the negative tests taken at the care facilities.

Virus Isolation

Virus isolation of the clinical specimen was performed on Vero E6 cells in 96 well plates. In brief, media was removed from wells and replaced with 100 µL of undiluted swab sample, or swab sample diluted 1:10 in DMEM supplemented with 2% fetal bovine serum (GIBCO), 1 mM L-glutamine (GIBCO), 50 U/mL penicillin and 50 µg/mL streptomycin (GIBCO) (virus isolation medium). Diluted and undiluted samples were inoculated onto 7 wells. Spin inoculation was performed at 1000 x g for 1 hour at 35°C. Inoculum was removed and wells were washed twice with and replaced with 100 µL of virus isolation medium and incubated at 37°C and 5% CO₂. After 5 days, replicate wells were pooled, diluted 10x in virus isolation medium, and used to inoculate T25 flasks of Vero E6 cells in virus isolation medium and incubated at 37°C and 5% CO₂. Flasks were observed for cytopathic effect. RNA was extracted, as described above, for confirmation of SARS-CoV-2 by qRT-PCR and next generation sequencing.

Growth kinetics of SARS-CoV-2 isolates

Vero E6 cells were seeded in 6 well plates at a density of 4×10^5 cells/well in DMEM supplemented with 2% fetal bovine serum (GIBCO), 1 mM L-glutamine (GIBCO), 50 U/mL penicillin and 50 μ g/mL streptomycin (GIBCO) (virus isolation medium) and incubated overnight at 37°C and 5% CO₂. The following day, the media was removed from the wells and replaced with 1 mL of virus isolation medium containing virus at a MOI of 0.01. The patient day49 isolate and the USA/WA1/2020 strain were tested in triplicate, with mock control wells in triplicate. After a 1-hour incubation at 37°C and 5% CO₂, the inoculum was removed, and wells were washed 3x with PBS and replaced with a fresh 2 mL of virus isolation medium. Supernatant samples were taken at 0, 12, 24, 48, 72, 96, and 120 hours post inoculation. Titer of infectious virus from supernatant was determined by endpoint titration in Vero E6 cells, as described above, but using 4 replicates per sample to determine the TCID₅₀/mL using the Spearman-Kärber method. The EpiAlveolar cell growth kinetic experiment was set up similar to the Vero E6 cells but with the following differences. Cells were provided by MatTek with 2.5×10^5 cells/transwell insert. Cells were infected by adding 75 μ L of ALI medium containing virus at an MOI of 0.01 to the apical side of the transwell insert. After the above outlined incubation, the inoculum was removed, wells were washed 1x with PBS and replaced with 75 μ L of ALI medium upon the apical surface. During sampling of the EpiAlveolar cells, 500 μ L of DMEM medium was added to the apical side, gently pipetted to mix, removed, and 75 μ L of fresh ALI medium replaced on the apical surface.

Expression and Purification of SARS-CoV-2 Spike and Receptor Binding Domain

Expression plasmids encoding the codon optimized SARS-CoV-2 full length spike and receptor binding domain (RBD) were kindly provided Kizzmekia Corbett and Barney Graham (Vaccine Research Center, Bethesda, USA) and Florian Krammer (Icahn School of Medicine at Mt. Sinai, New York, USA), respectively (Wrapp et al., 2020; Amanat et al., 2020). Both plasmids were expressed in Freestyle 293-F cells (ThermoFisher), maintained in Freestyle 293 Expression Medium (GIBCO/ThermoFisher) at 37°C and 8% CO₂ in a humidified incubator shaking at 130 rpm. Cultures totaling 500 mL were transfected with PEI at a density of one million cells per mL. Supernatant was harvested 7 days post transfection, clarified by centrifugation and sterile filtered through a 0.22 μ m membrane. The protein was purified using Ni-NTA immobilized metal-affinity chromatography (IMAC) using Ni Sepharose 6 Fast Flow Resin (GE Lifesciences) or NiNTA Agarose (QIAGEN) and gravity flow. After elution the protein was buffer exchanged into 10 mM Tris pH8, 150 mM NaCl buffer before further use or frozen at –80°C for storage.

Enzyme-Linked Immunosorbent Assay (ELISA)

Purified SARS-CoV-2 full length spike or RBD protein was diluted to 1 μ g/mL in PBS. Maxisorp plates (Nunc) were coated with 100 μ L per well (100 ng protein per well) and incubated overnight at 4°C. Plates were washed 3x with PBST (0.1% Tween) and blocked with 100 μ L casein in PBS blocking buffer (ThermoFisher) for 1 hour at room temp. Plates were again washed 3x with PBST (0.1% Tween), and 100 μ L of serum samples, serially diluted 2 fold in casein in PBS blocking buffer, in duplicate, was added to the wells and incubated at room temperature for 1 hour. Plates were washed 4x with PBST (0.1% Tween), and 100 μ L secondary antibody, rabbit anti-human IgG Fc HRP (Novus Biologicals, NBP1-73529) diluted 1:4000 in casein in PBS blocking buffer, was added to the wells and incubated for 1 hour at room temperature. The wells were washed 5x with PBST (0.1% Tween) and developed with the KPL TMP 2-component peroxidase substrate kit (Seracare, 5120-0047). The reaction was stopped with KPL stop solution (Seracare, 5150-0020) and read at 450 nm. The threshold for positivity was calculated as the average plus 3 times the standard deviation of negative control sera. Reported titers are the reciprocal value of the highest dilution at which signal was observed above the calculated threshold.

Virus Neutralization assay

Serum and plasma samples were heat inactivated at 56°C for 30 minutes. Two-fold serial dilutions were prepared in DMEM supplemented with 2% FBS, with each sample diluted in duplicate in 96 well plate format. 100 TCID₅₀ of SARS-CoV-2, in virus isolation medium, was then added to each well. The virus-serum/plasma mixture was incubated at 37°C for 1 hour to allow for neutralization, then 100 μ L per well was added to Vero E6 cells in 96 well plates and incubated at 37°C and 5% CO₂. After 5 days, wells were observed for cytopathic effect. The virus neutralization titer is displayed as the reciprocal value of the highest dilution of serum/plasma that still inhibited virus replication at which no cytopathic effect was observed.

Next generation sequencing of patient clinical samples and isolates

Clinical Samples - Viral RNA was extracted from patient nasopharyngeal swabs using Trizol (Invitrogen) for use with the ARTIC nCoV-2019 sequencing protocol V.1 (Protocols.io; <https://www.protocols.io/view/ncov-2019-sequencing-protocol-bbmuik6w>). 30-35 PCR cycles were used to generate tiled-PCR amplicons. Primer pools consisted of the ARTIC nCoV-2019 v3 Panel (Integrated DNA Technologies, Belgium) and were diluted and used in PCR reactions following the instructions. Products from Pool 1 and Pool 2 were combined, AmPure XP cleaned, and quantitated as per the instructions – through step 16.18. Following assessment on a BioAnalyzer DNA Chip (Agilent Technologies, Santa Clara, CA), a volume consisting of 500 ng of product was taken directly into TruSeq DNA PCR-Free Library Preparation Guide, Revision D. (Illumina, San Diego, CA) beginning with the Repair Ends step (q.s. to 50 μ L with RSB) and subsequent cleanup consisted of a single 1:1 AmPure XP/reaction ratio. All downstream steps followed the manufacturer's instructions. Final libraries were visualized on a BioAnalyzer HS chip (Agilent Technologies, Santa Clara, CA) and quantified using KAPA Library Quant Kit (Illumina) Universal qPCR Mix (Kapa Biosystems, Wilmington, MA) on a CFX96 Real-Time System (BioRad, Hercules, CA).

Isolates - Viral RNA was extracted from clarified cell culture supernatant using Trizol (Invitrogen). Extracted RNA was depleted of rRNA using Ribo-Zero Gold H/M/R (Illumina, San Diego, CA) based on manufacturer's protocols. After Ampure RNAClean XP (Beckman Coulter, Brea, CA) purification, the enriched RNA was eluted in 6 μ L of water and assessed on a BioAnalyzer RNA Pico Chip (Agilent Technologies, Santa Clara, CA). Following the Truseq Stranded mRNA Library Preparation Guide, Revision E., (Illumina, San Diego, CA), the remaining RNA was added to Elute-Frag-Prime Buffer and continued through second-strand cDNA synthesis. The resulting double-stranded cDNAs were treated with a combined mixture of RiboShredder RNase Blend (Lucigen, Middleton, WI) and high concentration DNase-free RNase (Roche Diagnostics, Indianapolis, IN). After AMPure XP purification (Beckman Coulter, Brea, CA), samples were analyzed on a RNA Pico chip to confirm no remaining RNA. Library preparation continued with adenylation of ends following manufacturer's recommendations. All downstream steps followed the manufacturer's instructions. Final libraries were visualized on a BioAnalyzer DNA1000 chip (Agilent Technologies, Santa Clara, CA) and quantified using KAPA Library Quant Kit (Illumina) Universal qPCR Mix (Kapa Biosystems, Wilmington, MA) on a CFX96 Real-Time System (BioRad, Hercules, CA).

Sequencing and bioinformatics

Libraries were diluted to 2 nM stock, pooled together as needed in equimolar concentrations and sequenced on the MiSeq (Illumina, Inc, San Diego, CA) using on-board cluster generation and 2 \times 150 paired-end sequencing. Raw image files were converted to fastq files using bcl2fastq (v2.20.0.422, Illumina, Inc. San Diego, CA) and trimmed of adaptor sequences using cutadapt version 1.12 (Martin, 2011). Adaptor-trimmed reads were trimmed and filtered to remove low quality sequence using fastq_quality_trimmer and fastq_quality_filter tools from the FASTX Toolkit, v 0.0.14 (Gordon, 2018). Singletons were removed and quality filtered reads were coordinate-order sorted using a custom perl script.

Reads were filtered for repeat sequence, rRNA, and PhiX contaminants and then mapped to the SARS-CoV-2 isolate 2019-nCoV/USA_WA1 (MN985325.1) reference genome using bowtie2 with `-no-mixed -no-unal -X 1500` options (Langmead and Salzberg, 2012). Aligned SAM files were converted to BAM format, then sorted and indexed using SAMtools (Li et al., 2009). Duplicate reads were removed from the mapped reads using picard's MarkDuplicates tool (Broad Institute, 2018).

To process the ARTIC data a custom pipeline was developed. Fastq read pairs were first compared to a database of ARTIC primer pairs to identify read pairs that had correct, matching primers on each end. Once identified, the ARTIC primer sequence was trimmed off. Read pairs that did not have the correct ARTIC primer pairs were discarded. Remaining read pairs were collapsed into one sequence using AdapterRemoval (Schubert et al., 2016), requiring a minimum 25 base overlap and 300 base minimum length, generating ARTIC amplicon sequences. Identical amplicon sequences were removed and the unique amplicon sequences were then mapped to the SARS-CoV-2 genome (MN985325.1) using Bowtie2 (Langmead and Salzberg, 2012). Aligned SAM files were converted to BAM format, then sorted and indexed using SAMtools (Li et al., 2009).

Variant calling was performed using Genome Analysis Toolkit (GATK, version 4.1.2) HaplotypeCaller with ploidy set to 2 (McKenna et al., 2010). Single nucleotide polymorphic variants were filtered for QUAL > 200 and quality by depth (QD) > 20 and indels were filtered for QUAL > 500 and QD > 20 using the filter tool in bcftools, v1.9 (Li et al., 2009). The accuracy of the filtered variant calls was manually inspected in Broad's Integrative Genomics Viewer (IGV) (Robinson et al., 2017). Consensus sequences were generated using bcftools consensus (Li et al., 2009) and subsequently aligned using MAFFT (Katoh and Standley, 2013; Katoh et al., 2002) with 2,434 GISAID Washington SARS2 reference sequences in addition to the 2019-nCoV/USA_WA1 genome used for mapping.

Phylogenomic Analysis

Available SARS-CoV-2 full genome sequences were downloaded from the GISAID database (<https://gisaid.org/>; Shu and McCauley, 2017). The sequences were then assigned to previously described lineages (Rambaut et al., 2020) using Pangolin v2.0.3 (<https://pangolin.cog-uk.io/>), and aligned using MAFFT v. 1.4 (Katoh and Standley, 2013; Katoh et al., 2002). A maximum likelihood tree with the patient SARS-CoV-2 genomes, the Wuhan-Hu-1/2019 genome sequence, the USA/WA-1/2020 genome, and a representative genome from the assigned lineages was inferred using PhyML v.3.3.20180621 (Guindon et al., 2010) implemented in Geneious Prime v.2020.1.2 (<https://www.geneious.com/>) with a general time reversible model of nucleotide substitution and rooted at the Wuhan-Hu-1/2019 SARS-CoV-2 strain. The final figure was made using FigTree v.1.4.4 (<http://tree.bio.ed.ac.uk/software/figtree/>). For the time tree, full SARS-CoV-2 genomes were subsampled from Washington state representing NextStrain clade 19B, including the four patient genomes sequences and the Wuhan-Hu-1/2019 genome sequence. The sequences were aligned using MAFFT v. 1.4 (Katoh and Standley, 2013; Katoh et al., 2002) implemented in Geneious Prime v. 2020.1.2 (<https://www.geneious.com/>), a maximum likelihood tree reconstructed with PhyML v.3.1 (Guindon et al., 2010), and the time tree showing temporal divergence inferred in Tree-Time v.0.7.6 (Hadfield et al., 2018) using the HKY85 model of nucleotide substitution and a fixed molecular clock at 8e-4 with a standard deviation of 4e-4 as implemented in the NextStrain pipeline (<https://nextstrain.org/sars-cov-2/>).

To evaluate the relationship between the SARS-CoV-2 genomes recovered from the patient swabs with other SARS-CoV-2 genomes from Washington state, genomes at the times of sampling (April 20, May 11, May 26, and June 15, 2020) from Washington state were downloaded from the GISAID database (<https://gisaid.org/>; Shu and McCauley, 2017). The sequences were aligned by MAFFT (Katoh and Standley, 2013; Katoh et al., 2002). The sequences were analyzed by the Nextclade server v0.7.5 (<https://clades.nextstrain.org/>) for quality and sequences that were not of sufficient quality were discarded. 1,789 sequences at April 20, 385 sequences between April 20 and May 11, 268 sequences between May 11 and May 26, and 709 sequences between May 26 and June 15 were kept for further phylogenetic analysis. Maximum likelihood trees using the curated sets of genomes, the four patient

genomes, and the USA/WA1/2020 genome, were inferred using ModelFinder (Kalyaanamoorthy et al., 2017) and ultrafast bootstrap (Hoang et al., 2018) implemented in IQ-TREE (Nguyen et al., 2015), and rooted at USA/WA1/2020. Final figures were made using FigTree v.1.4.4 (<http://tree.bio.ed.ac.uk/software/figtree/>). A table of acknowledgments for the GISAID genome sequences used to within this work is available at Mendeley Data at <https://dx.doi.org/10.17632/3n377gv8kb>.

Electron Microscopy

Vero E6 cells cultured in DMEM supplemented with 10% fetal bovine serum, 1 mM L-glutamine, 50 U/mL penicillin and 50 µg/mL streptomycin were plated at 5×10^4 cells/well in 24 well plates containing Thermanox coverslips (Ted Pella, Redding, CA) for transmission electron microscopy or silicon chips (Ted Pella, Redding, CA) for scanning electron microscopy in the wells, and incubated overnight at 37°C and 5% CO₂. The next day, media was carefully aspirated from the wells and replaced with 1 mL of virus isolation medium containing SARS-CoV-2 virus at a MOI of 1 and incubated for 1 hour at 37°C and 5% CO₂. Wells were washed three times with PBS, then replaced with 1 mL fresh virus isolation medium and incubated at 37°C and 5% CO₂. At 24 and 48 hours post-infection, wells were washed three times with PBS, then fixed as described below.

Scanning electron microscopy

Cells were fixed with Karnovsky's formulation of 2% paraformaldehyde/2.5% glutaraldehyde in 0.1 M Sorenson's phosphate buffer, and then post-fixed with 1.0% osmium tetroxide/0.8% potassium ferrocyanide in 0.1 M sodium cacodylate buffer washed with 0.1 M sodium cacodylate buffer then stained with 1% tannic acid in dH₂O. After additional buffer washes, the samples were further osmicated with 2% osmium tetroxide in 0.1M sodium cacodylate, then washed with dH₂O. Specimens were dehydrated with a graded ethanol series from 50%, 75%, 100% x 3 for 5 minutes each, critical point dried under CO₂ in a Bal-Tec model CPD 030 Drier (Balzers, Liechtenstein), mounted with double sided carbon tape on aluminum specimen mounts (Ted Pella), and sputter coated with 35 Å of iridium in a Quorum EMS300T D sputter coater (Electron Microscopy Sciences, Hatfield, PA) prior to viewing at 5 kV in a Hitachi SU-8000 field emission scanning electron microscope (Hitachi, Tokyo, Japan).

Transmission electron microscopy

Specimens were fixed as described above for scanning electron microscopy and additionally stained overnight with 1% uranyl acetate at 4°C after the second osmium staining and then dehydrated with the same graded ethanol series and embedded in Spurr's resin. Thin sections were cut with a Leica UC7 ultramicrotome (Buffalo Grove, IL) prior to viewing at 120 kV on a FEI BT Tecnai transmission electron microscope (ThermoFisher/FEI, Hillsboro, OR). Digital images were acquired with a Gatan Rio camera (Gatan, Pleasanton, CA).

Structure Mapping

The Pymol Molecular Graphics System (<https://www.schrodinger.com/pymol>) was used to map the location of the observed deletions onto a SARS-CoV-2 spike structure (PDB: 6ZGE; Wrobel et al., 2020). Nucleotide sequence alignments were generated using MAAFT align (Kato and Standley, 2013; Kato et al., 2002) implemented in Geneious Prime v.2020.1.2 (<https://www.geneious.com>) and amino acid sequence alignments were generated with Multalin (Corpet, 1988) and plotted with ESPript (Robert and Gouet, 2014).

QUANTIFICATION AND STATISTICAL ANALYSIS

Data and statistical analysis was performed using GraphPad Prism 8.2.0. Replicates and statistical details can also be found in the methods and figure legends. For ELISA and virus neutralization assays, the serum/plasma samples were diluted and tested in duplicate. For the growth curves, both virus isolates (day 49 patient isolate and USA/WA1/2020) were tested in three replicate wells for both Vero E6 cells and the primary human alveolar epithelial cells. The growth curve data shown are the mean and standard error of the mean for the three independent replicates. The statistical analysis was performed using a 2-way ANOVA in Graphpad Prism 8.2.0. Further methods to determine whether the data met assumptions of the statistical approach were not relevant for these analyses.

Supplemental Figures

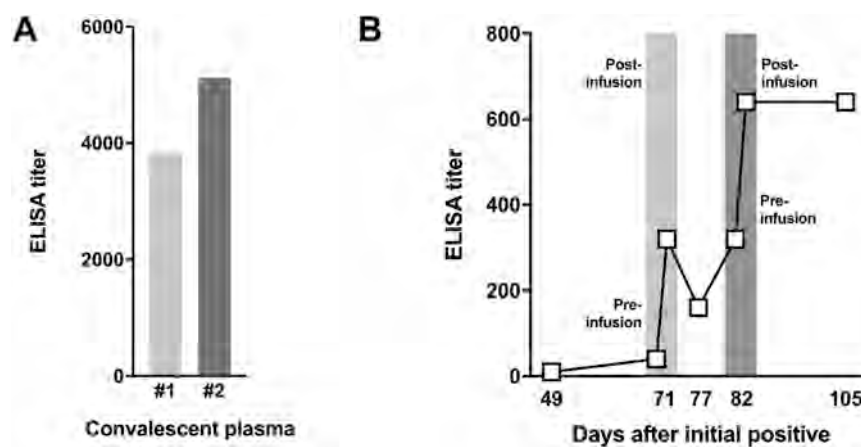

Figure S1. ELISA Titers against the SARS-CoV-2 RBD, Related to Figure 2

(A) IgG titers against SARS-CoV-2 receptor binding domain (RBD) were determined in ELISA on convalescent plasma used for transfusion. The light gray bar is the IgG titer of the first donor (convalescent plasma 1) and the dark gray is the second donor (convalescent plasma 2). (B) IgG titers against SARS-CoV-2 (RBD) were determined in ELISA on patient serum collected on several time points, including immediately before and after transfusion with convalescent plasma at day 71 (light gray) and day 82 (dark gray). Each serum/plasma sample was tested in duplicate.

Abstract

Choral singing has become a major risk during COVID-19 pandemic due to high infection rates. Our visualisation and velocimetry results reveal that majority of droplets expelled during singing follow the ambient airflow pattern. These results points toward the possibility of COVID-19 spread by small airborne droplets during singing.

Background

Singing in group settings has become an apparent risk for outbreaks of COVID-19 [1]. While social distancing is effective in normal social interactions, singing can produce a substantially larger number of respiratory droplets and aerosols than speaking, as it is louder and sustained for longer durations [2]. This may require further measures to be put into place to mitigate risks. In contained smaller spaces, the transmission risk may be higher, as respiratory aerosols may saturate the whole indoor environment [3]. Despite this, at present there is not a collective approach or response to the potential risks of group singing. Certain countries, including Germany and the Netherlands, have banned all group singing activities [4].

Choir-related outbreaks of COVID-19 in Berlin, Amsterdam, and Washington State had high attack rates of 75.6%, 78.5% and 86.9% respectively [1,4,5]. Since restrictions have eased globally, a rise in outbreaks related to singing has been reported [6]. A large proportion of these documented outbreaks associated with singing (approx. 69%), were reported from the United States resulting in over 544 cases [1].

COVID-19 is assumed to be transmitted through respiratory and contact routes; and transmission by respiratory droplets is believed to occur only in close contact (within 1-2 m) with someone who is infectious [7]. However, there is uncertainty about the dynamics of respiratory emissions during singing. Additionally, studies have shown that droplet and airborne transmission may not be mutually exclusive modes of transmission and exist as a continuum [8]. Hence, unravelling the spread of respiratory particles during singing, especially in closed environments, could inform infection control policy and practice.

Methods

To quantify and understand the spread of infection during singing we performed a detailed flow visualization of aerosols and droplets expelled during singing using an image-based flow diagnostic system. The visualisation technique employs a LED based light source (GS Vitec MultiLED PT) with a spherical lens to control the divergence of the light beam, along with a high-speed camera (nac MEMRECAM HX-7s) to capture the light scattered by the droplets expelled during singing. To capture the video, the head of the subject was adjusted in front of black backdrop/background and the light was positioned in a forward scatter arrangement to maximize the scattering from expelled droplets (Figure 1).

Once the position is adjusted, the subject was asked to sing a major scale using the solfège system and the high-speed video was captured with an exposure of 600 μ s per frame at a resolution of 2 Megapixels. In addition to singing, the subject also counted from 1 to 10 and coughed voluntarily. The horizontal field of view captured in the high-speed video, from the mouth of the subject, was 26 cm approximately. Frames obtained from the video were first calibrated and a 2-axis stabilisation was applied to subject's head (Further details on this procedure can be found in [9]). Thereafter, all the frames were processed with a hybrid Particle Tracking Velocimetry technique [10]. This technique first performs a Particle Image Velocimetry (PIV) procedure to estimate flow velocity and these estimates are subsequently refined using a particle tracking algorithm applied to each droplet. Specifically, for the PIV step we used a variable interrogation window with an initial size of 96×96 pixels and a final size of 48×48 pixels with an overlap of 75%. For particle tracking we used a correlation window of 64 pixels and particle size range of 2 to 100 pixels in order to cover the entire size range of visible droplets. The flow visualisation together with detailed particle tracking results are included in supplementary video.

Results and Discussion

The results of detailed particle tracking (in supplementary video) reveals that the maximum velocity of droplets expelled, specifically for certain syllables such as ‘do’, ‘fa’ and ‘ti’, is approx. 6 m/s, which is similar to the velocities reported for speaking [11]. Upon further examining the motion of droplets at a distance of 15 cm from the mouth, we observed that almost 90% of the droplets are moving at velocities less than 1 m/s (Figure 2a). The droplets moving with velocities greater than 1 m/s are moving in the direction between $120^\circ - 240^\circ$ ($\theta = 0^\circ$ towards subject (Figure 1)) and move away from the mouth. Moreover, approx. 75% of droplets observed are moving at velocities less than 0.5 m/s and the motion is equally distributed in all the directions, which implies that they do not settle rapidly and may follow the ambient airflow pattern. These results points toward high aerosol generation, as the behaviour of these droplets is like airborne particles [12]. Nevertheless, to accurately quantify the size, future work using particle counters, is essential to better understand the dynamics of these droplets.

Figure 2b shows the distribution of droplet velocities obtained at 15 cm from the mouth for syllable ‘fa’ and the direction in which these droplets are moving. Approximately 50% of the droplets are moving at velocities less than 0.5 m/s and more than 75% are moving away from mouth ($\theta = 120^\circ$ to 240°), which is also evident in the supplementary video. Figure 2c shows the velocity distribution of droplets that are visible while the subject was singing syllable ‘sol’ & ‘la’ and the direction in which these droplets are moving. It can be observed that all droplets are moving at velocities less than 0.5 m/s and are equally distributed in all directions. The direction in which these droplets are moving is important because it implies that for a normal choir configuration with multiple rows and heights, these droplets can pose a risk to those in the adjacent rows as well as to those in the distant rows.

Figure 2d and 2e shows the distribution for counting and coughing, respectively. In the case of coughing approximately 50% of the detected droplets were moving at velocities greater than 6 m/s whereas in case of speaking only 15% were moving at velocities greater than 6 m/s.

We note, the loudness measured during singing was within the range of 66 – 72 decibels. Further, it is also worth noting that some degree of variability is expected in the number of droplets expelled between different individuals, and due to other parameters, such as loudness, notes, consonants, and duration of each note sung. Nevertheless, the droplets observed do not appear to be settling down rapidly and without adequate ventilation, these droplets can potentially saturate the indoor environment which can likely explain the very high attack rates of COVID-19 seen in choirs in the US and Europe (almost 87% in Skagit County, Washington) [1].

We note the present study only provides visual evidence of the droplets and aerosols expelled during singing and compare the associated velocities and directions with speaking and coughing. However, these droplets have the capacity to potentially transmit viruses such as SARS-CoV-2. We only used a basic major scale for our experiments and during singing various other factors comes into play, such as pitch, rhythm, diction, etc. and it would be valuable to investigate all these aspects for future studies to have a better understanding of droplet and aerosol generation while singing. Nonetheless, the data presented combined with high infection rate among the choir members (60 – 90%) [1] points towards the possibility of airborne spread of COVID-19 during singing events, hence, should be considered when designing safety guidelines for public singing events.

These findings could inform safety guidelines for restarting choirs during and after the COVID-19 pandemic and other similar respiratory infection outbreaks. For example, rehearsals could be done with fewer people, greater physical distancing between singers, or face coverings and masks to reduce droplet and aerosol expulsion [13]. In addition to that either well ventilated large spaces or outdoor performances should be utilised to minimize the risk of infection.

Understanding the risk of infection from household- and community-exposures and the transmissibility of asymptomatic infections is critical to SARS-CoV-2 control. Limited previous evidence is based primarily on virologic testing, which disproportionately misses mild and asymptomatic infections. Serologic measures are more likely to capture all previously infected individuals. We apply household transmission models to data from a cross-sectional, household-based population serosurvey of 4,534 people ≥ 5 years from 2,267 households enrolled April-June 2020 in Geneva, Switzerland. We found that the risk of infection from exposure to a single infected household member aged ≥ 5 years (17.3%, 13.7–21.7) was more than three-times that of extra-household exposures over the first pandemic wave (5.1%, 4.5–5.8). Young children had a lower risk of infection from household members. Working-age adults had the highest extra-household infection risk. Seropositive asymptomatic household members had 69.4% lower odds (95%CrI, 31.8–88.8%) of infecting another household member compared to those reporting symptoms, accounting for 14.5% (95%CrI, 7.2–22.7%) of all household infections.

Household-centered studies provide an enumerable set of individuals known to be exposed to an infectious person, hence, they have played an important role for estimating key transmission properties of SARS-CoV-2. However, most published studies of SARS-CoV-2 household transmission rely on clinical disease (COVID-19), and/or PCR-based viral detection to identify infected individuals^{1,2}. Due to the narrow time window after exposure in which RT-PCR can be highly sensitive³, case ascertainment based on virologic testing may miss infections, especially those that are mild or asymptomatic⁴. This can lead to important biases and limit what can be studied, including underestimates of the importance of sub-clinical infections and household secondary attack rates⁴.

Serologic studies provide an alternative tool for understanding SARS-CoV-2 transmission. Serological tests remain sensitive to detecting past infections well beyond the period when the virus is detectable^{5–7}, thereby providing a measure of whether individuals have ever been infected.

Virologic and serologic studies have each provided important insights into SARS-CoV-2 transmission. These include estimates of the household secondary attack rate (e.g., 17% in a meta-analysis²) and evidence of reduced infection rates among young children^{2,8,9}. However, in general, these estimates do not distinguish between intra- and extra-household transmission nor do they provide an estimate of transmission risk from a single infected individual. A notable exception is a household study from Guangzhou, China¹⁰, but this PCR-based study suffered from the limitations of virologic testing noted above. Hence, a number of critical gaps in the evidence remain, including the relative role of transmission between household members, the frequency of viral introductions into households from the community, the infectiousness of asymptomatic individuals, and the effect of age on transmission.

To help fill these gaps, we apply household transmission models to data from a cross-sectional, household-based population serosurvey of 4534 people from 2267 households in Geneva, Switzerland (SEROCoV-POP). We provide a serology-based assessment of transmission between intra- and extra-household contacts, identify risk factors for infection and transmission and estimate the relative risk of asymptomatic transmission. By doing so, we provide important evidence for guiding the COVID-19 pandemic response.

Results

Between April 3rd and June 30th, during the first wave of the SARS-CoV-2 pandemic in Geneva, 8344 individuals coming from 4393 households were successfully enrolled in the SEROCov-POP study (Figs. 1 and S1)¹¹. The median enrollment date was May 22nd, 86 days after the first case was detected in Geneva (February 26th, 2020). In 2267 of these households, all members of the household were eligible, available, and provided a blood sample for detection of anti-SARS-CoV-2 IgG antibodies by ELISA (4354 individuals). The majority of these households were either one (37.9%, $n=860$) or two (39.2%, $n=889$) person households (Fig. S2, Table S1). The median household size in our study (2.0, interquartile range [IQR]=1,2) was similar to the general population in Geneva canton (median=2.0, IQR=1,3)¹².

The median age of participants was 53 years (IQR=34,65), and 53.6% were female. Compared with the general canton population, our study sample included more individuals 50 years and older and fewer 20–49 year olds. Individuals in older age groups were more likely to live in smaller households: 94.6% (1100/1163) of people who were 65 years and older lived alone or in two-person households versus 44.5% (588/1302) of those 20–49 years old (Table 1). Our study sample, like that of the original

Fig. 1 Epidemic curve and recruitment period of household serosurvey.

a daily confirmed COVID-19 cases reported in Geneva up to July 1st, 2020. **b** Daily number of recruited households over the 12-week study period. First detected case in Geneva canton was reported on February 26th, and the first epidemic wave lasted about two months. Yellow bands indicate time periods of study enrollment for each week. This includes all 4438 households enrolled in the SEROCov-POP study, not restricted to the complete households used in these analyses for which serostatus of all household members were available.

SEROCoV-POP study, had a higher level of formal education than the general canton population with only 8.5% not having a high school degree or equivalent, compared with 23.5% in the general canton population (Table S5)¹³.

Overall, 6.6% (298/4534) of individuals tested positive for SARS-CoV-2 anti-S1 IgG antibodies by ELISA. Of the 2267 households included in the analyses, 222 (9.8%) had at least one seropositive household member. The proportion of households with seropositive members increased from 4.8% (41/860) in households of size one, to 17.0% (39/229) in households of size three, and was relatively constant in larger households (Fig. S2, Table 1, Fig. S3). Symptoms consistent with COVID-19 were reported by 69.5% (207/298) of seropositive individuals although this was significantly lower in young children (37.5%, 3/8), similar to the results of an early modeling study¹⁴.

We fit household transmission models and estimated that from the start of the epidemic in Geneva through the time of the serosurvey, the cumulative risk of infection from extra-household exposures was 5.1% (95% Credible Interval [CrI] 4.5–5.8%). The probability of being infected from a single infected household member was 17.3% (95% CrI 13.7–21.7%, Fig. 2).

The risk of being infected by a household member was the lowest among 5–9 years old and highest among those 65 years and older, with teenagers and working age adults sharing similar risks (Figs. 2, 3). Compared to 20–49 years olds, 5–9 years olds had less than half the odds of being infected by an infected household member (OR=0.4, 95%CrI 0.1–1.6), while those 65 years and older had nearly three times the odds (OR=2.7, 95%CrI 0.9–7.9). Though credible intervals on these estimates are wide, and both include the null value of 1, inclusion of age substantially improved model fit (Δ WAIC =14.8, Table S2). In contrast, the extra-household infection risk was the highest among working age adults (20–49 years olds). Compared to this group, 5–9 year olds (OR=0.5, 95%CrI 0.2–0.9) and those 65 years and older (OR=0.4, 95%CrI 0.3–0.6) had the lowest risk (Fig. 3, Tables S2 and S4). Models allowing for differential risk of transmission by

^aA self-assessment of whether the participants have reduced the number of people they meet since the start of the epidemic.^bAverage number of people participants meet outside of the people they lived with since the start of the epidemic.

the age of the infector were not well supported by the data (Δ WAIC –15.5 to –24.7) and included no significant differences between ages (Table S2).

Males were more likely to be infected outside (OR=1.4, 95% CrI 1.0–2.0), and possibly inside the household (OR=1.4, 95% CrI 0.6–3.1), though the latter estimate is less strongly supported by the data (Fig. 3 and Table S2).

Seropositive household members not reporting symptoms had 0.31 times the odds (95%CrI: 0.11–0.68) of infecting another household member compared to those reporting symptoms consistent with COVID-19 (Fig. 3). This difference was larger (OR=0.24, 95%CrI 0.09–0.54) when only considering those who reported symptoms more than two weeks before blood draw as symptomatic infections (Table S6, Fig. S6).

Fig. 2 Risk of extra-household transmission and within-household transmission from a single infected household member. a Estimated median probability of extra-household infection from the start of the epidemic in Geneva until the time of the serosurvey by age group and sex. **b** Estimated median probability of infection from a single infected household member by age group and sex. Dots and bars represent median and 95% credible intervals of the posterior distribution. Probabilities of being infected by sex and age group of the exposed individuals are estimated by a model only including age and sex of the exposed individuals (model 2, orange/green bars; see Table S2). Probabilities of being infected by the age group of the exposed individuals combining males and females (left four gray bars on both panels) are estimated with an age-only model (model 1). The overall probabilities of being infected (rightmost gray bar on both panels) are estimated with the null model (model 0).

Using posterior distributions of parameters, we simulated the source of infection for all individuals in the study. We estimate that 22.5% (95%CrI 20.1–24.2) of all infections were caused by another household member, with the proportion of infections attributable to household transmission increasing with household size (Table S3, Figs. S8 and S9). A larger proportion of infections were attributable to household transmission for those recruited after mid-May (last 6 weeks of the study, 27.8, 95%CrI 22.8–30.4) compared to those recruited in the first six weeks of the study (first 6 weeks: 20.5, 95%CrI 17.8, 22.4). In households with two individuals, 23.2% (95%CrI 19.6–25.9) of infections were between household members, increasing to 41.2% (95%CrI 29.4–47.1) in households of five people (Table S3). Of within-household infections, we estimate 14.5% (95%CrI 7.2–22.7) were due to individuals not reporting symptoms consistent with COVID-19.

Here we focus on the results of the best fitting models, but across the ten models considered (Table S2), estimates were qualitatively and quantitatively consistent with the primary findings. Similarly, we explored the sensitivity of our results to the ELISA seropositivity cutoff and found no qualitative differences in results (Fig. S4).

Discussion

The results presented here appropriately place symptomatic household transmission of SARS-CoV-2 in the context of community risk and asymptomatic spread. We show an approximate 1 in 6 risk (17.3%) of being infected by a single SARS-CoV-2 infected household member (Table S3). This contrasts with a 1 in 20 chance (5.1%) of being infected in the community over most of

the first epidemic wave in Geneva, a period of roughly 2 months. Despite the high risk of transmission from an infected household member, as in many cities in high-income nations, households are mostly small limiting opportunities for onward transmission. Thus, less than a quarter of cases could be attributed to transmission between household members. While asymptomatic individuals appear to be less than a third as likely to transmit, they cannot be dismissed as inconsequential to disease spread, and are responsible for one in six within-household transmissions in this study. Our results are suggestive of the dual roles of biology and social behavior in shaping age-specific infection patterns, with the age signature of risk within households indicative of lower biological susceptibility in the very young, and elevated susceptibility in the old; while extra-household risk seems more driven by behavior, with working age adults being at the highest risk.

It has long been thought that asymptomatic individuals are less likely to transmit than symptomatic ones, though studies have recovered similar concentrations of viral RNA from nasopharyngeal samples from these two groups¹⁵. By using serological data, we were able to show that those not reporting symptoms have one-third the odds of transmitting within households as symptomatic ones, similar to a study from Wuhan, China¹⁶, and ultimately caused about 15% of household infections. This reduced transmissibility may be due to reduced duration of viral shedding and reduced ability to mechanically spread virions (e.g., through coughs). We did not assess the role of asymptomatics in community spread, but it is plausible that they may play an even larger role there, as symptomatic

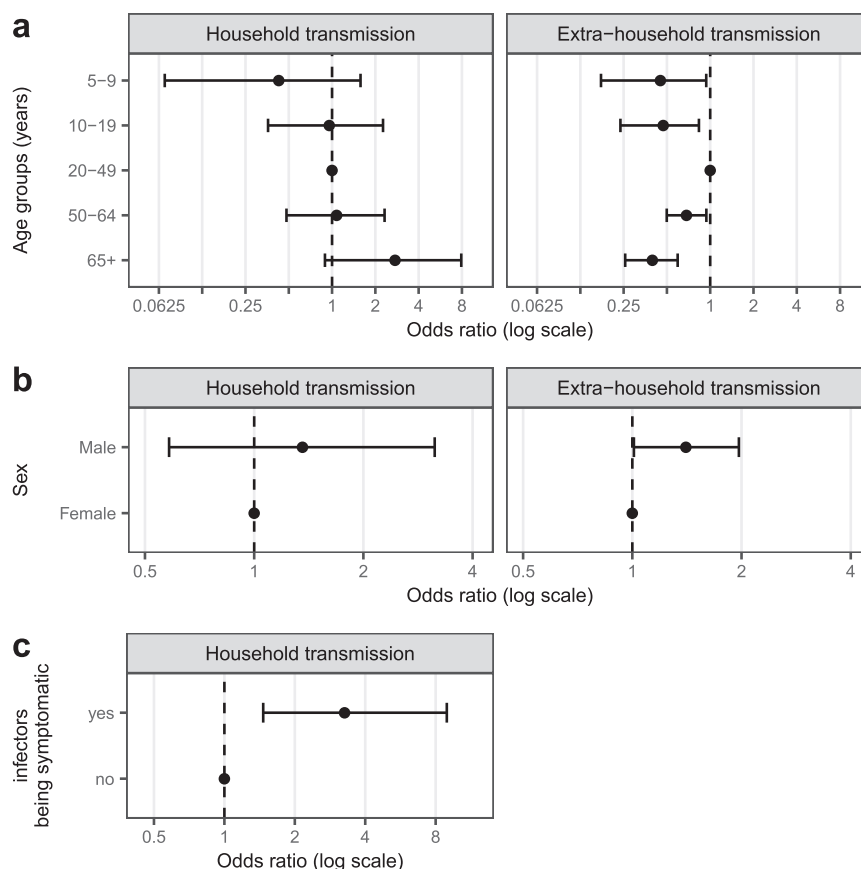

Fig. 3 Risk factors of SARS-CoV-2 infection and transmission. Relative odds of being infected outside the household and from a single infected household member by individual characteristics of the exposed individuals, **a** age group, **b** sex, and **c** potential infectors' symptom status. Odds ratios and credible intervals, shown on the log-scale, are estimates from model 4 (see Table S2).

individuals are more likely to stay home or take extra precautions to reduce exposures when sick.

As with previous studies of SARS-CoV-2 transmission among household members and other close contacts^{2,17,18}, we find evidence supporting a reduced risk of infection from household exposures among young children, and elevated risk of infection among those 65 or older. However, it is important to note that we only find this reduced risk among the youngest children in our study (5–9-year-olds), while 10–19 year olds have a similar risk profile to working age adults. The other PCR-based household study that reported per-exposure transmission did not report susceptibility results from this age group¹⁰. This is consistent with the hypothesis that young children may be biologically less susceptible to SARS-CoV-2 infection, though heterogeneity in social contact and other behaviors within households cannot be ruled out.

Patterns of extra-household infection suggest social factors dominate this risk, as both young children and older adults are at reduced risk of infection compared to working age adults. As children have returned to schools in Geneva (mid-May 2020), the social factors driving this pattern have likely changed significantly and we may see children become a more significant source of extra-household infections¹⁹, despite their apparently lower susceptibility. The risk that infected young children pose to their household members is unclear; the sample size was likely too low to detect small to moderate differences in risk. While there are mixed results in the literature on age-specific differences in infectiousness²⁰, a large study from Wuhan, China suggested that those less than 20 years old are more likely to infect others than adults 60 years and older, given the same amount of exposure¹⁶.

We did not find any significant relationship between the age of an infector and probability of transmission (nor did including these terms improve model fit), but children are less often symptomatic²¹ and we did find a strong relationship between symptoms and transmission.

Our study has a number of important limitations. Symptoms were self-reported and, given that the times of infection are unknown, they may not necessarily have been a result of the SARS-CoV-2 infection. We cannot exclude recall bias in symptom reports and other self-reported exposures. Further, we looked at only a narrow range of symptoms to increase specificity, which left out more general potentially SARS-CoV-2-related symptoms (e.g., nausea, diarrhea). We detected only eight seropositive children under the age of 10, leading to large uncertainty in age-specific risk estimates for this group. Although extra-household estimates are informed by data from all households, within-household estimates are only informed by data from households with at least one seropositive member (222/2267 households), thus limiting our statistical power. While validation data of the Euroimmun ELISA from across the world have confirmed its high specificity and sensitivity for detecting recent infections^{22–24}, most data are from adults, and it is possible that performance in young children may be different. Most of the participants in the study were recruited after the epidemic peak and it is possible that we did not fully capture all infections in each household due to insufficient time to mount a detectable response. Conversely, we may have also missed infections due to waning of responses. However, antibody responses appear to generally sustain over the first 4 months from infection, the plausible infection time window of participants in this study²⁵. When conducting stratified

analyses including households recruited early and late, we found few qualitative differences in the primary results (Figs. S5 and S7). We included only households where all household members provided blood samples in the main analysis, but sensitivity analyses of all enrolled individuals led to similar primary results (Table S6). Given the cross-sectional nature of our data, all transmission chains within households were equally likely within our modeling framework, which led to larger uncertainty than having prospectively collected data. However, collection of these data over thousands of households can be challenging, and we show that more commonly collected data from serosurveys can be leveraged to refine our understanding of transmission.

This study captures infections that occurred during the first wave of the pandemic in Geneva, a period of time when workplaces and schools were largely closed and peoples' social contacts were greatly reduced. In future phases of this pandemic, when social contact patterns change the proportion of transmission that occurs between household members and potentially age-sex specific risks could differ. While we found no evidence in previous analyses of these data for differences in seropositivity by neighborhood wealth or education²⁶, these and other indicators of wealth might be associated with transmission risk within Geneva or in other populations. Likewise, the general nature of the Geneva population and the control measures in place may limit the generalizability of our estimates of absolute risk of infection, attributable fraction, and extra-household risks. For example, the increasing importance of household transmission with increasing household size (Fig. S8) suggests household transmission would be far more important in settings with larger households. However, we believe our estimates of relative risks by age and symptom status within households, which are likely more biologically driven, should be generalizable to most settings; as should our general observations about how social and biological factors influence different types of transmission.

Our study highlights how biological and social factors might combine to shape the risk of SARS-CoV-2 infection. While we expect some differences across settings, we believe that the general trend in per-exposure infection risk by age and sex and increased infectiousness of symptomatic individuals are fundamental attributes of this pandemic. These differences have important implications for guiding patient care and public health policy. For example, increased susceptibility of the oldest individuals suggests that rapid and aggressive measures are needed to protect them as soon as there is any possibility that SARS-CoV-2 was introduced into their living environment. At the population level, quantifying the infectiousness of asymptomatics can help us understand the extent the pandemic is driven by asymptomatic infections. Our study provides a model for using cross-sectional serologic surveys to assess the relative contribution of household and community transmission. As countries continue to alter quarantine and self-isolation policies, disentangling the contribution of household and community transmission can help evaluate success of these intervention strategies. Continued serological and virologic monitoring of diverse populations with detailed analyses like those presented here are critical to the continued evidence-based response to this pandemic.

Methods

Study design, participants, and procedures. The SEROCov-POP study is a cross-sectional population-based survey of former participants of an annual survey of individuals 20–74 years old representative of the population of Geneva (Canton), Switzerland. The enrollment into the study occurred from April through June 2020 during the first wave of the SARS-CoV-2 pandemic in Geneva. First wave lockdown measures (including school closures) started in mid-March and largely

ended by the end of May. The full survey protocol is available online and a detailed description of the design and seroprevalence results were previously published^{11,26}.

The SEROCov-POP study invited all 10,587 participants of the previous annual surveys to participate in the study through email or post. Participants were invited to bring all members of their household aged 5 years and older to join the study. After providing informed written consent, participants either filled out a questionnaire online, in the days before their visit, or at the time of their visit at one of two enrollment locations (the main canton hospital and one satellite location) within Geneva. The questionnaire included questions about participants' demographics, household composition, symptoms since January 2020, details on the frequency of extra-household contacts and reduction in social interaction since the start of the pandemic. Only participants 14 years and older were asked about their frequency of extra-household contacts and changes in behavior. Despite this age cut off, we use more standard age cutoffs (10–19 years) in our analysis for comparability with other studies¹¹. We defined symptom presentation a priori as having reported any of: cough, fever, shortness of breath, or loss of smell or taste since January 2020 (symptoms reported in the 2-week prior to testing were excluded in a sensitivity analysis). We collected peripheral venous blood from each consenting participant. Households where all members provided blood samples were included in the present analysis (there was a 100% questionnaire response rate in this group). As blood was not collected from children under 5, all households with children in this age group were excluded. We conducted a sensitivity analysis with all households, regardless of whether all members provided blood samples, effectively treating household members outside the study as a community source of infection. All participants gave written informed consent before participation in the SEROCov-POP study. For individuals younger than 18 years, parents or a legal representative provided consent. The study was approved by the Cantonal Research Ethics Commission of Geneva, Switzerland (CER16-363).

Laboratory analysis. We assessed anti-SARS-CoV-2 IgG antibodies in each participant using an ELISA (Euroimmun; Lübeck, Germany #EI 2606-9601 G) targeting the S1 domain of the spike protein of SARS-CoV-2; sera diluted 1:101 were processed on a EuroLabWorkstation ELISA (Euroimmun). An in-house validation study found that the manufacturer's recommended cutoff for positivity (≥ 1.1) had a specificity of 99% and sensitivity of 93%, based on positive controls tested between 0 and 39 days after symptom onset²⁴. In our primary analyses we defined seropositivity based on the cutoff recommended by the manufacturer and explored a higher cut-off of 1.5 (>1.5) in sensitivity analyses²⁴. As the presence of antibodies has been shown to be a reliable marker of past infection, we use the term "infected" to refer to a seropositive individual.

Statistical analyses. We fit chain binomial transmission models to estimate two primary quantities; the average probability of extra-household infection from the start of the epidemic through the time of blood draw across Geneva (referred to also as "community infections" over the first epidemic wave) and the probability of being infected from a single infected household member over the course of his/her infectious period (referred to as "household exposures"; see supplemental text for model assumptions)^{27,28}. We assume that serologic status is a perfect marker of having been infected, that individuals cannot get reinfected, and that all individuals were susceptible at the start of the pandemic. When fitting these models we explicitly consider all possible sequences of viral introductions to each household and subsequent transmission events within the household. For example, in a household

with 2 seropositive individuals, both could have been infected outside of the household, or one could have been infected outside and then infected one other person within the household. We adapted models to estimate the within household and extra-household transmission risk according to the characteristics of potential infectees (age, sex, self-reported extra-household contact behavior) and, for within-household risk, those of the potential infectors (symptoms, age). As extra-household contact questions were only asked to those over 14 years old, we compared extra-household transmission by self-reported reduction or frequency in social contacts only for those 20 years and older. We imputed a small number of missing data (1%, 36/3908) related to extra-household contacts among those who were 20 years and older based on household averages (see supplement). We simulate the proportion of infections attributable to extra-household and within household exposures.

We built a series of ten models including different combinations of individual-level characteristics (e.g., age, sex, self-reported contacts, symptoms) and compared their fit using the widely applicable information criterion (WAIC)²⁹. We implemented the models in the Stan probabilistic programming language and used the *rstan* package (version 2.21.0) to sample from the posterior distribution and analyse outputs³⁰. We used weakly informative priors on all parameters to be normally distributed on the logit scale with mean of 0 and standard error of 1.5. We ran four chains of 1,000 iterations each with 250 warm-up iterations and assessed convergence visually and using the Gelman-Rubin Convergence Statistic (R-hat)³¹. All estimates are means of the posterior samples with the 2.5th and 97.5th percentiles of this distribution reported as the 95% credible interval. Full model and inference details are provided in the supplement and code needed to reproduce analyses are available at <https://github.com/HopkinsIDD/serocovpop-households> (<https://doi.org/10.5281/zenodo.4740044>).

Effectiveness of Mask Wearing to Control Community Spread of SARS-CoV-2

John T. Brooks, MD; Jay C. Butler, MD

Prior to the coronavirus disease 2019 (COVID-19) pandemic, the efficacy of community mask wearing to reduce the spread of respiratory infections was controversial because there were no solid relevant data to support their use. During the pandemic, the scientific evidence has increased. Compelling data now demonstrate that community mask wearing is an effective nonpharmacologic intervention to reduce the spread of this infection, especially as source control to prevent spread from infected persons, but also as protection to reduce wearers' exposure to infection.

COVID-19 spreads primarily through respiratory droplets exhaled when infected people breathe, talk, cough, sneeze, or sing. Most of these droplets are smaller than 10 μm in diameter, often referred to as *aerosols*. The amount of small droplets and particles increases with the rate and force of airflow during exhalation (eg, shouting, vigorous exercise). Exposure is greater the closer a person is to the source of exhalations. Larger droplets fall out of the air rapidly, but small droplets and the dried particles formed from them (ie, droplet nuclei) can remain suspended in the air. In circumstances with poor ventilation, typically indoor enclosed spaces where an infected person is present for an extended period, the concentrations of these small droplets and particles can build sufficiently to transmit infection.

Community mask wearing substantially reduces transmission of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) in 2 ways. First, masks prevent infected persons from exposing others to SARS-CoV-2 by blocking exhalation of virus-containing droplets into the air (termed *source control*). This aspect of mask wearing is especially important because it is estimated that at least 50% or more of transmissions are from persons who never develop symptoms or those who are in the presymptomatic phase of COVID-19 illness.¹ In recent laboratory experiments, multilayer cloth masks were more effective than single-layer masks, blocking as much as 50% to 70% of exhaled small droplets and particles.^{2,3} In some cases, cloth masks have performed similar to surgical or procedure masks for source control. Second, masks protect uninfected wearers. Masks form a barrier to large respiratory droplets that could land on exposed mucous membranes of the eye, nose, and mouth. Masks can also partially filter out small droplets and particles from inhaled air. Multiple layers of fabric and fabrics with higher thread counts improve filtration. However, the observed effectiveness of cloth masks to protect the wearer is lower than their effectiveness for source control,³ and the filtration capacity of cloth masks can be highly dependent on design, fit, and materials used. Standards for cloth masks are needed to help consumers select marketed products.

Epidemiological investigations have helped quantify the benefit of mask wearing to prevent the spread of SARS-CoV-2 (Table; Supplement). At a hair salon in which all staff and clients were required to wear a mask under local ordinance and company policy, 2 symptomatic, infected stylists attended to 139 clients and no infections were observed in the 67 clients who were reached for interviewing and testing. During a COVID-19 outbreak on the USS Theodore Roosevelt,

persons who wore masks experienced a 70% lower risk of testing positive for SARS-CoV-2 infection.⁴ Similar reductions have been reported in case contact investigations when contacts were masked⁵ and in household clusters in which household members were masked.⁶

An increasing number of ecological studies have also provided persuasive evidence that universal mandatory mask wearing policies have been associated with reductions in the number or rate of infections and deaths (Table). These studies did not distinguish the types of masks (cloth, surgical, or N95) used in the community. This association is strengthened because, in many cases, other mitigation strategies (eg, school and workplace closures, recommendations for social distancing, hand hygiene) had already been deployed before enactment of mask wearing policies, after which the reductions were observed. A study that examined changes in growth rates for infections in 15 states and the District of Columbia before and after mask mandates showed that rates were growing before the mandates were enacted and slowed significantly after, with greater benefit the longer the mandates had been in place.⁷

Wearing a mask can become uncomfortable, particularly for long periods in warm environments, and covering the nose and mouth may inhibit verbal and nonverbal communication, particularly for children and deaf individuals. However, children aged 7 to 13 years have been shown to be able to make accurate inferences about the emotions of others with partially covered faces,⁸ and the US Food and Drug Administration recently approved a transparent surgical mask that may be useful in such circumstances. Concerns about reduced oxygen saturation and carbon dioxide retention when wearing a mask have not been supported by available data.⁹

The overall community benefit of wearing masks derives from their combined ability to limit both exhalation and inhalation of infectious virus. Similar to the principle of herd immunity for vaccination, the greater the extent to which the intervention—mask wearing in this case—is adopted by the community, the larger the benefit to each individual member. The prevalence of mask use in the community may be of greater importance than the type of mask worn. It merits noting that a recent study has been improperly characterized by some sources as showing that cloth or surgical masks offer no benefit. This randomized trial in Denmark was designed to detect at least a 50% reduction in risk for persons wearing surgical masks. Findings were inconclusive,¹⁰ most likely because the actual reduction in exposure these masks provided for the wearer was lower. More importantly, the study was far too small (ie, enrolled about 0.1% of the population) to assess the community benefit achieved when wearer protection is combined with reduced source transmission from mask wearers to others.

During past national crises, persons in the US have willingly united and endured temporary sacrifices for the common good. Recovery of the nation from the COVID-19 pandemic requires the combined efforts of families, friends, and neighbors working together in unified public health action. When masks are worn and combined with other recommended mitigation measures, they protect not only the wearer but also the greater community. Recommendations for masks will likely

Table. Studies of the Effect of Mask Wearing on SARS-CoV-2 Infection Risk^a

Source	Location	Population studied	Intervention	Outcome
Hendrix et al	Hair salon in Springfield, Missouri	139 Patrons at a salon with 2 infected and symptomatic stylists	Universal mask wearing in salon (by local ordinance and company policy)	No COVID-19 infections among 67 patrons who were available for follow-up
Payne et al	USS Theodore Roosevelt, Guam	382 US Navy service members	Self-reported mask wearing	Mask wearing reduced risk of infection by 70% (unadjusted odds ratio, 0.30 [95% CI, 0.17-0.52])
Wang Y et al	Households in Beijing, China	124 Households of diagnosed cases comprising 335 people	Self-reported mask wearing by index cases or ≥1 household member prior to index case's diagnosis	Mask wearing reduced risk of secondary infection by 79% (adjusted odds ratio, 0.21 [95% CI, 0.06-0.79])
Doung-ngern et al	Bangkok, Thailand	839 Close contacts of 211 index cases	Self-reported mask wearing by contact at time of high-risk exposure to case	Always having used a mask reduced infection risk by 77% (adjusted odds ratio, 0.23 [95% CI, 0.09-0.60])
Gallaway et al	Arizona	State population	Mandatory mask wearing in public	Temporal association between institution of mask wearing policy and subsequent decline in new diagnoses
Rader et al	US	374 021 Persons who completed web-based surveys	Self-reported mask wearing in grocery stores and in the homes of family or friends	A 10% increase in mask wearing tripled the likelihood of stopping community transmission (adjusted odds ratio, 3.53 [95% CI, 2.03-6.43])
Wang X et al	Boston, Massachusetts	9850 Health care workers (HCWs)	Universal masking of HCWs and patients in the Mass General Brigham health care system	Estimated weekly decline in new diagnoses among HCWs of 3.4% after full implementation of the mask wearing policy
Mitze et al	Jena (Thuringia), Germany	City population aged ≥15 y	Mandatory mask wearing in public spaces (eg, public transport, shops)	Estimated daily decline in new diagnoses of 1.32% after implementation of the mask mandate
Van Dyke et al	Kansas	State population	Mandatory mask wearing in public spaces	Estimated case rate per 100 000 persons decreased by 0.08 in counties with mask mandates but increased by 0.11 in those without
Lyu and Wehby	15 US states and Washington, DC	State populations	Mandatory mask wearing in public	Estimated overall initial daily decline in new diagnoses of 0.9% grew to 2.0% at 21 days following mandates
Karaivanov et al	Canada	Country population	Mandatory mask wearing indoors	Estimated weekly 25%-40% decline in new diagnoses following mask mandates

change as more is learned about various mask types and as the pandemic evolves. With the emergence of more transmissible SARS-CoV-2 variants, it is even more important to adopt widespread mask

wearing as well as to redouble efforts with use of all other nonpharmaceutical prevention measures until effective levels of vaccination are achieved nationally.

Abstract

Background

There is disagreement about the level of asymptomatic severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection. We conducted a living systematic review and meta-analysis to address three questions: (1) Amongst people who become infected with SARS-CoV-2, what proportion does not experience symptoms at all during their infection? (2) Amongst people with SARS-CoV-2 infection who are asymptomatic when diagnosed, what proportion will develop symptoms later? (3) What proportion of SARS-CoV-2 transmission is accounted for by people who are either asymptomatic throughout infection or presymptomatic?

Methods and findings

We searched PubMed, Embase, bioRxiv, and medRxiv using a database of SARS-CoV-2 literature that is updated daily, on 25 March 2020, 20 April 2020, and 10 June 2020. Studies of people with SARS-CoV-2 diagnosed by reverse transcriptase PCR (RT-PCR) that documented follow-up and symptom status at the beginning and end of follow-up or modelling studies were included. One reviewer extracted data and a second verified the extraction, with disagreement resolved by discussion or a third reviewer. Risk of bias in empirical studies was assessed with an adapted checklist for case series, and the relevance and credibility of modelling studies were assessed using a published checklist. We included a total of 94 studies. The overall estimate of the proportion of people who become infected with SARS-CoV-2 and remain asymptomatic throughout infection was 20% (95% confidence interval [CI] 17–25) with a prediction interval of 3%–67% in 79 studies that addressed this review question. There was some evidence that biases in the selection of participants influence the estimate. In seven studies of defined populations screened for SARS-CoV-2 and then

Competing interests: I have read the journal's policy and the authors of this manuscript have the following competing interests: GS has participated in two scientific meetings for Merck and Biogen. NL is a member of the PLOS Medicine editorial board.

Abbreviations: CI, confidence interval; COVID-19, coronavirus disease 2019; CrI, credibility interval; E, number of secondary transmission events; F, female; GI, generation interval; IQR, interquartile range; M, male; NR, not reported; RT-PCR, reverse transcriptase PCR; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2; USA, United States of America.

followed, 31% (95% CI 26%–37%, prediction interval 24%–38%) remained asymptomatic. The proportion of people that is presymptomatic could not be summarised, owing to heterogeneity. The secondary attack rate was lower in contacts of people with asymptomatic infection than those with symptomatic infection (relative risk 0.35, 95% CI 0.10–1.27). Modelling studies fit to data found a higher proportion of all SARS-CoV-2 infections resulting from transmission from presymptomatic individuals than from asymptomatic individuals. Limitations of the review include that most included studies were not designed to estimate the proportion of asymptomatic SARS-CoV-2 infections and were at risk of selection biases; we did not consider the possible impact of false negative RT-PCR results, which would underestimate the proportion of asymptomatic infections; and the database does not include all sources.

Conclusions

The findings of this living systematic review suggest that most people who become infected with SARS-CoV-2 will not remain asymptomatic throughout the course of the infection. The contribution of presymptomatic and asymptomatic infections to overall SARS-CoV-2 transmission means that combination prevention measures, with enhanced hand hygiene, masks, testing tracing, and isolation strategies and social distancing, will continue to be needed.

Author summary

Why was this study done?

- The proportion of people who will remain asymptomatic throughout the course of infection with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the cause of coronavirus disease 2019 (COVID-19), is not known.
- Studies that assess people at just one time point will overestimate the proportion of true asymptomatic infection because those who go on to develop COVID-19 symptoms will be wrongly classified as asymptomatic rather than presymptomatic.
- The amount, and infectiousness, of asymptomatic SARS-CoV-2 infection will determine what kind of measures will prevent transmission most effectively.

What did the researchers do and find?

- We did a living systematic review through 10 June 2020, using automated workflows that speed up the review processes and allow the review to be updated when relevant new evidence becomes available.
- Overall, in 79 studies in a range of different settings, 20% (95% confidence interval [CI] 17%–25%, prediction interval 3%–67%) of people with SARS-CoV-2 infection remained asymptomatic during follow-up, but biases in study designs limit the certainty of this estimate.
- In seven studies of defined populations screened for SARS-CoV-2 and then followed, 31% (95% CI 26%–37%, prediction interval 24%–38%) remained asymptomatic.

- We found some evidence that SARS-CoV-2 infection in contacts of people with asymptomatic infection is less likely than in contacts of people with symptomatic infection (relative risk 0.35, 95% CI 0.10–1.27).

What do these findings mean?

- The findings of this living systematic review suggest that most people who become infected with SARS-CoV-2 will not remain asymptomatic throughout the course of infection.
- Future studies should be designed specifically to determine the true proportion of asymptomatic SARS-CoV-2 infections, using methods to minimise biases in the selection of study participants and ascertainment of symptom status during follow-up.
- The contribution of presymptomatic and asymptomatic infections to overall SARS-CoV-2 transmission means that combination prevention measures, with enhanced hand hygiene, masks, testing tracing, and isolation strategies and social distancing, will continue to be needed.

Introduction

There is ongoing discussion about the level of asymptomatic severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection. The authors of a narrative review report a range of proportions of participants positive for SARS-CoV-2 but asymptomatic in different studies from 6% to 96% [1]. The discrepancy results, in part, from the interpretation of studies that report a proportion of asymptomatic people with SARS-CoV-2 detected at a single point. The studies cited include both people who will remain asymptomatic throughout and those, known as presymptomatic, who will develop symptoms of coronavirus disease 2019 (COVID-19) if followed up [2]. The full spectrum and distribution of COVID-19, from completely asymptomatic, to mild and nonspecific symptoms, viral pneumonia, respiratory distress syndrome, and death, are not yet known [3]. Without follow-up, however, the proportions of asymptomatic and presymptomatic infections cannot be determined.

Accurate estimates of the proportions of true asymptomatic and presymptomatic infections are needed urgently because their contribution to overall SARS-CoV-2 transmission at the population level will determine the appropriate balance of control measures [3]. If the predominant route of transmission is from people who have symptoms, then strategies should focus on testing, followed by isolation of infected individuals and quarantine of their contacts. If, however, most transmission is from people without symptoms, social distancing measures that reduce contact with people who might be infectious should be prioritised, enhanced by active case-finding through testing of asymptomatic people.

The objectives of this study were to address three questions: (1) Amongst people who become infected with SARS-CoV-2, what proportion do not experience symptoms at all during their infection? (2) Amongst people with SARS-CoV-2 infection who are asymptomatic when diagnosed, what proportion will develop symptoms later? (3) What proportion of SARS-CoV-2 transmission is accounted for by people who are either asymptomatic throughout infection or presymptomatic?

Methods

We conducted a living systematic review, a systematic review that provides an online summary of findings and is updated when relevant new evidence becomes available [4]. The review follows a published protocol (<https://osf.io/9ewys/>), which describes in detail the methods used to speed up review tasks [5] and to assess relevant evidence rapidly during a public health emergency [6]. The first two versions of the review have been published as preprints [7,8]. We report our findings according to the statement on preferred reporting items for systematic reviews and meta-analyses (S1 PRISMA Checklist) [9]. Ethics committee review was not required for this study. Box 1 shows our definitions of symptoms, asymptomatic infection, and presymptomatic status. We use the term asymptomatic SARS-CoV-2 infection for people without symptoms of COVID-19 who remain asymptomatic throughout the course of infection. We use the term presymptomatic for people who do not have symptoms of COVID-19 when enrolled in a study but who develop symptoms during adequate follow-up.

Box 1. Definitions of symptoms and symptom status in a person with SARS-CoV-2 infections

Symptoms: symptoms that a person experiences and reports. We used the authors' definitions. We searched included manuscripts for an explicit statement that the study participant did not report symptoms that they experienced. Some authors defined 'asymptomatic' as an absence of self-reported symptoms. We did not include clinical signs observed or elicited on examination.

Asymptomatic infection: a person with laboratory-confirmed SARS-CoV-2 infection, who has no symptoms, according to the authors' report, at the time of first clinical assessment and had no symptoms at the end of follow-up. The end of follow-up was defined as any of the following: virological cure, with one or more negative reverse transcriptase PCR (RT-PCR) test results; follow-up for 14 days or more after the last possible exposure to an index case; follow-up for 7 days or more after the first RT-PCR positive result.

Presymptomatic: a person with laboratory-confirmed SARS-CoV-2 infection, who has no symptoms, according to the authors' report, at the time of first clinical assessment but who developed symptoms by the end of follow-up. The end of follow-up was defined as any of the following: virological cure, with one or more negative RT-PCR test results; follow-up for 14 days or more after the last possible exposure to an index case; follow-up for 7 days or more after the first RT-PCR positive result.

Information sources and search

We conducted the first search on 25 March 2020 and updated it on 20 April and 10 June 2020. We searched the COVID-19 living evidence database [10], which is generated using automated workflow processes [5] to (1) provide daily updates of searches of four electronic databases (Medline PubMed, Ovid Embase, bioRxiv, and medRxiv), using medical subject headings and free-text keywords for SARS-CoV-2 infection and COVID-19; (2) de-duplicate the records; (3) tag records that are preprints; and (4) allow searches of titles and abstracts using Boolean operators. We used the search function to identify studies of asymptomatic or presymptomatic SARS-CoV-2 infection using a search string of medical subject headings and free-text

keywords ([S1 Text](#)). We also examined articles suggested by experts and the reference lists of retrieved mathematical modelling studies and systematic reviews. Reports from this living rapid systematic review will be updated at 3-monthly intervals, with continuously updated searches.

Eligibility criteria

We included studies in any language of people with SARS-CoV-2 diagnosed by RT-PCR that documented follow-up and symptom status at the beginning and end of follow-up or investigated the contribution to SARS-CoV-2 transmission of asymptomatic or presymptomatic infection. We included contact-tracing investigations, case series, cohort studies, case-control studies, and statistical and mathematical modelling studies. We excluded the following study types: case reports of a single patient and case series in which participants were not enrolled consecutively. When multiple records included data from the same study population, we linked the records and extracted data from the most complete report.

Study selection and data extraction

Reviewers worked in pairs to screen records using an application programming interface in the electronic data capture system (REDCap, Vanderbilt University, Nashville, TN, USA). One reviewer selected potentially eligible studies and a second reviewer verified all included and excluded studies. We reported the identification, exclusion, and inclusion of studies in a flow-chart ([S1 Fig](#)). The reviewers determined which of the three review questions each study addressed, using the definitions in [Box 1](#). One reviewer extracted data using a pre-piloted extraction form in REDCap, and a second reviewer verified the extracted data using the query system. A third reviewer adjudicated on disagreements that could not be resolved by discussion. We contacted study authors for clarification when the study description was insufficient to reach a decision on inclusion or if reported data in the manuscript were internally inconsistent. The extracted variables included, but were not limited to, study design, country and/or region, study setting, population, age, primary outcomes, and length of follow-up. From empirical studies, we extracted raw numbers of individuals with any outcome and its relevant denominator. From statistical and mathematical modelling studies, we extracted proportions and uncertainty intervals reported by the authors.

The primary outcomes for each review question were (1) proportion with asymptomatic SARS-CoV-2 infection who did not experience symptoms at all during follow-up; (2) proportion with SARS-CoV-2 infections who did not have symptoms at the time of testing but developed symptoms during follow-up; (3) estimated proportion (with uncertainty interval) of SARS-CoV-2 transmission accounted for by people who are asymptomatic or presymptomatic. A secondary outcome for review question 3 was the secondary attack rate from asymptomatic or presymptomatic index cases.

Risk of bias in included studies

Two authors independently assessed the risk of bias. A third reviewer resolved disagreements. For observational epidemiological studies, we adapted the Joanna Briggs Institute Critical Appraisal Checklist for Case Series [11]. The adapted tool included items about inclusion criteria, measurement of asymptomatic status, follow-up of course of disease, and statistical analysis. We added items about selection biases affecting the study population from a tool for the assessment of risk of bias in prevalence studies [12]. For mathematical modelling studies, we used a checklist for assessing relevance and credibility [13].

Synthesis of the evidence

We used the ‘metaprop’ and ‘metabin’ functions from the ‘meta’ package (version 4.11–0) [14] in R (version 3.5.1) to display the study findings in forest plots and synthesise their findings. The 95% confidence intervals (CIs) for each study are estimated using the Clopper-Pearson method [15]. We examined heterogeneity visually in forest plots. We stratified studies according to the methods used to identify people with asymptomatic SARS-CoV-2 infection and the study setting. To synthesise proportions from comparable studies, in terms of design and population, we used stratified random-effects meta-analysis. For the stratified and overall summary estimates, we calculated prediction intervals, to represent the likely range of proportions that would be obtained in subsequent studies conducted in similar settings [16]. We calculated the secondary attack rate as the number of cases among contacts as a proportion of all close contacts ascertained. We did not account for potential clustering of contacts because the included studies did not report the size of clusters. We compared the secondary attack rate from asymptomatic or presymptomatic index cases with that from symptomatic cases. If there were no events in a group, we added 0.5 to each cell in the 2×2 table. We used random-effects meta-analysis with the Mantel-Haenszel method to estimate a summary risk ratio (with 95% CI).

Results

The living evidence database contained a total of 25,538 records about SARS-CoV-2 or COVID-19 by 10 June 2020. The searches for studies about asymptomatic or presymptomatic SARS-CoV-2 on 25 March, 20 April, and 10 June resulted in 89, 230, and 688 records for screening (S1 Fig). In the first version of the review [7], 11 articles were eligible for inclusion [17–27], version 2 [8] identified another 26 eligible records [28–53], and version 3 identified another 61 eligible records [54–114]. After excluding four articles for which more recent data became available in a subsequent version [25,29,30,35], the total number of articles included was 94 (S1 Table) [17–24,26–28,31–34,36–114]. The types of evidence changed across the three versions of the review (S1 Table). In the first version, six of 11 studies were contact investigations of single-family clusters with a total of 39 people. In the next versions, study designs included larger investigations of contacts and outbreaks, screening of defined groups, and studies of hospitalised adults and children. Across all three review versions, data from 79 empirical observational studies were collected in 19 countries or territories (Tables 1 and 2) and included 6,832 people with SARS-CoV-2 infection. Forty-seven of the studies, including 3,802 infected people, were done in China (S2 Table). At the time of their inclusion in the review, 23 of the included records were preprints; six of these had been published in peer-reviewed journals by 17 July 2020 [19,20,27,81,82,106].

Proportion of people with asymptomatic SARS-CoV-2 infection

We included 79 studies that reported empirical data about 6,616 people with SARS-CoV-2 infection (1,287 defined as having asymptomatic infection) [17,18,21–23,26–28,31,32,34,36,39–45,47–50,52–54,56–62,64,66–68,70–77,79–90,92–112,114] and one statistical modelling study [24] (Table 1). The sex distribution of the people with asymptomatic infection was reported in 41/79 studies, and the median age was reported in 35/79 studies (Table 1). The results of the studies were heterogeneous (S2 Fig). We defined seven strata, according to the method of selection of asymptomatic status and study settings. Study findings within some of these strata were more consistent (Fig 1). We considered the statistical modelling study of passengers on the *Diamond Princess* cruise ship passengers [24] separately, because of the different

method of analysis and overlap with the study population reported by Tabata and colleagues [27].

The main risks of bias across all categories of empirical studies were in the selection and enrolment of people with asymptomatic infection and mismeasurement of asymptomatic status because of absent or incomplete definitions (S3 Fig). Sources of bias specific to studies in particular settings are discussed with the relevant results.

The overall estimate of the proportion of people who become infected with SARS-CoV-2 and remain asymptomatic throughout the course of infection was 20% (95% CI 17%–25%, 79 studies), with a prediction interval of 3%–67% (Fig 1). One statistical modelling study was based on data from all 634 passengers from the *Diamond Princess* cruise ship with RT-PCR positive test results [24]. The authors adjusted for the proportion of people who would develop symptoms (right censoring) in a Bayesian framework to estimate that, if all were followed up until the end of the incubation period, the probability of asymptomatic infections would be 17.9% (95% credibility interval [CrI] 15.5%–20.2%).

The summary estimates of the proportion of people with asymptomatic SARS-CoV-2 infection differed according to study setting, although prediction intervals for all groups overlapped. The first three strata in Fig 1 involve studies that reported on different types of contact investigation, which start with an identified COVID-19 case. The studies reporting on single-family clusters (21 estimates from 16 studies in China, *n* = 102 people with SARS-CoV-2) all included at least one asymptomatic person [17,18,21–23,26,44,49,50,70,73–76,85,110]. The summary estimate was 34% (95% CI 26%–44%, prediction interval 25%–45%). In nine studies that reported on close contacts of infected individuals and aggregated data from clusters of both asymptomatic and symptomatic people with SARS-CoV-2 the summary estimate was 14% (95% CI 8%–23%, prediction interval 2%–53%) [36,47,60,62,66,72,105,108,111]. We included 12 studies (*n* = 675 people) that reported on outbreak investigations arising from a single symptomatic person or from the country's first imported cases of people with COVID-19 [32,43,48,58,61,68,71,90,94,95,97,100]. Four of the outbreaks involved nursing homes [58,68,71,94] and four involved occupational settings [43,61,90,95]. The summary estimate of

the proportion of asymptomatic SARS-CoV-2 infections was 18% (95% CI 10%–28%, prediction interval 2%–64%).

In seven studies, people with SARS-CoV-2 infection were detected through screening of all people in defined populations who were potentially exposed (303 infected people amongst 10,090 screened) [28,31,34,81,82,93,101]. The screened populations included healthcare workers [82,93,101]; people evacuated from a setting where SARS-CoV-2 transmission was confirmed, irrespective of symptom status [28,34]; the whole population of one village in Italy [81]; and blood donors [31]. In these studies, the summary estimate of the proportion asymptomatic was 31% (95% CI 26%–37%, prediction interval 24%–38%). There is a risk of selection bias in studies of certain groups, such as healthcare workers and blood donors, because people with symptoms are excluded [31,82,93,101], or from nonresponders in population-based screening [81]. Retrospective symptom ascertainment could also increase the proportion determined asymptomatic [81,82,101].

The remaining studies, in hospital settings, included adult patients only (15 studies, *n* = 3,228) [27,39,45,52,53,56,57,64,80,83,89,92,103,107,114], children only (10 studies, *n* = 285) [40–42,59,84,87,98,99,104,106], or adults and children (10 studies, *n* = 1,518) [54,67,77,79,86,88,96,102,109,112] (Table 1, Fig 1). The types of hospital and clinical severity of patients differed, including settings in which anyone with SARS-CoV-2 infection was admitted for isolation and traditional hospitals.

Proportion of presymptomatic SARS-CoV-2 infections

We included 31 studies in which the people with no symptoms of COVID-19 at enrolment were followed up, and the proportion that develops symptoms is defined as presymptomatic (Table 2, Fig 2) [21,27,28,31,34,37,38,41,45,46,49,52,55,56,58,67,68,71,73,76,77,79,81,90,93,95,103,110,111,113,114]. Four studies addressed only this review question [37,38,55,113]. The findings from the 31 studies were heterogeneous (S4 Fig), even when categorised according to the method of selection of asymptomatic participants, and we did not estimate a summary measure (Fig 2).

Additional analyses

We investigated heterogeneity in the estimates of the proportion of asymptomatic SARS-CoV-2 infections in subgroup analyses that were not specified in the original protocol. In studies of

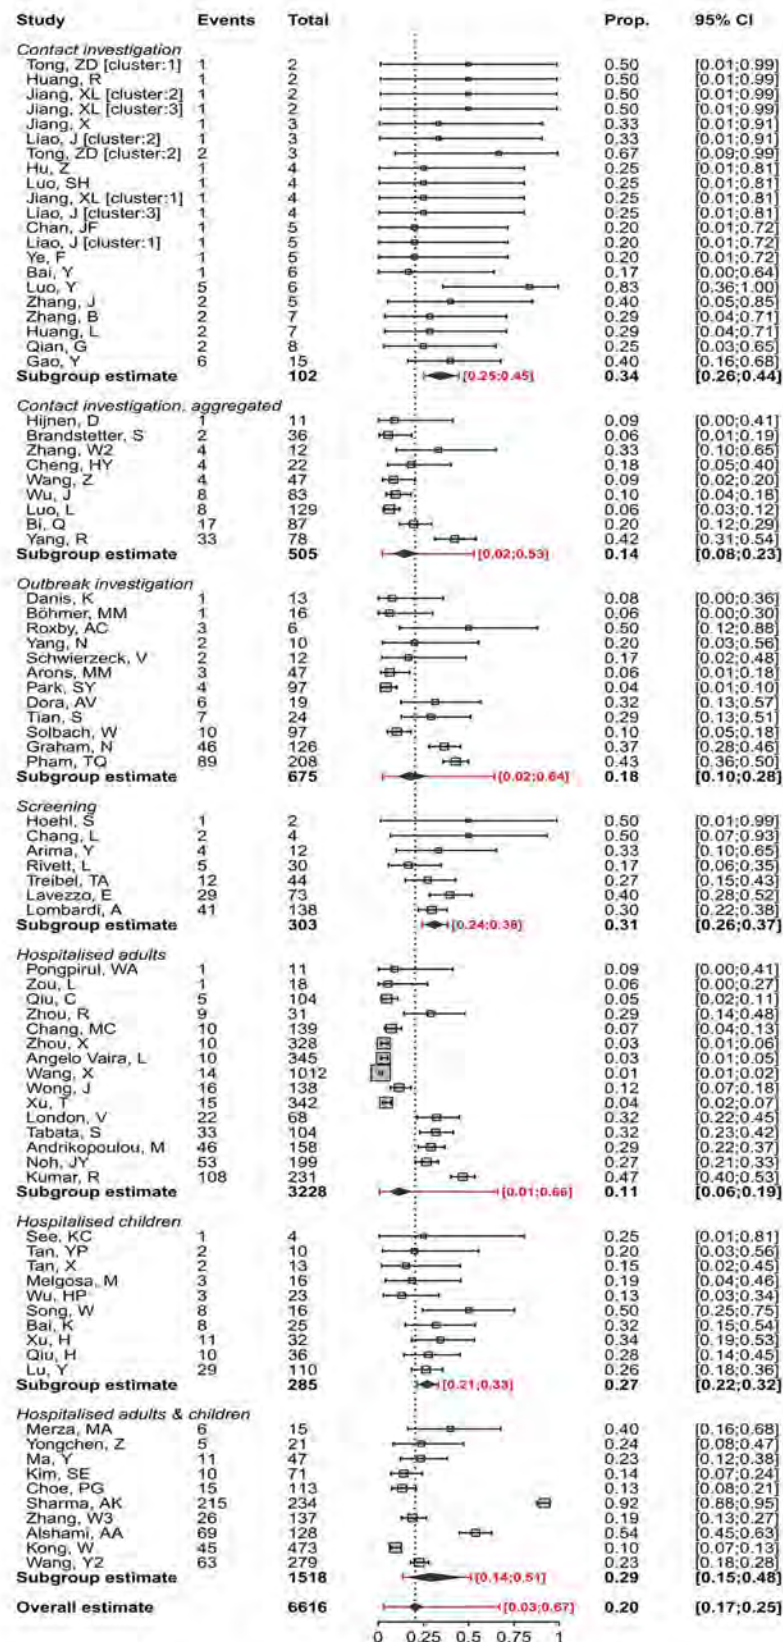

Fig 1. Forest plot of proportion ('Prop.') of people with asymptomatic SARS-CoV-2 infection, stratified by setting. In the setting 'Contact investigations', in which more than one cluster was reported, clusters are annotated with '[cluster]'. The diamond shows the summary estimate and its 95% CI. The red bar and red text show the prediction interval. CI, confidence interval; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2.

<https://doi.org/10.1371/journal.pmed.1003346.g001>

hospitalised children, the point estimate was higher (27%, 95% CI 22%–32%, 10 studies) than in adults (11%, 95% CI 6%–19%, 15 studies) (Fig 1). The proportion of asymptomatic SARS-CoV-2 infection estimated in studies of hospitalised patients (35 studies, 19%, 95% CI 14%–25%) was similar to that in all other settings (44 studies, 22%, 95% CI 17%–29%, S5 Fig). To examine publication status, we conducted a sensitivity analysis, omitting studies that were identified as preprints at the time of data extraction (S6 Fig). The estimate of the proportion of asymptomatic infection in all settings (18%, 95% CI 14%–22%) and setting-specific estimates were very similar to the main analysis.

Contribution of asymptomatic and presymptomatic infection to SARS-CoV-2 to transmission

Five of the studies that conducted detailed contact investigations provided enough data to calculate a secondary attack rate according to the symptom status of the index cases (Fig 3) [36,65,66,90,111]. The summary risk ratio for asymptomatic compared with symptomatic was 0.35 (95% CI 0.1–1.27) and for presymptomatic compared with symptomatic people was 0.63 (95% CI 0.18–2.26) [66,90]. The risk of bias in ascertainment of contacts was judged to be low in all studies.

Fig 2. Forest plot of proportion ('Prop.') of people with presymptomatic SARS-CoV-2 infection, stratified by setting. CI, confidence interval; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2.

<https://doi.org/10.1371/journal.pmed.1003346.g003>

We included eight mathematical modelling studies (Fig 4) [19,20,33,51,63,69,78,91]. The models in five studies were informed by analysis of data from contact investigations in China, South Korea, Singapore, and the *Diamond Princess* cruise ship, using data to estimate the serial interval or generation time [19,20,33,69,78], and in three studies the authors used previously published estimates [51,63,91].

Estimates of the contributions of both asymptomatic and presymptomatic infections SARS-CoV-2 transmission were very heterogeneous. In two studies, the contributions to SARS-CoV-2 transmission of asymptomatic infection were estimated to be 6% (95% CrI 0%–57%) [19] and 69% (95% CrI 20%–85%) [69] (Fig 4). The estimates have large uncertainty intervals and the disparate predictions result from differences in the proportion of asymptomatic infections and relative infectiousness of asymptomatic infection. Ferretti and colleagues provide an interactive web application [19] that shows how these parameters affect the model results.

Models of the contribution of presymptomatic transmission used different assumptions about the durations and distributions of infection parameters such as incubation period,

Fig 4. Forest plot of proportion ('Prop.') of SARS-CoV-2 infection resulting from asymptomatic or presymptomatic transmission. For studies that report outcomes in multiple settings, these are annotated in brackets. CI, confidence interval; GI, generation interval; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2; SI, serial interval.

<https://doi.org/10.1371/journal.pmed.1003346.g004>

generation time, and serial interval [19,20,33,51,63,78,91]. In models that accounted for uncertainty appropriately, most estimates of the proportion of transmission resulting from people with SARS-CoV-2 who are presymptomatic ranged from 20% to 70%. In one study that estimated a contribution of <1% [91], the model-fitted serial interval was longer than observed in empirical studies [115]. The credibility of most modelling studies was limited by the absence of external validation. The data to which the models were fitted were generally from small samples (S7 Fig).

Discussion

Summary of main findings

The summary proportion of SARS-CoV-2 that is asymptomatic throughout the course of infection was estimated, across all study settings, to be 20% (95% CI 17%–25%, 79 studies), with a prediction interval of 3%–67%. In studies that identified SARS-CoV-2 infection through screening of defined populations, the proportion of asymptomatic infections was 31% (95% CI 26%–37%, 7 studies). In 31 studies reporting on people who are presymptomatic but who go on to develop symptoms, the results were too heterogeneous to combine. The secondary attack rate from asymptomatic infections may be lower than that from symptomatic infections (relative risk 0.35, 95% CI 0.1–1.27). Modelling studies estimated a wide range of the proportion of all SARS-CoV-2 infections that result from transmission from asymptomatic and presymptomatic individuals.

Strengths and weaknesses

A strength of this review is that we used clear definitions and separated review questions to distinguish between SARS-CoV-2 infections that remain asymptomatic throughout their course from those that become symptomatic and to separate proportions of people with infection from their contribution to transmission in a population. This living systematic review uses methods to minimise bias whilst increasing the speed of the review process [5,6] and will be updated regularly. We only included studies that provided information about follow-up through the course of infection, which allowed reliable assessment about the proportion of asymptomatic people in different settings. In the statistical synthesis of proportions, we used a method that accounts for the binary nature of the data and avoids the normality approximation (weighted logistic regression).

Limitations of the review are that most included studies were not designed to estimate the proportion of asymptomatic SARS-CoV-2 infection and definitions of asymptomatic status were often incomplete or absent. The risks of bias, particularly those affecting selection of participants, differed between studies and could result in both underestimation and overestimation of the true proportion of asymptomatic infections. Also, we did not consider the possible impact of false negative RT-PCR results, which might be more likely to occur in asymptomatic infections [116] and would underestimate the proportion of asymptomatic infections [117]. The four databases that we searched are not comprehensive, but they cover the majority of publications and we do not believe that we have missed studies that would change our conclusions.

Comparison with other reviews

We found narrative reviews that reported wide ranges (5%–96%) of infections that might be asymptomatic [1,118]. These reviews presented cross-sectional studies alongside longitudinal studies and did not distinguish between asymptomatic and presymptomatic infection. We found three systematic reviews, which reported similar summary estimates from meta-analysis

of studies published up to May [119–121]. In two reviews, authors applied inclusion criteria to reduce the risks of selection bias, with summary estimates of 11% (95% CI 4%–18%, 6 studies) [120] and 15% (95% CI 12%–18%, 9 studies) [121]. Our review includes all these studies, mostly in the categories of aggregated contact or outbreak investigations, with compatible summary estimates (Fig 1). We categorised one report [81] with other studies in which a defined population was screened. The summary estimate in the third systematic review (16%, 95% CI 10%–23%, 41 studies) [119] was similar to that of other systematic reviews, despite inclusion of studies with no information about follow-up. In comparison with other reviews, rather than restricting inclusion, we give a comprehensive overview of studies with adequate follow-up, with assessment of risks of bias and exploration of heterogeneity (S2–S7 Figs). The three versions of this review to date have shown how types of evidence change over time, from single-family investigations to large screening studies (S1 Table).

Interpretation

The findings from systematic reviews, including ours [119–121], do not support the claim that a large majority of SARS-CoV-2 infections are asymptomatic [122]. We estimated that, across all study settings, the proportion of SARS-CoV-2 infections that are asymptomatic throughout the course of infection is 20% (95% CI 17%–25%). The wider prediction interval reflects the heterogeneity between studies and indicates that future studies with similar study designs and in similar settings will estimate a proportion of asymptomatic infections from 3% to 67%. Studies that detect SARS-CoV-2 through screening of defined populations irrespective of infection status at enrolment should be less affected by selection biases. In this group of studies, the estimated proportion of asymptomatic infection was 31% (95% CI 26%–37%, prediction interval 24%–38%). This estimate suggests that other studies might have had an overrepresentation of participants diagnosed because of symptoms, but there were also potential selection biases in screening studies that might have overestimated the proportion of asymptomatic infections. Our knowledge to date is based on data collected during the acute phase of an international public health emergency, mostly for other purposes. To estimate the true proportion of asymptomatic SARS-CoV-2 infections, researchers need to design prospective longitudinal studies with clear definitions, methods that minimise selection and measurement biases, and transparent reporting. Serological tests, in combination with virological diagnostic methods, might improve ascertainment of SARS-CoV-2 infection in asymptomatic populations. Prospective documentation of symptom status would be required, and improvements in the performance of serological tests are still needed [123].

Our review adds to information about the relative contributions of asymptomatic and pre-symptomatic infection to overall SARS-CoV-2 transmission. Since all people infected with SARS-CoV-2 are initially asymptomatic, the proportion that will go on to develop symptoms can be derived by subtraction from the estimated proportion with true asymptomatic infections; from our review, we would estimate this fraction to be 80% (95% CI 75%–83%). Since SARS-CoV-2 can be transmitted a few days before the onset of symptoms [124], presymptomatic transmission likely contributes substantially to overall SARS-CoV-2 epidemics. The analysis of secondary attack rates provides some evidence of lower infectiousness of people with asymptomatic than symptomatic infection (Fig 3) [36,65,66,90,111], but more studies are needed to quantify this association more precisely. If both the proportion and transmissibility of asymptomatic infection are relatively low, people with asymptomatic SARS-CoV-2 infection should account for a smaller proportion of overall transmission than presymptomatic individuals. This is consistent with the findings of the only mathematical modelling study in our review that explored this question [19]. Uncertainties in estimates of the true proportion and

the relative infectiousness of asymptomatic SARS-CoV-2 infection and other infection parameters contributed to heterogeneous predictions about the proportion of presymptomatic transmission [20,33,51,63,78,91].

Implications and unanswered questions

Integration of evidence from epidemiological, clinical, and laboratory studies will help to clarify the relative infectiousness of asymptomatic SARS-CoV-2. Studies using viral culture as well as RNA detection are needed, since RT-PCR defined viral loads appear to be broadly similar in asymptomatic and symptomatic people [116,125]. Age might play a role as children appear more likely than adults to have an asymptomatic course of infection (Fig 1) [126]; age was poorly reported in studies included in this review (Table 1).

SARS-CoV-2 transmission from people who are either asymptomatic or presymptomatic has implications for prevention. Social distancing measures will need to be sustained at some level because droplet transmission from close contact with people with asymptomatic and presymptomatic infection occurs. Easing of restrictions will, however, only be possible with wide access to testing, contact tracing, and rapid isolation of infected individuals. Quarantine of close contacts is also essential to prevent onward transmission during asymptomatic or presymptomatic periods of those that have become infected. Digital, proximity tracing could supplement classical contact tracing to speed up detection of contacts to interrupt transmission during the presymptomatic phase if shown to be effective [19,127]. The findings of this systematic review of publications early in the pandemic suggests that most SARS-CoV-2 infections are not asymptomatic throughout the course of infection. The contribution of presymptomatic and asymptomatic infections to overall SARS-CoV-2 transmission means that combination prevention measures, with enhanced hand and respiratory hygiene, testing tracing, and isolation strategies and social distancing, will continue to be needed.

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) spread rapidly in Manaus, the capital of Amazonas state in northern Brazil. The attack rate there is an estimate of the final size of the largely unmitigated epidemic that occurred in Manaus. We use a convenience sample of blood donors to show that by June 2020, 1 month after the epidemic peak in Manaus, 44% of the population had detectable immunoglobulin G (IgG) antibodies. Correcting for cases without a detectable antibody response and for antibody waning, we estimate a 66% attack rate in June, rising to 76% in October. This is higher than in São Paulo, in southeastern Brazil, where the estimated attack rate in October was 29%. These results confirm that when poorly controlled, COVID-19 can infect a large proportion of the population, causing high mortality.

Brazil has experienced one of the world's most rapidly growing COVID-19 epidemics, with the Amazon being the worst-hit region (1). Manaus is the largest metropolis in the Amazon, with a population of more than 2 million and a population density of 158 inhabitants/km². The first severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) case in Manaus was confirmed on 13 March 2020 (2) and was followed by an explosive epidemic, peaking in early May with 4.5-fold excess mortality (3). This was followed by a sustained drop in new cases despite relaxation of nonpharmaceutical interventions (NPIs). The prevalence of antibodies to SARS-CoV-2 is an estimate of the attack rate in Manaus and provides a data-based estimate of the extent of COVID-19 spread in the absence of effective mitigation.

Given a basic reproduction number (R_0) of 2.5 to 3.0 for Amazonas state (4), the expected attack rate during an unmitigated epidemic in a homogeneously mixed population is 89 to 94% (5). When the percentage of infected people

exceeds the herd immunity threshold of 60 to 67%, or $100 \times [1 - (1/R_0)]$, each infection generates fewer than one secondary case (case reproduction number $R_t < 1$) and incidence declines. We sought to measure the SARS-CoV-2 attack rate in Manaus and to explore whether the epidemic was contained ($R_t < 1$) because infection reached the herd immunity threshold, or because of other factors such as behavioral changes and NPIs. We compared data from Manaus with findings from São Paulo, where the first Brazilian COVID-19 cases were detected (2, 6) and both the rise and fall in mortality were slower and more protracted.

We used a chemiluminescent microparticle immunoassay (CMIA; AdviseDx, Abbott) that detects immunoglobulin G (IgG) antibodies to the SARS-CoV-2 nucleocapsid (N) protein. To infer the attack rate from antibody test positivity, we need to account for the sensitivity and specificity of the test (7). The specificity of the CMIA is high (>99.0%) (8–10), but previous high (>90.0%) sensitivity estimates (8, 10) may not apply to blood donor screening (11, 12)

for two reasons. First, most SARS-CoV-2 infections in blood donors are asymptomatic, and weaker antibody responses in asymptomatic disease (13) may lead to a lower initial seroconversion rate (i.e., more “serosilent” infections). Second, as a result of antibody waning, sensitivity falls over time (14), such that test positivity increasingly underestimates the true attack rate.

We used a variety of clinical samples at different time points to gain insight into the dynamics of the anti-N IgG detected by the Abbott CMIA (Fig. 1). In samples from hospitalized COVID-19 patients collected at 20 to 33 days after symptom onset, reflecting high disease severity and optimal timing of blood collection, sensitivity was 91.8% [95% confidence interval (CI), 80.8% to 96.8%], which suggests that ~8% of severe convalescent cases do not develop detectable antibodies. Among a cohort of symptomatic cases with mild disease also tested in the early convalescent period, sensitivity fell to 84.5% (95% CI, 78.7% to 88.9%), indicating that initial seroconversion is lower in milder cases. In samples drawn later (50 to 131 days) from the same mild disease cohort, sensitivity was lower still (80.4%; 95% CI, 71.8% to 86.8%), reflecting antibody waning. Indeed, in a subset of 104 patients with two consecutive blood draws, the signal-to-cutoff (S/C) declined over the period observed (Fig. 1B) and among 88 individuals with a positive reading at the first time point, the mean rate of decay was $-0.9 \log_2$ S/C units every 100 days (95% CI, -1.1 to -0.75), equating to a half-life of 106 days (95% CI, 89 to 132 days) (Fig. 1C).

Finally, we tested 1000 blood donations given in São Paulo in July 2020 in parallel, using a second high-specificity [>99.0% (15)] immunoassay less prone to antibody waning (14) (Roche Elecsys). Of these, 103 samples were positive using the Abbott CMIA and an additional 30 were positive using the Roche assay. Assuming that all 133 samples were true positives, the sensitivity of the Abbott N IgG assay was 77.4% (95% CI, 69.6% to 83.7%) on asymptomatic blood donor samples. Samples in July were donated 4 months into the ongoing epidemic in São Paulo; accordingly, the false negatives using the Abbott assay include cases that did not initially seroconvert, as well as past infections that had subsequently seroreverted.

Fig. 1. Abbott SARS-CoV-2 N IgG chemiluminescence assay performance and antibody dynamics in different clinical samples.

(A) Signal-to-cutoff (S/C) values using the Abbott chemiluminescence assay (CMIA) in the following clinical samples (from left to right): 821 routine blood donation samples from Manaus in February 2020, >1 month before the first notified case in the city; 49 samples collected at 20 to 33 days after symptom onset from SARS-CoV-2 PCR-positive patients in São Paulo requiring hospital care; 193 patients in São Paulo with PCR-confirmed symptomatic COVID-19 not requiring hospital care, with plasma donation samples taken in the early convalescent period; 107 samples from the same nonhospitalized plasma donor cohort from the late convalescent period; 133 samples that tested positive on either the Abbott CMIA or the Roche Elecsys assay out of 1000 routine blood donations collected in July 2020 and tested in parallel from the Fundação Pró-Sangue blood center (São Paulo). Upper dashed line denotes the manufacturer's threshold for positive result of 1.4 S/C; lower dashed line denotes an alternative threshold of 0.4 S/C. In the box plots of Abbott IgG CMIA S/C, the central line is the median; upper and lower hinges are the 25th and 75th centiles, respectively; whiskers show the range, extending to a maximum of 1.5 times the interquartile range from the hinge.

(B) S/C values of the Abbott CMIA for 104 convalescent plasma donors who were sampled at two different times. **(C)** Histogram of the slopes among 88 individuals shown in (B) who tested positive (>1.4 S/C) at the first time point. POS, post-onset of symptoms.

Because specificity was high, with only one false positive result in 821 pre-epidemic donations from Manaus (Fig. 1A), we also attempted to improve assay performance by reducing the threshold for a positive result from 1.4 S/C (as per the manufacturer) to 0.4 S/C. This resulted in 27 false positives and a specificity of 96.7% but substantially improved sensitivity at this threshold (Fig. 1A and table S1).

To estimate the proportion of the population with IgG antibodies to SARS-CoV-2, we used a convenience sample of routine blood donations made at the Fundação Pró-Sangue blood bank in São Paulo and the Fundação Hospitalar de Hematologia e Hemoterapia do Amazonas (HEMOAM) in Manaus. The monthly sample size and sampling dates, spanning February to October, are shown in table S2.

The prevalence of SARS-CoV-2 antibodies in February and March was low (<1%) in both São Paulo and Manaus. This is consistent with the timing of the first confirmed cases that were diagnosed on 13 March in Manaus and on 25 February in São Paulo (2). In Manaus, after adjustment for the sensitivity and specificity of the test (but not antibody waning) and reweighting for age and sex, the prevalence

of SARS-CoV-2 IgG antibodies was 4.8% (95% CI, 3.3% to 6.8%) in April and 44.5% (95% CI, 39.2% to 50.0%) in May, reaching a peak of 52.5% (47.6% to 57.5%) in June (Fig. 2 and table S2). The increasing seroprevalence closely followed the curve of cumulative deaths. In São Paulo, the prevalence of SARS-CoV-2 IgG in blood donors also increased steadily, reaching 13.6% (95% CI, 12.0% to 15.1%) in June.

Between June and October, the effect of seroreversion became apparent in both cities. In Manaus, after the peak antibody prevalence in June, the proportion of blood donors who tested positive fell steadily to 25.8% in October. Excluding extreme negative samples (<0.4 S/C), the median assay signal fell steadily from May: 3.9 (May), 3.5 (June), 2.3 (July), 1.7 (August), 1.4 (September), and 1.3 (October) (Fig. 2B). Similarly, in São Paulo, antibody prevalence remained stable between June and October while the number of daily COVID-19 deaths also remained relatively stable, reflecting a balance between antibody waning from infections earlier in the outbreak and seroconversions following recent infections (Fig. 2C).

In Manaus, the effect of antibody waning on apparent prevalence was partially ameliorated by reducing the threshold for a positive

result from 1.4 S/C to 0.4 S/C and correcting for the resulting increased false positive rate. However, the results in São Paulo were largely unchanged by this correction (Fig. 2 and table S2).

We further corrected for seroreversion with a model-based approach (see supplementary materials). Briefly, we assumed that the probability of an individual seroreverting exactly m months after recovery decays exponentially with m . We estimated the decay rate and the proportion of patients who seroreverted using the seroprevalence data from Manaus to find the decay rate that minimized the number of new cases in July and August while avoiding decreases in prevalence—that is, assuming there were few cases in Manaus in July and August and that changes in seroprevalence were due mainly to waning antibodies. The results of these corrections are shown in Fig. 2 and table S2. After adjusting for seroreversion, we find that cumulative incidence in Manaus may have reached as high as 66.2% (95% CI, 61.5% to 80.1%) in July and 76.0% (95% CI, 66.6% to 97.9%) in October. The reliability of this estimate depends on the validity of the exponential decay assumption, and in the absence of an accepted approach to account for

seroreversion, these results should be interpreted with caution.

To calculate infection fatality ratios (IFRs), we used the prevalence (adjusted for sensitivity and specificity, and reweighted for age and sex) in June, as this followed the epidemic peak in Manaus but preceded appreciable seroreversion. In Manaus, the IFRs were 0.17% and 0.28%, taking into consideration the numbers of polymerase chain reaction (PCR)-confirmed COVID-19 deaths and probable COVID-19 deaths based on syndromic identification, respectively. In São Paulo, the global IFRs were 0.46% and 0.72%, respectively. The difference may be explained by an older population structure in São Paulo (fig. S1A). Supporting this inference, the age-specific IFRs were similar in the two cities, and were similar to estimates based on data from China (16) (fig. S1B) and a recent systematic review (17). We also obtained similar age-specific IFRs using the seroreversion-corrected prevalence estimates from October (fig. S1).

Blood donors may not be representative of the wider population. In both cities, the eligible age range for blood donation in Brazil (16 to 69 years) and the sex distribution of donors are different from those of the under-

lying population (fig. S2). Reweighting our estimates for age and sex (Fig. 2 and table S2) resulted in a slight reduction in prevalence, particularly in Manaus, where men were overrepresented among donors and also had a higher seroprevalence (fig. S3). Self-reported ethnicity in donors was similar to that of the census populations (fig. S2). The median income in blood donors' census tracts of residence was marginally higher than a population-weighted average for both cities (fig. S4). Regarding the spatial distribution of donors, there was a similar antibody prevalence across different regions sampled in both cities (fig. S5), and we achieved good geographic coverage in both cities (see supplementary materials and fig. S5).

Because potential donors are deferred if they have a positive SARS-CoV-2 PCR test or clinical diagnosis of COVID-19, increasing access to testing might have reduced the pool of eligible donors through time. However, only 2.7% of residents in Manaus and 8.5% in São Paulo reported having a PCR test performed by September (fig. S6). As such, changing access to testing is unlikely to have been important. Considering these factors together,

we suggest that our results can be cautiously extrapolated to the population aged 16 to 69 years in Manaus and São Paulo. Within this group, studies of blood donors may underestimate the true exposure to SARS-CoV-2 because donors may have higher socioeconomic profiles and greater health awareness and engagement, and because symptomatic donors are deferred. However, it is likely that seroprevalence in children and older adults is lower.

Our results show that between 44% and 66% of the population of Manaus was infected with SARS-CoV-2 by July, following the epidemic peak there. The lower estimate does not account for false negative cases or antibody waning; the upper estimate accounts for both. R_t fell to <1 (fig. S7) in late April when cumulative infections were between 5% and 46% of the population. NPIs (table S3) were implemented in mid- to late March when physical distancing also increased (fig. S8). It is likely that these factors worked in tandem with growing population immunity to contain the epidemic. Transmission has since continued in Manaus, albeit to a lesser extent than in April and May (Fig. 2 and fig. S7). From the second

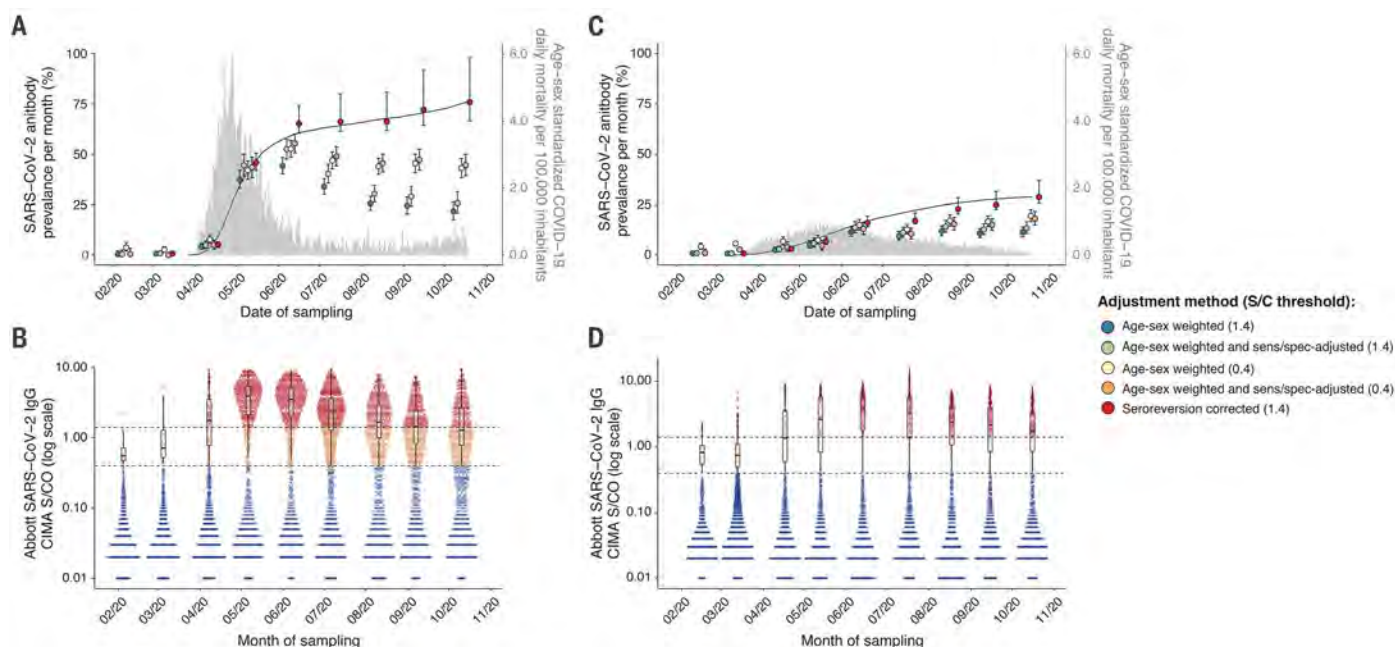

Fig. 2. Monthly antibody prevalence and signal-to-cutoff (S/C) reading in Manaus and São Paulo. (A and C) SARS-CoV-2 antibody prevalence estimates in Manaus (A) and São Paulo (C) with a range of corrections, from left to right: reweighting positive tests, at positivity threshold of 1.4 S/C, to the age and sex distribution of each city; further correcting for sensitivity and specificity at this assay threshold; reweighting positive tests for age and sex at a reduced threshold of 0.4 S/C; correcting for sensitivity and specificity at this threshold; and finally correcting for seroreversion. Error bars are 95% confidence intervals. Gray bars are standardized daily mortality using confirmed COVID-19 deaths from the SIVEP-Gripe (Sistema de Informação de Vigilância Epidemiológica da Gripe; <https://covid.saude.gov.br/>) notification system and standardized by the

direct method using the total projected Brazilian population for 2020 as reference. Black lines are rescaled cumulative deaths, such that the maximum is set to the maximum seroprevalence estimate for each city. Mortality data are plotted according to the date of death. (B and D) Distribution of S/C values over the nine monthly samples are shown for Manaus (B) and São Paulo (D). Each point represents the S/C reading for a single donation sample. Upper dashed line denotes the manufacturer's threshold (1.4 S/C units); lower dashed line denotes an alternative threshold (0.4 S/C units); black box plots show the median (central lines), interquartile range (hinges), and range extending to 1.5 times the interquartile range from each hinge (whiskers) of S/C values above 0.4 (i.e., excluding very low and likely true-negative values).

week of August there has been a small increase in the number of cases (18), which, at the time of writing, has begun to decline. Consequently, the attack rate rose to 76% in October. This remains lower than predicted in a homogeneously mixed population with no mitigation strategies (~90%). Homogeneous mixing is unlikely to be a valid assumption (19), and behavioral change and NPIs may explain why the estimated final epidemic size has not yet reached 89 to 94%, as expected for R_0 values between 2.5 and 3.0 (4).

By 1 October, Manaus recorded 2642 [1193/million inhabitants (mil)] COVID-19 confirmed deaths and 3789 (1710/mil) severe acute respiratory syndrome deaths; São Paulo recorded 12,988 (1070/mil) and 20,063 (1652/mil), respectively. The cumulative mortality proportions were similar in both cities and high relative to other locations such as the United Kingdom (620/mil), France (490/mil), or the United States (625/mil) as of 1 October (20). The different attack rates in Manaus and São Paulo (76% versus 29% of people infected), despite similar overall mortality rates, are due to the higher IFR in São Paulo. The age-standardized mortality ratio was 2.0 comparing observed deaths in Manaus to those expected from projecting the age-specific mortality in São Paulo onto the age structure of Manaus. The R_0 was similar in the two cities (fig. S7), but cases and deaths increased and then decreased more slowly in São Paulo than in Manaus where both the rise and fall were more abrupt (fig. S7). The lower attack rate in São Paulo is partly explained by the larger population size (2.2 million versus 12.2 million inhabitants). As population size increases, the time to reach a given attack rate also increases (21).

The attack rate in Manaus is higher than estimates based on seroprevalence studies conducted in Europe and North America (8, 22, 23) and on recent results from Kenyan blood donors (24). A similarly high seroprevalence (~50%) was observed in slums in Mumbai, India (25). In Brazil, one population-based serosurvey in São Paulo (26) found a prevalence similar to that in our study (26.2% versus 28.8% in blood donors, in October). In Manaus, a lower seroprevalence (14%, in June) was found in a random household sample of 250 people (1). But this study was not powered at the city level and used the lower-sensitivity Wondfo (27) rapid test. As such, the results are not directly comparable.

Future investigations should be conducted to determine what accounted for such extensive transmission of SARS-CoV-2 in Manaus. Possible explanations include socioeconomic conditions, household crowding (28), limited access to clean water, and reliance on boat travel (1) in which overcrowding results in accelerated contagion, similar to that seen

on cruise ships (29). The young mobile population with potentially low preexisting immunity to SARS-CoV-2 (30), as well as the early circulation of multiple virus lineages introduced from multiple locations, may have contributed to the large scale of the outbreak.

Our data show that >70% of the population had been infected in Manaus about 7 months after the virus first arrived in the city. This is above the theoretical herd immunity threshold. However, prior infection may not confer long-lasting immunity (30, 31). Indeed, we observed rapid antibody waning in Manaus, consistent with other reports that have shown signal waning on the Abbott IgG assay (14, 32). However, other commercial assays, with different designs or targeting different antigens, have more stable signal (14), and there is evidence for a robust neutralizing antibody response several months out from infection (33). Rare reports of reinfection have been confirmed (34), but the frequency of its occurrence remains an open question (35). Manaus represents a “sentinel” population, giving us a data-based indication of what may happen if SARS-CoV-2 is allowed to spread largely unmitigated. Further seroepidemiological, molecular, and genomic surveillance studies in the region are required urgently to determine the longevity of population immunity, the correlation with the observed antibody waning, and the diversity of circulating lineages. Monitoring of new cases and the ratio of local versus imported cases will also be vital to understand the extent to which population immunity might prevent future transmission, and the potential need for booster vaccinations to bolster protective immunity.

Estimating the extent of asymptomatic COVID-19 and its potential for community transmission: Systematic review and meta-analysis

Oyungerel Byambasuren MD¹ , Magnolia Cardona PhD¹ , Katy Bell PhD², Justin Clark BA¹, Mary-Louise McLaws PhD³, Paul Glasziou PhD¹

BACKGROUND: Knowing the prevalence of true asymptomatic coronavirus disease 2019 (COVID-19) cases is critical for designing mitigation measures against the pandemic. We aimed to synthesize all available research on asymptomatic cases and transmission rates. **METHODS:** We searched PubMed, Embase, Cochrane COVID-19 trials, and Europe PMC for primary studies on asymptomatic prevalence in which (1) the sample frame includes at-risk populations and (2) follow-up was sufficient to identify pre-symptomatic cases. Meta-analysis used fixed-effects and random-effects models. We assessed risk of bias by combination of questions adapted from risk of bias tools for prevalence and diagnostic accuracy studies. **RESULTS:** We screened 2,454 articles and included 13 low risk-of-bias studies from seven countries that tested 21,708 at-risk people, of which 663 were positive and 111 asymptomatic. Diagnosis in all studies was confirmed using a real-time reverse transcriptase–polymerase chain reaction test. The asymptomatic proportion ranged from 4% to 41%. Meta-analysis (fixed effects) found that the proportion of asymptomatic cases was 17% (95% CI 14% to 20%) overall and higher in aged care (20%; 95% CI 14% to 27%) than in non-aged care (16%; 95% CI 13% to 20%). The relative risk (RR) of asymptomatic transmission was 42% lower than that for symptomatic transmission (combined RR 0.58; 95% CI 0.34 to 0.99, $p = 0.047$). **CONCLUSIONS:** Our one-in-six estimate of the prevalence of asymptomatic COVID-19 cases and asymptomatic transmission rates is lower than those of many highly publicized studies but still sufficient to warrant policy attention. Further robust epidemiological evidence is urgently needed, including in subpopulations such as children, to better understand how asymptomatic cases contribute to the pandemic.

KEYWORDS: emerging or re-emerging diseases, epidemiology, evidence-based medicine, public health policy

HISTORIQUE : Il est essentiel de connaître la prévalence des véritables cas asymptomatiques de maladie à coronavirus 2019 (COVID-19) pour concevoir des mesures d'atténuation de la pandémie. Les chercheurs ont voulu synthétiser toutes les recherches disponibles sur les cas asymptomatiques et les taux de transmission. **MÉTHODOLOGIE :** Les chercheurs ont fouillé les bases de données PubMed, Embase, Cochrane pour trouver les études sur la COVID-19, et Europe PMC pour colliger les études primaires sur la prévalence des cas asymptomatiques dans lesquelles 1) le cadre d'échantillonnage incluait une population à risque et 2) le suivi était suffisant pour dépister les cas présymptomatiques. La méta-analyse a fait appel à des modèles d'effets fixes et d'effets aléatoires. Nous avons évalué le risque de biais par une combinaison de questions adaptées d'outils sur les risques de biais des études de prévalence et de précision diagnostique. **RÉSULTATS :** Les chercheurs ont extrait 2 454 articles, dont 13 études à faible risque de biais de sept pays dans lesquelles 21 708 personnes à risque ont subi le test de dépistage, soit 663 cas positifs et 111 cas asymptomatiques. Dans toutes les études, le diagnostic a été confirmé au moyen du test d'amplification en chaîne par polymérase après transcriptase inverse en temps réel. La proportion de cas asymptomatiques se situait entre 4 % et 41 %. La méta-analyse (à effets fixes) a établi que la proportion de cas asymptomatiques s'élevait à 17 % (IC à 95 %, 14 % à 20 %) dans l'ensemble, mais qu'elles étaient plus élevées dans les soins aux aînés (20 %; IC à 95 %, 14 % à 27 %) qu'auprès du reste de la population (16 %; IC à 95 %, 13 % à 20 %). Le risque relatif [RR] de transmission de cas asymptomatiques était plus faible de 42 % que celui de cas symptomatiques (RR combiné de 0,58; IC à 95 %, 0,34 à 0,99, $p = 0,047$). **CONCLUSIONS :** L'évaluation de la prévalence d'un sixième de cas asymptomatiques de COVID-19 et de taux de transmission de cas asymptomatiques est inférieure à celle de nombreuses études hautement publicisées, mais suffit tout de même pour justifier l'intérêt de la santé publique. D'autres données épidémiologiques solides s'imposent de toute urgence, y compris dans des sous-populations comme les enfants, pour mieux comprendre l'effet des cas asymptomatiques sur la pandémie.

INTRODUCTION

Asymptomatic cases of any infection are of considerable concern for public health policies to manage epidemics. Such asymptomatic cases complicate the tracking of an epidemic and prevent reliable estimates of transmission, tracing, and tracking strategies for containing an epidemic through isolation and quarantine. This has been a significant concern in the current coronavirus disease 2019 (COVID-19) pandemic (1).

The possibility of asymptomatic transmission of COVID-19 cases was first raised by a case report in China in which a traveller from Wuhan was presumed to have transmitted the infection to five other family members in other locations while she remained asymptomatic for the entire 21-day follow-up period (2). Subsequently, other reports confirmed not only the possibility of such transmission but began quantifying the potential proportions. For example, the outbreak on the Diamond Princess cruise ship included a substantial proportion of asymptomatic cases after widespread testing of those on board the ship (3). An early rapid review by the Centre for Evidence-Based Medicine in Oxford, United Kingdom, found that the estimated proportion of asymptomatic COVID-19 cases ranged from 5% to 80% (4). However, many of the identified studies were either poorly executed or poorly documented, making the validity of these estimates questionable.

We therefore sought to identify all studies that had attempted to estimate the proportion of asymptomatic COVID-19 cases, select those with low risk of bias, and synthesize them to provide an overall estimate and potential range. We also aimed to estimate the rate of forward transmission from asymptomatic cases if sufficient data were found.

METHODS

We conducted a systematic review and meta-analysis using enhanced processes with an initial report completed within 2 weeks and daily short team meetings to review progress, plan the next actions, and resolve discrepancies and other obstacles (5). We also used locally developed open access automation tools and programs such as the Polyglot Search Translator, SearchRefiner, and the SRA Helper to design, refine, and convert our search strategy for all the databases

we searched and to speed up the screening process (6). We searched the PROSPERO database to rule out the existence of a similar review and PubMed, Embase, and Cochrane COVID-19 trials for published studies and Europe PMC for pre-prints from January 2020 to July 20, 2020. A search string composed of MeSH terms and words was developed in PubMed and was translated to be run in other databases using the Polyglot Search Translator. The search strategies for all databases are presented in Supplemental Appendix 1. We also conducted forward and backward citation searches of the included studies in the Scopus citation database.

We restricted publication types to reports of primary data collection released in full (including pre-prints) with sufficient details to enable a risk-of-bias assessment, and we contacted authors for clarifications on follow-up times and sampling frames. We anticipated that cross-sectional prevalence surveys with follow-up and cohort studies would be the bulk of eligible reports. No restrictions on language were imposed. We excluded studies for the following reasons: sampling frame in part determined by presence or absence of symptoms; no or unclear follow-up; no data on asymptomatic cases; single case study or small cluster; modelling or simulation studies (but sources of real data were checked for possible inclusion); non-severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) studies; antiviral treatment studies; and study protocols, guidelines, editorials, or historical accounts without data to calculate primary outcomes.

Participants

We included studies of people of any age in which all those at risk of contracting SARS-CoV-2 were tested regardless of presence or absence of symptoms; diagnosis was confirmed by a positive result on a real-time reverse transcriptase-polymerase chain reaction (RT-PCR), and all cases had a follow-up period of at least 7 days to distinguish asymptomatic cases from pre-symptomatic cases (Figure 1).

Outcomes

Our primary outcome was the proportion of all people with SARS-Cov-2 infection who were completely asymptomatic at the time of the test and throughout the follow-up period, where the denominator included all tested individuals in the

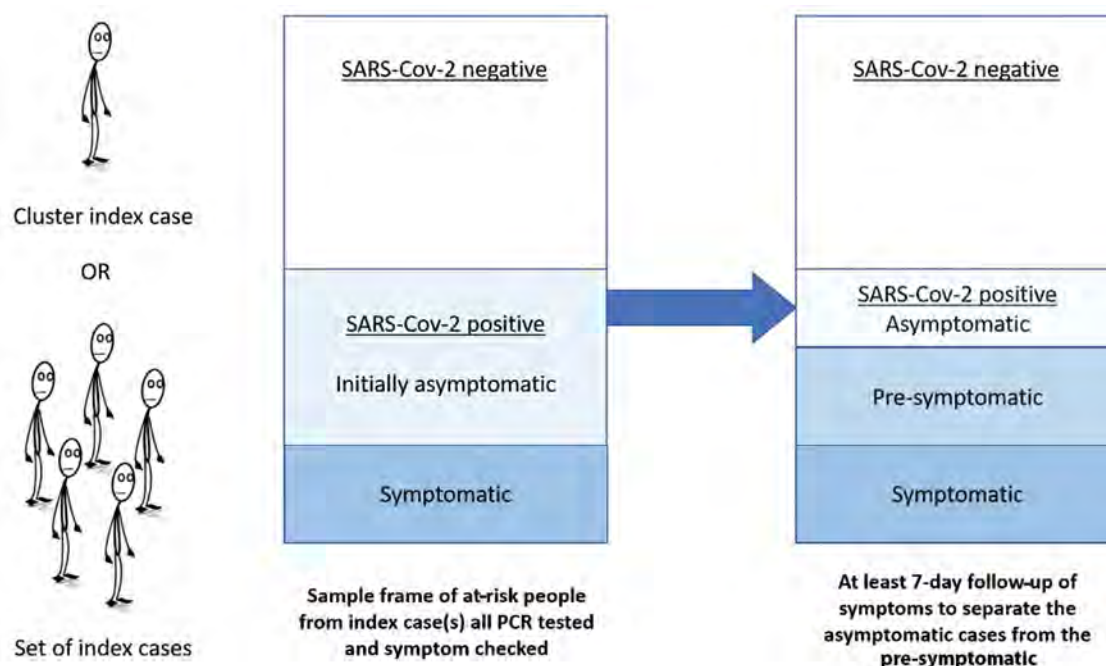

Figure 1: Depiction of ideal study flow and criteria used for study inclusion: (1) sample frame of at-risk people and (2) adequate follow-up on symptoms

SARS-Cov-2 = Severe acute respiratory syndrome coronavirus 2; PCR = Polymerase chain reaction

study sample whose result was positive, and the numerator included those who tested positive and had no symptoms. Our secondary outcome was estimate of onward transmission of the infection from asymptomatic cases.

Study selection and screening

Two authors (OB and MC) independently screened titles, abstracts, and full texts according to eligibility criteria. All discrepancies were resolved via group discussion with the other authors. Reasons for exclusion were documented for all full-text articles deemed ineligible (Supplemental Appendix 2); see the Preferred Reporting Information for Systematic Reviews and Meta-Analyses diagram (Figure 2).

Data extraction

Three authors (OB, MC, KB) used a Microsoft Excel spreadsheet to extract the following information:

1. Methods: study authors, year of publication, country, publication type, duration of study, duration of follow-up
2. Participants: sample size, age (mean or median, range), setting (community, province, aged care facility, hospital, screening clinic), presence or absence of symptoms, test results
3. History of illness and diagnosis: type of test; numerator (number of asymptomatic); denominator (sampling

frame); mildly symptomatic or symptomatic subjects; and number or proportion of people infected by the asymptomatic case.

4. Case definitions were as follows:

- Asymptomatic: confirmed via any testing specified earlier with report of no symptoms for the duration of sufficient follow-up to differentiate from pre-symptomatic cases.
- Exposure: contact with a confirmed case or potential contact with another pre-symptomatic person (e.g., came from an endemic area or linked with an infected traveller).

The World Health Organization recommends that “for confirmed asymptomatic cases, the period of contact is measured as the 2 days before through the 14 days after the date on which the sample was taken which led to confirmation” (7, p.11).

Risk-of-bias assessment

Three authors (OB, MC, KB) assessed the risk of bias of potentially includable studies. We used a combination of risk-of-bias tools for prevalence studies and diagnostic accuracy and adapted the key signaling questions on sampling frame, ascertainment of infectious disease status, acceptability of methods to identify denominators, case

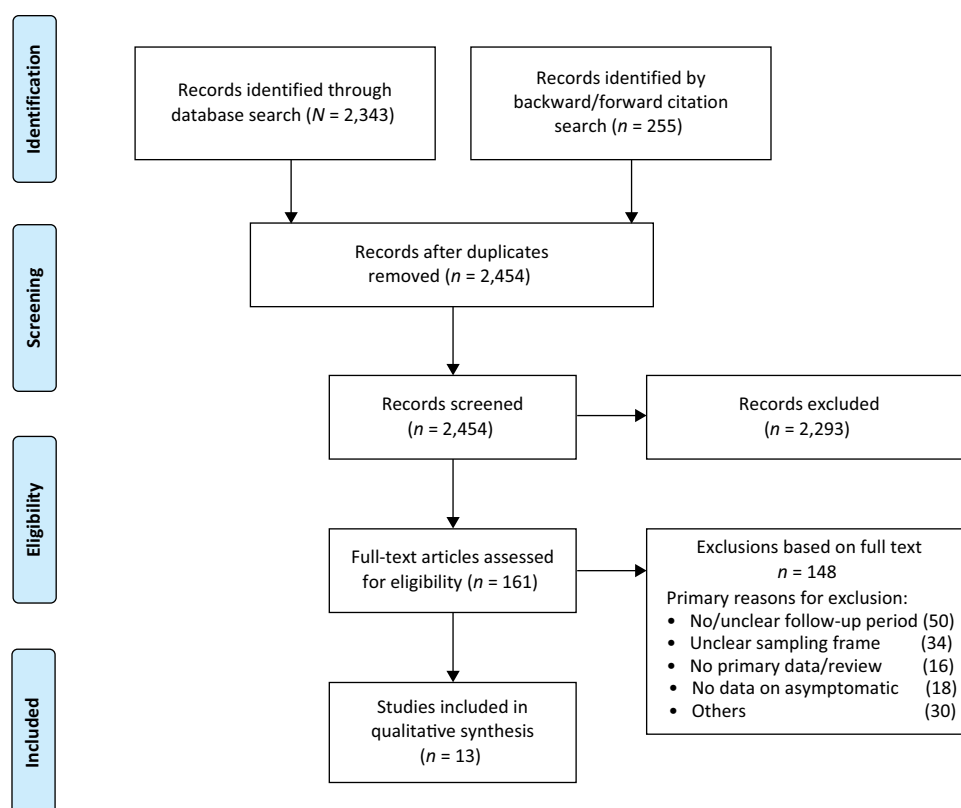

Figure 2: Screening and selection of articles

definition of *asymptomatic* for the numerator, and length of follow-up, as shown in Table 2 and in Supplemental Appendix 3 in full (8,9).

Data analysis

We estimated the proportion of COVID-19 cases who were asymptomatic for each included study population, assuming a binomial distribution and calculating exact Clopper–Pearson confidence intervals. We then pooled data from all included studies using (1) fixed-effects meta-analysis and (2) random-effects meta-analysis. All analyses were conducted using SAS version 9.4 (SAS Institute, Cary, NC); the FREQ procedure was used for individual studies and the fixed-effects meta-analysis; the NLMIXED procedure was used for the random-effects meta-analysis.

We also meta-analyzed the forward transmission rates from asymptomatic and symptomatic cases when there were sufficient data and report the pooled RR comparing the two. We planned to undertake subgroup analysis for age (between studies, and within studies when age was reported separately for asymptomatic and symptomatic cases). Because the analysis included only studies deemed to be of high quality on items

1 and 2 after risk-of-bias appraisal, no sensitivity analysis of high- versus low-quality studies was undertaken. Instead, we did a sensitivity analysis in which we omitted studies with a follow-up duration of less than 14 days.

RESULTS

A total of 2,454 articles were screened for title and abstract, and 161 full-text articles were assessed for inclusion (Figure 2). Major reasons for exclusion were inadequate sampling frame and insufficient follow-up time to accurately classify the asymptomatic cases. The full list of excluded studies with reasons is presented in Supplemental Appendix 2. Thirteen articles—nine published and four preprints—from seven countries (China, $n = 4$; United States, $n = 4$; Taiwan, $n = 1$; Brunei, $n = 1$; Korea, $n = 1$; France, $n = 1$; and Italy, $n = 1$) that tested 21,708 close contacts of at least 849 confirmed COVID-19 cases, of which 663 were positive and 111 were asymptomatic, met the eligibility criteria for the estimation of the primary outcome (10–22).

The sampling frames of the selected studies included residents of skilled nursing facilities (SNFs; 10, 12, 15, 19, 20); high-risk close contacts of confirmed COVID-19 cases

Table 1: Characteristics of included studies ($N = 13$)

Study (country) and publication status	Study population (sampling frame)	Sample size and age	Diagnostic testing and frequency	Length of follow-up for asymptomatic cases
Roxby et al (20) (United States) Published	Residents of independent and assisted living communities (Facility 1) in Seattle after two confirmed cases between 5 and 9 Mar	$N = 79$; mean age of cohort 86 y	Nasal swab, RT-PCR, twice, 1 wk apart	7 d
Patel et al (19) (United States) Published	Residents and staff of skilled nursing facility in Illinois on 15 Mar	$N = 126$; median age of cases 82 y.	Nasal swab, RT-PCR, once	30 d
Dora et al (15) (United States) Published	Residents of skilled nursing facility in Veterans Affairs Greater Los Angeles Healthcare System between 29 Mar and 23 Apr	$N = 99$; median age of cohort 75 y.	Nasal swab, RT-PCR, repeated every 10 d	At least 14 d
Blain et al (12) (France) Published	Nursing home residents in France tested weekly since early Mar	$N = 79$; mean age 86 y	Nasal swab, RT-PCR, repeated weekly	6 wk
Arons et al (10) (United States) Published	Residents of skilled nursing facility (Facility A) in Seattle after a confirmed case on 1 Mar	$N = 86$; mean age of cohort 77 y, mean age of cases 79 y.	Nasal swab, RT-PCR, twice, 1 wk apart	7 d
Zhang et al (22) (China) Published	Close contacts of confirmed cases between 28 Jan and 15 Mar in Guangzhou, China	$N = 369$; median age 35 y.	Nasal swab, RT-PCR, at least twice	14 d
Tian et al (21) (China) Preprint	Close contacts (coworkers, family members, customers) of a confirmed supermarket employee (super-spreader) in Liaocheng, China.	$N \approx 8,000$; mean age of cases 48 y	Nasal swab, RT-PCR, repeated every 2 days	16 ± 6.15 d
Cheng et al (14) (Taiwan) Published	High-risk close contacts (household members, HCWs) of first 100 cases in Taiwan	$N = 849$; mean age of cohort 42 y, mean age of cases 41 y	Nasal swab, RT-PCR, repeated during 14 d quarantine	14 d
Lavezzo et al (16) (Italy) Published	Majority of population of Italian town of Vò after a COVID-19 death on 21 Feb.	$N = 2,812$; mean age of cohort 47 y, mean age of cases 58 y	Nasal swab, RT-PCR, twice, 7–14 d apart	7–14 d
Bi et al (11) (China) Published	Close contacts of cases confirmed before 9 Feb in Shenzhen, China	$N = 1,286$; mean age of cohort 38 y, mean age of cases 43 y	Nasal swab, RT-PCR, repeated during 14 d quarantine	95% followed up for ≥ 12 d
Chaw et al (13) (Brunei) Preprint	Bruneian attendants of a religious event in Malaysia, where a confirmed case was present	$N = 1,830$; mean age of cohort 31 y, mean age of cases 33 y	Nasal swab, RT-PCR, repeated weekly	14 d

(Continued)

Table 1: Characteristics of included studies (*N* = 13) (*Continued*)

Study (country) and publication status	Study population (sampling frame)	Sample size and age	Diagnostic testing and frequency	Length of follow-up for asymptomatic cases
Luo et al (17) (China) Preprint	Close contacts of 347 confirmed COVID-19 patients identified between 13 Jan and 6 Mar in Guangzhou, China	<i>N</i> = 4,950; mean age of cohort 38 y, mean age of cases 44 y	Nasal swab, RT-PCR, repeated every 2 d	14 d
Park et al (18) (Korea) Published	Employees, residents, and visitors of a commercial and residential building where a confirmed case worked	<i>N</i> = 1,143; mean age of cohort 38 y	Nasal swab, RT-PCR, repeated during 14 d quarantine	14 d

RT-PCR = Reverse transcriptase–polymerase chain reaction; HCWs = Health care workers; COVID-19 = Coronavirus disease 2019

(11, 13, 14, 17, 18, 21); and a whole district surveillance program in Italy (16). The demographic characteristics (Table 1) indicate that most of the tested individuals were adults, with a mean age of more than 75 years in the five SNF studies and a mean age of more than 31 years in the non-aged care studies. The proportions of children and young people (0–20 years) ranged from 6% to 23.5%.

Diagnosis in all studies was confirmed via RT-PCR and in two cases was supplemented with radiological evidence (17, 21). Testing of individuals in the study sample varied across settings but was generally very high: all contacts regardless of symptoms (11, 13, 14, 17, 18, 21), more than 97% of SNF residents (10, 12, 15, 19, 20), and 85.9% of an entire town (16). The length of follow-up for monitored individuals in the SNF studies ranged from 7 to 30 days (10, 12, 15, 19, 20); 14 days for the Bruneian (13), Taiwanese (14), Korean (18), and Chinese close contacts (17, 22); 7–14 days in the Italian community (16); 12 days for 95% of all contacts in the Shenzhen community surveillance (11); and a mean of 16 (SD 6) days in Liaocheng, China (21).

The proportion of asymptomatic cases in the 13 included studies ranged from 4% (95% CI 1% to 10%) in Korea (18) to 40% in Vò, Italy (16) and in an aged care facility in the United States (20). Combining data from all 13 studies, we estimate that 17% of cases were asymptomatic (fixed effects 95% CI 14% to 20%); for the eight non-aged care studies, 16% (95% CI 13% to 19%); and for the five studies of SNFs, 20% (95% CI 14% to 27%) (Figure 3). The corresponding estimated proportions in the random-effects meta-analysis were, overall, 18% (95% CI 9% to 26%); non-aged care, 16% (95% CI 7% to 26%); and aged care, 21% (95% CI 5% to 36%). The 95% prediction interval was 4% to 52%. In the sensitivity analysis, which omitted studies in which length of follow-up was less than 14 days (10, 11, 16, 20), the overall estimate was modestly lower at 15% (fixed-effects 95% CI 12% to 18%)

or 17% (random-effects 95% CI 8 to 26%). Heterogeneity as expressed by I^2 was 84%.

Five studies reported data on secondary infection transmission from asymptomatic cases (Table 2). The asymptomatic transmission rates ranged from none to 2.2%, whereas symptomatic transmission rates ranged between 0.8% and 15.4%. Cycle threshold from real-time RT-PCR assays or the viral load did not differ between asymptomatic and symptomatic individuals in three of the studies (10, 14, 16). Overall, the RR of asymptomatic transmission was 42% lower than that of symptomatic transmission (pooled RR 0.58, fixed-effects 95% CI 0.335 to 0.994, p = 0.047; RR 0.38, random-effects 95% CI 0.13 to 1.083, p = 0.07; I^2 = 43.4%).

Risk of bias of included studies

Table 3 summarizes the overall risk-of-bias assessment of the nine included studies (the full list of risk-of-bias questions is in Supplemental Appendix 3). All of the studies were evaluated as low risk of bias for the sampling frame and length of follow-up domains (domains 1 and 5), which were part of the inclusion criteria. Two studies had potential non-response bias because not all of the eligible participants were tested (14% [463/3,275] of the target population was not tested in the Lavezzo et al study [16]) or results were not reported for all tested participants (87/98 cases were reported in the Bi et al study [11]; domain 2). Four studies either had not tested the study population at least twice during the follow-up period or had not provided clear information on testing (11, 13, 14, 21) (domain 3). Nine studies did not explicitly state the asymptomatic case definition they adhered to or had additional bias because of a high percentage of people in the SNFs with severe cognitive impairment (10–12, 14–16, 19–21) (domain 4).

Figure 3: Pooled estimates of proportion of asymptomatic carriers by subpopulations
N = Positive cases; n = Asymptomatic cases

Table 2: Comparison of secondary transmission rates

Study	No./N (%)		Relative risk
	Asymptomatic transmission rate	Symptomatic transmission rate	
Zhang et al (22)	1/119 (0.8)	11/250 (4.4)	0.2
Cheng et al (14)	0/91 (0)	22/2644 (0.8)	0.66
Chaw et al (13)	15/691 (2.2)	28/1010 (2.8)	0.78
Luo et al (17)	1/305 (0.3)	117/2305 (5.1)	0.06
Park et al (18)	0/4 (0)	34/221 (15.4)	0.72

Excluded studies

Several well-publicized studies did not meet our inclusion criteria. The outbreak on the Diamond Princess cruise ship involved 3,711 passengers, of whom more than 600 acquired COVID-19 (3). Many of the positive cases were relocated to medical facilities in Japan without details of their clinical progression. To correct for the lack of follow-up, Mizumoto et al applied a statistical adjustment for the right censoring

and estimated that 17.9% (95% CI 15.5% to 20.2%) of positive cases were asymptomatic.

An open-invitation screening of the Icelandic population suggested that around 0.8% of the population were SARS-CoV-2 positive, with half classified as (initially) asymptomatic (2). However, because there was no follow-up, we cannot separate asymptomatic from pre-symptomatic individuals. Moreover, the study excluded symptomatic people undergoing

Table 3: Risk of bias in 13 included studies*

Included Studies	Risk-of-bias assessment questions				
	1. Was the sampling frame a true or close representation of the target population?	2. Was the likelihood of non-response bias among those at risk of infection minimal?	3. Is the reference standard used likely to correctly classify all SARS-CoV-2 infections?	4. Was an acceptable case definition used in the study?	5. Was the length of follow-up to define case definition appropriate?

targeted testing, which impeded estimation of an overall asymptomatic rate.

A study of 215 pregnant women in New York identified 33 SARS-CoV-2-positive women (23). On admission to the delivery unit, 4 of the 33 positive cases were symptomatic and 3 became symptomatic before postpartum discharge, suggesting an asymptomatic rate of 79% (26/33). However, the 2 days of follow-up were insufficient to meet our inclusion criteria.

A case report of a pre-symptomatic Chinese businessman transmitting COVID-19 to a German business partner was also excluded because despite three other people acquiring the infection from the infected German source, none of them was asymptomatic at follow-up (24). A 5-day point-prevalence testing of adults living in homeless shelters in Boston found 147 positive cases, of which the majority had mild or no symptoms (25). We excluded this study because no numeric estimate was included of those who were truly asymptomatic, and there was no follow-up assessment.

Two studies examined people repatriated from overseas to their home countries by plane. Neither study was clear on whether symptomatic people could board the plane and be included, and if they were excluded, the asymptomatic rates

would be overestimated. A study of 565 Japanese citizens repatriated from China (26) found 13 positives—4 asymptomatic and 9 symptomatic, based on screening on arrival. Another study of 383 Greek citizens repatriated from the United Kingdom, Spain, and Turkey (27) found 40 asymptomatic positive people on arrival, 4 of whom later self-reported symptoms. Again, the likely initial exclusion of symptomatic people and the lack of comprehensive follow-up would both result in overestimation of the asymptomatic rates.

DISCUSSION

Principal findings

Although the rate of asymptomatic COVID-19 cases has received considerable attention, we found only 13 studies that provided an adequate sample frame and follow-up to ascertain a valid estimate of the proportion of asymptomatic cases. The combined estimate of the asymptomatic proportion was 17% (95% CI 14% to 20%) but had considerable heterogeneity ($I^2 = 84\%$) and a 95% prediction interval that ranged from 4% to 52%. There was no clear difference in the proportions between aged care and non-aged care studies. Only 5 of the

13 studies provided data on transmission rates from asymptomatic cases. The transmission risk from asymptomatic cases appeared to be lower than that of symptomatic cases, but there was considerable uncertainty in the extent of this (RR 0.58; 95% CI 0.335 to 0.994, $p = 0.047$).

Strengths and weaknesses of the study

Strengths of our systematic review include achieving full methodological rigor within a much shorter time frame than traditional reviews using enhanced processes and automation tools (5). We also critically assessed the risk of bias of all full-text articles we screened to include studies with the least risk of bias in sampling frame and length of follow-up domains to be able to differentiate between asymptomatic and pre-symptomatic cases.

Our findings have several limitations. First, our search focused on published and pre-print articles, and we may have missed some public health reports that are either unpublished or only available on organisational websites. Second, the design and reporting of most of the studies had a number of important deficits that could affect their inclusion or our estimates. These deficits include poor reporting of the sample frame, testing and symptom check, and follow-up processes. Such reporting would have been considerably aided by including a flow chart of cases (as Lavezzo et al [16] did) with identification, testing, and follow-up, including missing data. A further important limitation was the poor reporting of symptoms, which was often simply dichotomised into symptomatic versus asymptomatic without clear definitions and details of possible mild symptoms. The included studies did not report sufficient data to examine the impact of age and underlying comorbidities on the asymptomatic rate. Finally, all included studies relied on RT-qPCR; hence, some cases might have been missed because of false-negative results, especially when study participants were only tested once (28). If the tests missed more asymptomatic cases, then the true proportion of asymptomatic cases could be higher than our estimates. However, false-positive results, which may occur when people without symptoms are tested in low-prevalence settings, would mean the true prevalence of asymptomatic cases was lower than our estimates.

Strengths and weaknesses compared with other studies

Several other non-systematic and systematic reviews have examined the proportion of asymptomatic cases. The non-systematic reviews estimated asymptomatic rates as between 5% and 80% (4, 29). However, they included only early cross-sectional reports and did not critically appraise the study design, nor did they attempt to pool the most valid studies. Five other systematic reviews reported pooled estimates of asymptomatic rate as between 8% and 16% (30–34). However,

these reviews included studies that we excluded because of high risk of bias in the sampling frame. Ongoing monitoring for new studies is warranted but should include robust methodological assessment, including ensuring included studies have a sufficient follow-up period to differentiate the asymptomatic from the pre-symptomatic cases. Our review currently also has a more recent search date than other reviews and includes sensitivity analysis by length of follow-up time. Our estimate of risk of transmission by asymptomatic cases was comparable to those reported in two other empirical reviews by Buitrago-Garcia et al (RR 0.35) and Koh et al (RR 0.39) (32, 34).

Meaning of the study

Estimates of the proportion of the cases that are asymptomatic and the risk of transmission are vital parameters for modelling studies. Our estimates of the proportion of asymptomatic cases and their risk of transmission suggest that asymptomatic spread is unlikely to be a major driver of clusters or community transmission of infection, but the extent of transmission risk for pre-symptomatic and minor symptomatic cases remains unknown. The generalisability of the overall estimate is unclear, and we observed considerable variation across the included studies, which had different settings, countries, and study design, reflected in the reasonably wide prediction interval.

Unanswered questions and future research

Many unanswered questions about asymptomatic cases remain. Only one of the more recent studies we included tested patients for immunoglobulin G antibodies to determine seroconversion among elderly individuals. Without repeated and widespread RT-PCR and antibody tests, it is difficult to accurately estimate the prevalence of COVID-19 infection and inform our infection prevention strategies (35). The role of viral load and virus shedding dynamics in asymptomatic and symptomatic cases will further help answer the question of forward transmission and disease length and severity. Other unknowns include whether there is a difference in the proportion of cases that are asymptomatic according to age (particularly children versus adults), sex, or underlying comorbidities, and whether asymptomatic cases develop long-term immunity to new infections. For most studies, the PCR (positive) cases were traced from the index cases, and the testing was carried out mostly at the beginning of the pandemic wave for the locale. So, for this review of inception cohorts, people with long-term persistent positive testing were unlikely to be misclassified as asymptomatic. The issue of persistent PCR positivity after a person has recovered from infection might be of concern to more recent studies conducted at some time after the first wave of the pandemic. In such

studies, researchers will need to ask about history of illness compatible with COVID-19 even if this occurred months ago, and PCR testing could be supplemented by other tests such as viral culture and anti-SARS-CoV-2 antibody tests.

Our recommendations for future research also include improved clearer reporting of methods, sampling frames, case definition of *asymptomatic*, extent of contact tracing, duration of follow-up periods, presentation of age distribution of asymptomatic cases, and separation of pre-symptomatic and mild cases from asymptomatic cases in results tables. Most studies used a limited definition of asymptomatic COVID-19 case, which could lead to mixing paucisymptomatic cases with asymptomatic cases. If that were a common issue, then the true prevalence of asymptomatic cases would be even lower than the current estimates. A reliable estimate of the proportion of asymptomatic cases and the burden of disease is imperative in understanding the infection transmission capacity of asymptomatic cases to inform public health measures for these individuals who, according to our findings, appear to pose lower risk of transmission. Until we have further immunological and epidemiological evidence, we advise that the importance of asymptomatic cases for driving the spread of pandemic to be considered with caution.

DOI: <https://doi.org/10.3201/eid2606.200412>

To determine possible modes of virus transmission, we investigated a cluster of coronavirus disease cases associated with a shopping mall in Wenzhou, China. Data indicated that indirect transmission of the causative virus occurred, perhaps resulting from virus contamination of common objects, virus aerosolization in a confined space, or spread from asymptomatic infected persons.

¹These authors contributed equally to this article.

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the causative agent of coronavirus disease (COVID-19), is presumed to spread primarily via respiratory droplets and close contact. However, these transmission modes do not explain all cases. To determine how the virus may have spread among a cluster of COVID-19 cases associated with a shopping mall in Wenzhou (a city with 8 million residents), China, we monitored and traced close contacts and hypothesized possible transmission modes. We analyzed clinical and laboratory data for cases by using real-time reverse transcription PCR (1). The study was approved with written consent from the Ethics Committee of Wenzhou Central Hospital and written informed consent from all case-patients.

On January 20, 2020, a 23-year-old man (patient E) sought care at a hospital after 11 days of fever and headache. On January 21, COVID-19 was confirmed for patient E and his co-worker, patient G. The Wenzhou Center for Disease Control and Prevention traced and tested their contacts, and by January 28, COVID-19 was confirmed for 7 persons (patients A–G) from the same office (on floor 7).

Patient A, a 30-year-old woman, the only case-patient who indicated that she had been in Wuhan, China, returned from Wuhan on December 18, 2019. On January 15–16, 2020, she had a fever, but symptoms resolved without treatment. Despite symptom resolution, on January 30 she was confirmed to have SARS-CoV-2 infection. If patient A is the index patient, infected in Wuhan, her incubation period would have been 28 days, which would be extremely long, according to updated information (W.J. Guan et al., unpub. data, <https://www.medrxiv.org/content/10.1101/2020.02.06.20020974v1>). Asymptomatic carrier transmission has been reported for SARS-CoV-2 (2); hence, patient A could have been screened as a close contact during her incubation period and then hospitalized on the basis of a positive test (PCR) result only. However, her clinical symptoms did not appear until after hospitalization. Because persons with asymptomatic COVID-19 can spread the virus, patient A also could have been an asymptomatic carrier with a persistent infection (3).

On January 22, the mall was shut down. During January 19–February 9, COVID-19 was diagnosed for 7 mall staff from floors B1–3 and for 10 mall customers. Close contacts associated with the mall were traced, and COVID-19 was confirmed for 11 persons. Sixteen patients had had direct contact with other patients or had gone shopping in the mall. The average incubation period was 7.3 (range 1–17) days.

The mall has 8 floors above ground and several basement levels; floors B1 to 6 are commercial

RESEARCH LETTERS

shopping space, and floor 7 contains shopping and office space. We created an illustration showing the floors where the eventual COVID-19 case-patients worked or shopped, along with dates of symptom onset, potential incubation periods, symptom durations, confirmed times of positive diagnosis, and times of discharge (Figure 1, panel A).

Except for those who had been on floor 7, all other case-patients denied direct close contact with other case-patients. The possibility of customers being infected from other sources cannot be excluded. However, most customers reported early symptom onset in a concentrated time frame (Figure 1, panel B). We found no convincing evidence of definitive transmission pathways in this building. Patients A–G (Figure 1, panel A) worked in the same room on floor 7. Other case-patients who had been on other floors denied any direct contact with confirmed patients from floor 7, but they shared common building facilities (e.g., restrooms, elevators). Also, staff from floor 7 visited shops on other floors daily.

Until now, no evidence has shown that SARS-CoV-2 can survive outside the body for long. However, Middle East respiratory syndrome coronavirus demonstrates high robustness and a strong capability to survive outside the body and can remain infectious for up to 60 minutes after aerosolization (4). Hence, the rapid spread of SARS-CoV-2 in our study could have resulted from spread via fomites (e.g., elevator buttons or restroom taps) or virus aerosolization in a confined public space (e.g., restrooms or elevators). All case-patients other than those on floor 7 were female, including a restroom cleaner, so common restroom use could have been the infection source. For case-patients who were customers in the shopping mall but did not report using the restroom, the source of infection could have been the elevators. The Guangzhou Center for Disease Control and Prevention detected the nucleic acid of SARS-CoV-2 on a doorknob at a patient's house (5), but Wenzhou Center for Disease Control and Prevention test results for an environmental sample from the surface of a mall elevator wall and button were negative.

We cannot exclude the possibility of unknown infected persons (e.g., asymptomatic carriers) spreading

the virus. However, according to screening protocols implemented by the Wenzhou Center for Disease Control and Prevention, we traced all close contacts and included all patients with positive PCR results, including the asymptomatic carrier (patient A), in this study. Our findings appear to indicate that low intensity transmission occurred without prolonged close contact in this mall; that is, the virus spread by indirect transmission.

The work was supported by Major Project of Wenzhou Municipal Science and Technology Bureau (ZY202004).

Updated: Public health management of cases and contacts associated with COVID-19

Updated July 5, 2021

Note

This page is continually under review and updated as this situation evolves. Select updates have been made to the last version (April 22, 2021) in the following sections:

- Introductory content
- Contact management
- Persons possibly exposed through travel
- Contact tracing for airline passengers and flight crew

The updates in this version:

- Reflect emerging evidence regarding vaccine effectiveness and increasing vaccine coverage in the Canadian population
- Classify fully vaccinated contacts as low risk for the purposes of determining recommended public health authority (PHA) actions. This includes relaxation of quarantine recommendations for fully vaccinated contacts of cases (see Table 1), unless the risk assessment conducted by the PHA indicates otherwise
- Adjust quarantine period language to allow for flexibility in situations where a combination of testing and quarantine may be used
- Incorporate changes to reflect [border measures policies](#)

Please visit the [provincial and territorial resources for COVID-19](#) page for updated guidance specific to your province or territory

On this page

The Public Health Agency of Canada (PHAC), in collaboration with Canadian public health experts, has developed this guidance for federal/provincial/territorial (FPT) public health authorities (PHAs) to support the management of individuals infected with or who may have been infected with the SARS-CoV-2 virus (i.e., "cases") and contacts of

COVID-19 cases within their jurisdictions. *It is recognized that PHAs may adjust case and contact management recommendations based on a risk assessment that would include the local epidemiology, vaccination coverage in the community, vaccination status of the contacts, etc.*

The strategy outlined in this guidance focuses on case and contact management to mitigate the health impacts of COVID-19 on individuals in Canada¹. This guidance is set in the Canadian context and is based on the available scientific evidence and expert opinion. In interpreting and applying this guidance, it is important to recognize that the health, disability, economic, social, or other circumstances faced by some individuals and households may limit their ability to follow the recommended measures. This may necessitate adapted case management and contact responses by PHAs.

The response to the COVID-19 pandemic has been further strengthened by the availability of vaccines, but is further challenged by the emergence of variants of concern (VOC) within Canada and worldwide. Mutations in the SARS-CoV-2 virus that result in it being designated as a VOC are those which may cause increased transmissibility and/or potential changes in virulence and/or the possibility for immune escape. Monitoring for VOCs in general, particularly those with evidence of escape from natural/vaccine immunity, and those with increased transmissibility/severity is an important public health action to help inform case and contact management.

Evidence on the effectiveness of COVID-19 vaccines against asymptomatic infection in adults has begun to emerge from international post-marketing studies. Evidence suggests mRNA vaccines are moderately to highly effective against asymptomatic SARS-CoV-2 infection after a first dose (depending on time since vaccination as at least 2 weeks is needed for the immune response to develop) and highly effective against asymptomatic SARS-CoV-2 infection after a second dose. There are currently limited data specific to other COVID-19 vaccines, but studies are ongoing. Evidence on the effectiveness of COVID-19 vaccines authorized for use in Canada is summarized in the National Advisory Committee on Immunization's (NACI) Recommendations on the use of COVID-19 vaccines statement and is updated as evidence evolves.

Provincial and territorial (PT) PHAs continue to adjust restrictive community-based measures (CBMs) based on the epidemiology of COVID-19 and vaccination coverage in their jurisdictions, taking into consideration other important indicators, such as sufficient public health capacity to test, to trace, to isolate and to quarantine a high proportion of cases and contacts, respectively, sufficient health care capacity to respond to surges and risk reduction measures are in place for high-risk populations (i.e., those at higher risk of developing more severe disease or outcomes) and settings.

This guidance is subject to change as new information on transmissibility and epidemiology becomes available. It should be read in conjunction with relevant PT and local legislation, regulations and policies. Coronavirus disease (COVID-19) outbreak updates are available.

Case management

Reporting and notification

The national case definition for COVID-19 provides surveillance case definitions as well as associated surveillance reporting requirements.

It is important for frontline health care providers to notify PHAs of cases of COVID-19 in accordance with jurisdictional reporting requirements. PHAs need to provide overall co-ordination with health care providers and provincial laboratories for the management and reporting of cases, and to establish communication links with all involved health care providers for the full duration of illness. PHAs should report confirmed cases of COVID-19, as

well as probable cases where feasible, to PHAC within 24 hours of receipt of their own notification. [National surveillance for Coronavirus disease \(COVID-19\) guidance](#) is available. At the time of publication, a process for national reporting of VOCs has been approved, and provinces and territories are working closely with PHAC to implement and optimize this process to ensure national surveillance of VOCs.

In some instances, cases or contacts of cases are identified with epidemiological linkages that span two or more jurisdictions within and/or between provinces/territories. During case investigation, it may also be identified that the case acquired their infection, or was potentially exposed, in another jurisdiction. PHAs should use established inter-jurisdictional processes to enable timely case and contact management. Examples where this may be required include when a case travelled between jurisdictions during their communicable period; or when contacts reside in a different jurisdiction than a case.

Laboratory testing and screening

Laboratory testing strategies have evolved over time. Each PT has modified their approach (e.g., who is being tested and how) based on factors such as emerging evidence, new technology, laboratory capacity and local epidemiological circumstances. [Information is available](#) on the important roles that FPT governments play in COVID-19 testing.

At present, a [validated reverse transcription polymerase chain reaction \(RT-PCR\) test](#) on a clinically appropriate sample collected by a trained health care provider is the gold standard for the diagnosis of SARS-CoV-2 infection.

Appropriate laboratory testing for COVID-19 infection should be accessible by health care providers through community-based, hospital or reference laboratory services (e.g., a provincial public health laboratory (PHL) running a validated assay), or the National Microbiology Laboratory. In addition, PTs should have a process for screening and sequencing positive specimens for mutations common to VOCs. The establishment of screening assays looking for mutations specific to VOCs can provide results sooner than sequencing of virus samples and may be useful for informing timely public health action. However, not all VOCs will have common mutations so surveillance using partial or whole genome sequencing must be established by the PT. Although ideally, all positive specimens should be sequenced, when volumes preclude this, it is recommended that specimens from travelers, outbreaks and patients admitted to hospital should be prioritized and a subset of community-based specimens should also be selected for sequencing.

[Guidance for health professionals related to laboratory testing](#) is available. In addition, the Respiratory Virus Infections Working Group of the Canadian Public Health Laboratory Network has developed [laboratory testing best practices for COVID-19](#) and has updated its [protocol on microbiological investigation of emerging respiratory pathogens, including severe acute respiratory infections](#) ^{2 3}.

Rapid testing for COVID-19 using non-molecular assays has the potential to increase testing capacity; however, current data suggest that these methods are less sensitive than the current RT-PCR assays ⁴. The quick turn-around times and ease of use by a wide range of users allows rapid testing to be an important tool in a broader testing strategy (e.g., rapid testing of asymptomatic individuals in a cohort in which an outbreak is occurring or as part of a broader community-based testing strategy to help bring community transmission under control) ⁵. Interim guidance is available for use of the [nucleic acid-](#) and [antigen-based](#) rapid detection tests.

Re-infection

There is evidence that, although uncommon, individuals can become re-infected with SARS-CoV-2 ⁶. The dynamics, duration, and nature of immunity produced during infection with SARS-CoV-2 are still unclear, but there is good evidence of immunity for at least several months in the majority of individuals previously infected ⁷. The evidence will be monitored to determine if there is a higher risk of re-infection associated with VOCs, which may impact future guidance on testing. Refer to guidance for [laboratory testing for individuals suspected of being re-infected](#) for more information.

Clinical management/treatment

Clinical management of the case, whether in the home or in an acute care setting, is based on the case's condition and at the discretion of the case's health care provider. Refer to relevant guidance on [clinical management of patients with COVID-19](#).

Health care providers involved in home care for a case should follow interim guidance developed for [infection prevention and control in home care settings](#). Guidance for household members providing care for a case in the home, or occupants/staff in a co-living setting, are detailed in [Appendix 1](#).

Case management in the community

Epidemiologic evidence suggests that the majority of people with COVID-19 do not require care in a hospital ⁸.

When care in a hospital is not required, cases should isolate themselves as soon as possible. If they are isolating in the home or co-living setting (e.g., student residence, group home, shelter, etc.), they should isolate away from other household members or occupants, as directed by their PHA.

Those who live alone, or in a home where the members of the household are in isolation or quarantine, should identify community and social supports (e.g., family, friends, social services) where possible to assist with essential needs, including [care of pets](#) when required, or consult with their local PHA for information about additional community resources.

Appendices 1 and 2 provide information regarding recommendations for isolation and assessment of a suitable isolation location respectively.

Seeking medical care

In the event of a medical emergency, the case or their caregiver should contact emergency medical services (911) or the local emergency helpline for medical assistance, including transportation to the hospital or clinic if necessary. If using an ambulance to travel to a hospital or clinic, inform the dispatcher that the person requiring medical care has COVID-19. Public transportation should not be used to seek medical care (if possible).

If using a private vehicle to seek medical care:

- Call ahead to inform the hospital or clinic that the individual has COVID-19, and follow any directions provided;
- When traveling in a private vehicle:
 - minimize occupants in the vehicle (e.g., only the driver and case, if possible)
 - maximize distance between all occupants in the vehicle (e.g., case in the back seat, opposite to the driver in the car; or third row in larger vehicles)
 - open all windows if possible and safe to do so ⁹;
 - the case should be wearing a medical mask ^a, if no contraindications to doing so
 - all other occupants in the vehicle should wear medical masks ^a;

- The case and those assisting with transport should follow strict adherence to personal preventive practices to help reduce risk of transmission (e.g., frequent hand hygiene, respiratory etiquette).

Isolating in the community

When advising individuals to isolate in the community-at home or in a co-living setting-it is important that the risk of transmission from the case to other members of the household or occupants in the co-living setting be minimized as much as possible.

Guidance for isolating at home or in other co-living settings, as well as recommendations when strict adherence to isolation requirements may not be possible, are available in [Appendix 1](#).

Assessing suitability for isolation in the community

The PHA, in collaboration with the case and their health care provider, will determine the location where a case of COVID-19 isolates, as appropriate. It is important that cases who do not require hospital-level care convalesce in a suitable environment where effective isolation can be maintained and appropriate monitoring (e.g., for worsening of illness) can be provided.

Considerations for a suitable environment will depend on the individual and their living situation; and may vary depending on the sex, gender, or other socioeconomic or identity factors of the case. The vaccination status of other household members may also be taken into consideration. When feasible and as directed by the PHA, an alternate dwelling (e.g., hotel, self-containing unit) may be used for isolation of a case.

The PHA plays an important role in assessing the suitability of the case's isolation setting, and the considerations listed above are detailed in [Appendix 2](#).

Psychosocial considerations

PHAs should encourage individuals, families and communities to create a supportive environment for people who are isolating to take care of their mental health, and minimize stress and hardship associated with isolation as the financial, social, and psychological impact can be substantial.

Obtaining and maintaining public trust are key to successful implementation of these measures. Clear messages about isolation, including the criteria, rationale, justifications, and duration, as well as ways in which persons will be supported during the isolation period, will help to generate public trust. Messaging should also be sensitive and tailored to the needs of populations confronting social, economic, cultural or other vulnerabilities. Additional information on [the psychological impacts of COVID-19](#) is available.

For Indigenous Peoples, mandatory isolation away from home due to COVID-19 may trigger re-traumatization issues associated with experiences of forced removals in the past. There is also the potential for new trauma if their ability to be with their community, practice cultural and/or spiritual activities is limited. To avoid relocation of persons with COVID-19 to locations outside of their community, many Indigenous communities have re-purposed facilities or set up temporary structures to use as isolation sites so that community members may safely isolate in situations where their home setting is not suitable.

Public health monitoring of cases

Ideally, PHAs should provide or facilitate active daily monitoring of cases of COVID-19, including those infected with a VOC, as long as feasible based on available resources. If there are insufficient resources available to provide daily monitoring for all cases, PHAs should give consideration to prioritizing daily monitoring for cases infected with a VOC.

It is recognized that the frequency of monitoring of COVID-19 cases may vary by PHA and the local context, but generally, should include the following actions or advice:

- The ability to adhere to the standard isolation measures recommended;
- Appropriate information on infection prevention and control precautions, personal preventive practices, and environmental cleaning;
- Advice for self-monitoring for symptoms, including daily temperature checks;
- Steps to take if symptoms worsen, including instruction on self-care and how/when to access medical care; and
- When and where to access further diagnostic testing for COVID-19, if appropriate based on provincial/territorial testing strategies;
- Monitoring for symptom-onset in household contacts (if relevant) and/or identifying additional contacts.

PHAs should provide additional information about VOCs as required, such as when VOCs are circulating in the community or when a case has been diagnosed with a variant strain, including heightened vigilance for increased transmissibility if isolating at home or in a co-living setting with other household members or occupants.

Cases of COVID-19 should be monitored until they have met the criteria set by the PHA for discontinuing isolation.

Discontinuation of isolation for cases in the community

The PHA should direct the discontinuation of isolation of cases in the community (i.e., those not hospitalized or residents of long-term care facilities) ^b. Criteria may include:

- For symptomatic cases:
 - At least 10 days have passed since onset of first symptom.
 - The case is afebrile and has improved clinically.
 - Absence of anosmia or fatigue/tiredness should not be required.
 - Absence of cough should also not be required for those known to have chronic cough or for those who are experiencing reactive airways post infection.
- For asymptomatic cases:
 - At least 10 days have passed since the date their positive specimen was collected and the case remained asymptomatic.

In general, repeat laboratory testing (e.g., a negative test result) as the basis for discontinuing home isolation is not recommended. In most individuals with competent immune systems and those recovered from mild or moderate illness, prolonged or renewed RNA detection is not believed to reflect infectious virus, but rather non-infectious viral fragments, as viable virus has rarely been reported to persist for longer than 10 days in these populations. Additional information can be found in [Guidance for repeated PCR testing in individuals previously positive for COVID-19](#).

There may be exceptions to these criteria for which PHA and/or clinical care providers may determine a longer isolation period is warranted (e.g., immunocompromised individuals, those hospitalized due to COVID-19). Discontinuation of isolation is not related to clinical management of cases. In some cases, clinical management may continue to be required after discontinuation of isolation.

Contact management

Contact management for community-based cases of COVID is the responsibility of local and provincial public health authorities, and is evolving as vaccine coverage in Canada increases and cases of COVID-19 are lowering in many jurisdictions.

It is important to identify and manage the contacts of cases of COVID-19 to reduce ongoing transmission of the virus in the community¹⁰. Several objectives may be achieved through contact management activities by PHAs, including:

- To facilitate rapid identification of secondary cases of COVID-19 (or source cases, in the context of backward contact tracing);
- To facilitate early implementation of public health measures as appropriate, depending on the contacts' exposure risks; and
- To gain a better understanding of the epidemiology of COVID-19.

Early identification of contacts, and direction regarding diagnostic testing for COVID-19 based on existing PT testing strategies, is a key component of rapid case identification and management to reduce transmission of the coronavirus. With the many unknowns associated with VOCs, testing of vaccinated individuals will be an important consideration of contact management.

In an outbreak context, contact tracing and management also serves the purpose of active case finding during an investigation. Where an outbreak is suspected, the PHA may adopt a situation-specific definition for those at high risk of exposure (i.e., "close contact") to help efficiently target their contact investigation and case finding efforts. For example, all individuals at an event associated with a high risk of transmission could be evaluated as being at high risk of exposure (e.g., all guests at a wedding, or participants of an indoor fitness class). This approach may be considered when the outbreak setting results in a high risk of exposure for most participants, or where risk assessments for individuals are not feasible.

Outbreaks may have a greater impact on certain groups due to their social, economic, health, or other risk factors, such as older age, having chronic medical conditions, living in a remote and isolated community, or living in poverty or crowded settings.

PHAs should give consideration to engaging in more rigorous outbreak investigation activities when an outbreak involves a VOC. This may include backward contact tracing or mass asymptomatic testing of individuals with known or suspected close contact exposure to a case with a VOC.

Contact tracing

The public health approach to COVID-19 case and contact management to date has largely focused on interrupting chains of transmission through contact tracing by identifying individuals at risk of exposure to SARS-CoV-2 from an identified case. The primary goal of contact tracing is to identify and to quarantine, or to facilitate self-monitoring of, individuals who are potentially exposed to a case to stop future chains of transmission.

Contacts should be identified and managed as per the recommendations in this document, where feasible based on public health resources. The level and intensity of public health actions may vary among jurisdictions according to the local epidemiology of COVID-19 at a given time and the identification of VOCs. Alternative contact management strategies that PHAs may consider when resources are constrained are detailed below.

The risk assessment conducted by the PHA can help identify each contact's exposure risk level, determine the appropriate intervention for the individual (e.g., quarantine, self-monitoring) and PHA actions for the recommended monitoring period. If the contact has been vaccinated, the PHA risk assessment may consider

additional factors that could influence risk categorization and subsequent PHA actions. For example, these factors could include whether the contact has been partially or fully vaccinated, if the contact had been previously infected, if the contact is immune compromised, the time since last dose of vaccine or the potential risk of transmission to others, especially unvaccinated individuals who are at risk of more severe disease or outcomes from COVID-19. In addition, if there is significant spread of VOCs within the community or there is uncertainty about the risk assessment for a contact of a case infected with a VOC, PHAs may choose to adopt a more cautious approach when managing contacts as either high- or low-risk of exposure (see [Table 1](#) below).

Given that transmission of SARS-CoV-2 can occur from cases who are symptomatic, pre-symptomatic, or asymptomatic, contact tracing should include:

- Identifying people who were exposed to a symptomatic case in the period starting 48 hours prior to the case developing a symptom consistent with COVID-19, and until the case was no longer considered infectious (e.g., 10 days following symptom onset for a non-hospitalized case).
- Identifying people who were exposed to a laboratory confirmed asymptomatic case in the period starting 48 hours prior to the day their positive specimen was collected, and until the case was no longer considered infectious (e.g., 10 days after specimen collection date) ¹¹.

For operational purposes, a minimum period of 48 hours prior to symptom onset (or positive test result) should be considered by jurisdictions for contact tracing. Under certain circumstances (e.g., outbreak management, VOCs, backward contact tracing), and given that in some instances the infectious period of a COVID-19 case may be longer than 48 hours, jurisdictions may extend contact tracing greater than 48 hours when public health capacity and/or the risk assessment warrants it.

Table 1 provides guidance for classifying contacts as either high or low risk, depending on their exposure, for the purposes of determining recommended actions. Fully vaccinated in this context means at least 14 days have passed since the completion of the recommended number of doses of a Health Canada approved COVID-19 vaccine. The information provided in Table 1 is not intended to replace more personalized public health advice provided to contacts, based on comprehensive risk assessments conducted by PHAs.

Table 1: Contact management recommendations by exposure risk level

Note: All potential exposures described below are considered to have occurred when the case was communicable in determining exposure risk level.

Risk Level	Description	Recommendations for the contact
------------	-------------	---------------------------------

<p>High risk exposure (close contact)</p>	<ul style="list-style-type: none"> • HCW who is not fully vaccinated and who provided direct physical care to a case, or a laboratory worker handling COVID-19 specimens, without consistent and appropriate use of recommended PPE and infection prevention and control practices ^d. • Anyone who is not fully vaccinated and lives with a case, has direct physical contact with a case, or is exposed to their infectious body fluids, including the case's caregiver, intimate partner, child receiving care from the case, etc. • Anyone who is not fully vaccinated and has shared an indoor space (e.g., same room) with a case for a prolonged period of time ^d, including closed spaces and crowded places, (e.g., social gatherings, workplaces, etc.), without adhering to appropriate individual-level and setting-specific risk mitigation measures ^e. • Anyone who is not fully vaccinated and has had a close-range conversation with a case or has been in settings where a case engaged in singing, shouting, or heavy breathing (e.g., exercise), without adhering to appropriate individual-level and setting-specific risk mitigation measures ^e. 	<ol style="list-style-type: none"> 1. Quarantine at home for 14 days from last exposure or for the recommended period determined by the local PHA ^f. 2. Follow recommended <u>personal preventive practices</u>. If living with the case, avoid further exposure to the case and wear <u>medical mask</u> or a <u>well-constructed and well-fitting, non-medical mask</u> ^f when in a shared space (e.g., same room) with the case. 3. Follow PHA directions related to testing requirements ^g. 4. Self-monitor for the appearance of <u>symptoms consistent with COVID-19</u> for 14 days following their last exposure to the case. 5. Take and record temperature daily and avoid the use of fever-reducing medications (e.g., acetaminophen, ibuprofen) as much as possible. These medications could mask an early symptom of COVID-19; if these medications must be taken, advise the PHA ¹². 6. If symptoms occur, isolate away from others within the home or co-living setting as quickly as possible; put on a medical mask ^a and contact the PHA for further direction, which will include: <ul style="list-style-type: none"> ◦ where to go for care, ◦ appropriate mode of transportation to use, and ◦ IPC precautions to be followed. 7. Avoid in-person interactions with others, especially <u>those who are at risk for developing more severe disease or outcomes from COVID-19</u>. 8. Contacts who are <u>at risk for developing more severe disease or outcomes</u> should not provide care for the case and should stay elsewhere if feasible.
--	---	---

Low risk exposure	<ul style="list-style-type: none"> • HCW (regardless of vaccination status) who provided direct physical care to a case, or a laboratory worker handling COVID-19 specimens, with consistent and appropriate use of recommended PPE and infection prevention and control practices ^ε. • Anyone (regardless of vaccination status) who has shared an indoor space (e.g., same room) with a case, including closed spaces and crowded places (e.g., social gatherings, workplaces, etc.), with adherence to appropriate individual-level and setting-specific risk mitigation measures ^ε. • Anyone (regardless of vaccination status) who has had a close-range conversation with a case or has been in settings where a case engaged in singing, shouting, or heavy breathing (e.g., exercise), with adherence to appropriate individual-level and setting-specific risk mitigation measures ^ε. • Fully vaccinated individuals in the above-mentioned high-risk exposure (close contact) situations would be considered to have a low risk exposure and be managed accordingly. 	<ol style="list-style-type: none"> 1. Self-monitor for <u>symptoms</u> for 14 days following their last exposure. 2. If symptoms occur, isolate away from others as quickly as possible, put on a medical mask ^a and contact the PHA for further direction, which will include: <ul style="list-style-type: none"> ◦ where to go for care, ◦ appropriate mode of transportation to use, and ◦ IPC precautions to be followed. 3. Where possible avoid interactions with <u>individuals at higher risk for severe illness</u> (this may not apply to HCWs who are using PPE and following IPC practices appropriately in their workplace) ^ε. 4. Follow PHA directions related to testing requirements. 5. Follow recommended <u>personal preventive practices</u>.
Acronyms:		
<ul style="list-style-type: none"> • HCW: health care worker • PPE: personal protective equipment • IPC: infection prevention and control 		

Although transmission of SARS-CoV-2, including VOCs, may occur during brief exposures, transient interactions (e.g., walking by a case) have not been identified as high- or low-risk exposures in Table 1 because identifying such contacts is typically not feasible outside of digital contact tracing applications (see Alternative contact management strategies below).

Based on a risk assessment, PHAs may consider more robust approaches to contact management and quarantine specifications, particularly in the context of outbreak investigations involving VOCs. PHAs may also need to consider modifications to quarantine recommendations in some circumstances, such as the need for essential workers to maintain critical services. In these circumstances, jurisdictions may consider reducing quarantine with negative test results. At present, there is limited evidence to support this as a widespread approach, as there remains a residual risk of transmission ¹³.

The duration of contact management for a contact who develops symptoms compatible with COVID-19 within 14 days of last exposure to a case should be based on the following considerations:

- If laboratory testing is conducted and the test result is **negative** for SARS-CoV-2, consider continuing to manage the individual as a contact for the duration of the possible 14-day incubation period, based on a risk assessment. The contact may be considered for re-testing if they have a worsening or progression of symptoms, and management would depend on the results of the second test.
- If laboratory testing is **not** conducted, the contact who develops symptoms should be managed as a probable/suspect case as applicable, and they should complete at least 10 days of isolation. Since they are still

a contact of a case and not a laboratory confirmed case themselves, depending on the timing of symptom onset and last exposure to a case, this individual may need to quarantine after the isolation period, for 14 days from the last known exposure. In this situation, the PHA should complete a risk assessment to determine the appropriate quarantine period based on the individual's level of risk (see [Table 1](#)).

Alternative contact management strategies

To complement or accommodate limited local resources, PHAs may consider alternative approaches to traditional contact tracing, particularly when they are experiencing a local surge in cases¹⁴. These may include the following:

- Using well-trained non-public health staff and volunteers for certain contact tracing activities;
- Repurposing existing resources, such as call centres or hotlines;
- Reducing the intensity of follow-up of contacts based on risk assessment, for example, automated calls or text messages to low-risk contacts, or follow-up text messages instead of daily calls; and
- Leveraging available technology, such as contact tracing software, as well as web-based and mobile phone applications (e.g., [COVID Alert](#)).

During local peaks in COVID-19 activity and declared outbreaks, PHAs may also consider prioritizing contact tracing activities for specific settings where people gather (e.g., schools, events, workplaces, remote communities, etc.), and in particular, when epidemiologic features suggest a change in transmission dynamics (e.g., when a VOC is suspected or confirmed). PHAs may also consider prioritizing follow-up of contacts (e.g., those with vulnerabilities, those who work in high-risk settings, or those who provide care to someone with vulnerabilities, etc.)¹⁵.

PHAs may also consider alternative approaches where cases, employers, or event coordinators notify contacts (i.e., simple referral); or notify contacts and provide additional information related to infection prevention and control, quarantine, and symptom monitoring (i.e., enhanced referral)¹⁶.

Backward contact tracing

PHAs may also consider 'backward' contact tracing, which focuses on trying to determine where and when the case likely acquired their infection. Backward contact tracing is routinely done as part of case or outbreak investigations for communicable diseases of public health significance, when PHAs collect information on a case's potential acquisition history. In this guidance, backward contact tracing is proposed as a less intensive activity, and therefore potentially less resource intensive, compared to outbreak investigation.

While COVID-19 has been observed to spread steadily in the community, with one case infecting one or two other individuals on average, clusters have been identified where some individuals disproportionately infect a larger number of individuals. This represents a statistical concept called over-dispersion, where there is high individual-level variation in the distribution of the number of secondary transmissions. Clusters associated with these cases have been referred to as super-spreading events (SSEs).

Mutations in the genetic code of SARS-CoV-2 can also cause the virus to act in ways that have significant impacts on case and contact management (e.g., increases in disease spread or severity; its ability to become undetectable by tests; or the effectiveness of vaccines or treatments).

In these circumstances, 'backward' contact tracing may help to:

- Identify the source case;
- Find additional cases by focusing on the setting where a case's exposure likely took place; and
- Interrupt additional chains of transmission by then tracing contacts of the newly identified cases.

If the source case is identified through backward contact tracing, contact tracing to identify individuals who may have been exposed to a case should be employed as detailed above, and contacts managed based on their risk of exposure as described in [Table 1](#). Depending on a given situation, testing requirements and public health interventions may need to be scaled based on local epidemiology.

Backward contact tracing is considered to be most useful when localized outbreaks may be occurring in areas experiencing relatively low levels of transmission. It may also be considered for investigating outbreaks with an epidemiologic feature suggestive of change in transmission dynamics (e.g., where a VOC is implicated).

It is considerably more challenging when there is widespread community transmission, due to the volume of cases and uncertainty created by having multiple potential sources of transmission for any given case. Backward contact tracing may also be less useful during periods of restrictive public health measures, due to fewer events or localized settings where outbreaks or SSEs might occur ¹⁷. Employing backward contact tracing approaches may have significant resource implications, depending on the specific contact tracing strategies used, approaches to testing, and local epidemiology.

There is currently limited evidence regarding the effectiveness of backward tracing for COVID-19, so it is not possible to be definitive about when it would be most useful or how it would be best implemented. A limited number of countries have utilized this strategy, and beneficial impact was correlated with low incidence and limited community transmission ^{18 19}.

Provinces/territories (PTs) should consider the utility of backward contact tracing based on their individual circumstances and available resources and, if implemented, consider evaluating the effectiveness in order to contribute to the evidence base for this practice.

Persons possibly exposed during travel

In response to the COVID-19 pandemic, all travellers entering Canada are subject to the rules set out by the [emergency orders](#) under the *Quarantine Act*.

Current information regarding travel, testing, quarantine and borders requirements can be found at [COVID-19: Travel, testing, quarantine and borders](#).

History of travel should be considered by PHAs during a risk assessment during contact tracing. Potential [travel-related exposures on specific conveyances \(e.g., flights, trains, cruise ships\)](#) may be available.

Contact tracing for airplane passengers and flight crew

Potential exposure to SARS-CoV-2 among passengers and crew during air travel is a topic of concern; however, risk mitigation measures such as vaccination status, mandatory use of masks, physical distancing, reduced occupancy, ventilation, environmental cleaning, and hand hygiene, applied in a layered approach, can significantly reduce the likelihood of transmission ²⁰.

Decisions related to contact tracing individual airplane passengers and flight crew who may have been exposed to a confirmed case of COVID-19 on any flight should be made based on available resources and a risk assessment. Risk assessments should be conducted by the PHA to which the case is notified, considering the following:

- Type, severity, and onset date of symptoms for symptomatic cases, or specimen collection date for asymptomatic cases, in relation to the flight date;
- Current messaging to all international travellers, specifically with respect to any federally mandated testing, quarantine or isolation requirements;

- Current legislation, regulations and policies that may be imposed on domestic travellers by a PT upon arrival to that PT;
- Timing of notification and likelihood of getting sufficient passenger contact information within the recommended timeframe; and
- Incremental benefit of individual communication to those seated within 2 metres (or more) ^b of the case versus public communication of the flight number.

If the province/territory determines that notification to potential contacts is required, the PHA can follow local protocols for publicly communicating when a case has had a history of travel during their period of communicability. The information required is the flight number, flight date, departure/arrival locations, and affected rows of the flight. Additionally, flight exposure notifications received by PHAC's Inter-jurisdictional Notices (IJN) team can be posted on the [COVID-19: Passenger transport where you may have been exposed](#) webpage.

Appendix 1: Recommendations for isolation of COVID-19 cases in the community

When care in a hospital is not required, cases of COVID-19 should isolate themselves as soon as possible. If they are isolating in the home or co-living setting (e.g., shelter, group home, or student residence), they should isolate away from other household members or occupants, as directed by their PHA. It is recommended the case isolate in a separate room for sleeping with access to a separate washroom from other household members or occupants, if possible. When feasible and as directed by the PHA, cases could isolate in an alternate dwelling such a hotel or self-containing unit. They should isolate for a minimum of 10 days from the onset of symptoms for a symptomatic case, or the collection date of a positive specimen for an asymptomatic case.

During isolation, the case should not leave the isolation setting, whether it is their home, co-living setting, or an alternate setting identified by their PHA or health care provider. They should:

- Avoid in-person interactions with others, including members of their household, if possible;
- Not go out unless required or directed to seek medical care;
 - If a case must go out to seek medical care, they should wear a medical mask ^a.
- Not go to school, work, or other public places; and
- Not take public transportation to seek medical care, if possible.

Isolating in the community

When advising individuals to isolate at home or in a co-living setting, it is important that the risk of transmission from the case to other members of the household or occupants in the co-living setting be minimized as much as possible. Advice is available for [individuals who are required to isolate at home due to COVID-19](#).

As much as possible, the following strategies should be used during isolation in the community:

- A case should have their own room and a dedicated washroom.
 - When awake, the case should wear a medical mask ^a, when they are in a shared space (e.g., kitchen, washroom, hallway), regardless if other household members or occupants in the co-living setting are present, to avoid aerosol transmission and/or contaminating shared surfaces and objects.
- The case and other members of the household or co-living setting should avoid any activities that put them in a shared space (e.g., in the same room) with one another. This includes avoiding shared activities like watching television, congregate dining (e.g., family meals), playing games, etc.

- When other members of the household or co-living setting are unable to avoid sharing a space (e.g., the same room) with the case, they should wear a medical mask or a properly worn, well-constructed and well-fitting non-medical mask¹. If household members are at high risk of more severe disease or outcomes, a medical mask should be worn².
- If a member of the household or co-living setting needs to provide care to the case, they should wear a medical mask². The case should only access an outdoor setting if it is a private space (i.e., their private backyard or balcony). If household members are present in this outdoor space, all individuals present should continue to wear masks and practice physical distancing.
- The case should avoid sharing personal items with others, as much as possible (e.g., towels, bed linen, cigarettes, unwashed eating utensils, toothbrushes, etc.).
- In situations where childcare is shared between two homes, wherever possible consider having the child stay in one home for the duration of the isolation or quarantine period.
- If possible, shared spaces (e.g., kitchen, washroom, hallways) should be well ventilated (e.g., windows open, as weather permits), regardless if individuals are present or not.
- The case and all household members or occupants of the co-living setting should strictly follow the recommended personal preventive practices.
- A list of supplies to have on-hand while isolating is available.

Recommendations when strict isolation is not possible

Cases of COVID-19 who have been directed to isolate may not be able to strictly follow instructions for isolation in the home or co-living setting. This may be due to the isolation setting itself, for instance, there are not enough rooms in the home for the case to have a separate room or a dedicated washroom, or occupants in a shelter who must share space. It may also be difficult to isolate due to other factors; for example, if the case is a child, has child-/elder- care responsibilities, or lives in a multigenerational household.

When it is not possible to relocate the case, or members of the household or co-living setting, the following approaches may be considered:

- In overcrowded housing, or where a dedicated room and washroom are not available for isolation, consider having the case, household members, or other occupants relocate to another location so the case can be isolated.
- Take steps to bring fresh air into the space, by opening windows and doors to the outside if possible (e.g., depending on weather) and safe (e.g., no fall hazards, outdoor air quality); and ensuring the mechanical ventilation system (e.g., heating, ventilation and air conditioning (HVAC) system) is functioning properly and turned on continuously if possible.
- Although the effectiveness is limited due to possible transmission of SARS-CoV-2 via respiratory droplets and aerosols, consideration may be given to separating the case from others with dividers such as curtains in a shared space (e.g., home with limited rooms, sharing space for sleeping).
 - If other members of the home or co-living setting are sleeping in the same room as a case, it is important to maintain as much distance as possible from the case (ideally a minimum of 2 metres)¹. This may be accomplished by separating beds and having occupants sleep head-to-toe.
- If a separate washroom is not available, open the window, turn on the exhaust fan to improve ventilation, put the lid of the toilet down before flushing and, when possible, clean and disinfect surfaces touched by the case after each use²¹.

Appendix 2: Assessment of a suitable isolation location for a case of COVID-19

The location where a COVID-19 case will be isolated should be determined by the public health authority (PHA), in collaboration with the case and their health care provider, as applicable. It is important that cases who do not require hospital-level care convalesce in a suitable environment where effective isolation and appropriate monitoring (e.g., for worsening of illness) can be provided.

Considerations for a suitable environment will depend on the individual and their living situations, and may vary depending on the sex, gender, or other socioeconomic or identity factors of cases.

Factors to consider when determining the suitability of an isolation location:

Can the case's clinical condition be managed as an outpatient?

For isolation in the community, including the home or a co-living setting (e.g., shelter, group home, student residence, etc.), it must be possible to manage the case as an outpatient, taking into consideration their baseline health status and the presence of risk factors for more severe disease or outcomes. If hospitalization is required (e.g., worsening condition, health emergency, direction of health care provider), home isolation will no longer be feasible.

Is the case able to manage their own care?

Symptomatic and asymptomatic cases should be able to monitor themselves for new or worsening symptoms; take appropriate action as advised by the PHA or their health care provider, including self-care; properly wear a medical mask ^a; maintain appropriate personal preventive practices (e.g., maintain proper hygiene practices, clean and disinfect high-touch surfaces, etc.), and isolate away from others.

A case's ability to manage their own care may be impacted by various factors, including:

- Social and economic circumstances, such as lost income or poverty (e.g., unable to purchase necessary supplies, housing instability, etc.), unstable employment, inflexible working conditions, food insecurity, and domestic violence or abuse;
- Individual skills, abilities and vulnerabilities, such as difficulty reading, speaking, understanding or communicating; physical or psychological difficulty undertaking personal preventive practices; need for assistance with personal or medical care activities or supplies; or need for ongoing supervision. COVID-19 guidance on considerations for people with disabilities in Canada is available.
- Social or geographic isolation such as lacking family, friends, or community resources for support ²², or residing in an area with reduced access to services or supports; including mental health and addiction support, as well as telecommunications access.
- The ability for the case to access plain-language instructions in the appropriate languages related to proper personal hygiene practices, isolating away from others, self-monitoring for symptoms, and when to seek help. Note that male cases are more likely to live alone and may be less likely to seek help ^{23 24}.

Does the case require care? Is someone available to provide the care?

Some circumstances may require a household member to provide care to the case; for example, when the case is a child, an elderly relative who requires support, or a case who is very ill. When this occurs, the following should be considered:

- The caregiver should be willing and able to provide the necessary care and monitoring for the case.

- If possible, the caregiver should not be a person who is at risk for more severe disease or outcomes.
- The caregiver should reduce their risk of COVID-19 infection by wearing a medical mask ^awhen providing care to the case. They should also use appropriate eye protection while providing care to the case (see Appendix 3).
- Advice is available to support those caring for someone with COVID-19 at home:
 - How to care for a child with COVID-19 at home: Advice for caregivers
 - How to care for someone with COVID-19 at home
 - How to care for a person with COVID-19 at home: Advice for caregivers

What are the characteristics of the home or co-living configuration?

Cases may be in various household configurations that may hinder their ability to isolate themselves. For instance, the case may be a single-parent who must provide care to a child, or they may live in a multi-generational home with shared child- and elder-care responsibilities. If the case provides care to a child where childcare is shared between parents in two separate homes, consideration should be given to the most appropriate location for the child while the case is isolating.

If the case is isolating in their home or co-living setting, they should isolate away from others as soon as they are notified they have or may have COVID-19. Special consideration is also needed to support cases living in homes where it is difficult to separate from others (e.g., a one-bedroom apartment), or are living in co-living settings, such as student residence, shelters, and overcrowded housing,. The preferred option is to provide the case in these settings with a single room and a private washroom, which may require relocating the case, their roommates, or other household members to another location, (e.g., hotel, self-containing unit), if possible and as directed by the PHA. Relocation will be dependent on a variety of factors, including guidance from the jurisdiction's PHA, financial support, and availability of alternate spaces.

If it is not possible to provide the case with a single room and a private washroom in the co-living setting, or to relocate the case, efforts should be made to cohort confirmed cases together. For example, if two cases reside in a co-living setting and single rooms are not available, they could share a double room. Specific guidance has been developed on the considerations for people experiencing homelessness and for post-secondary institutions.

Are there others with greater risk of more severe disease or outcomes in the home or co-living setting?

Household members, or other occupants in co-living settings, who are at risk for more severe disease or outcomes from COVID-19 should not provide care to the case and alternative arrangements may be necessary. This could include temporarily relocating these individuals or the case outside of the home to a location determined by public health, such as a designated hotel.

Is the home or co-living setting suitable for isolation?

The PHA should determine if the home or co-living setting is suitable for isolation of the case. Cases may live in conditions where they lack available space to provide a dedicated room and private washroom for the case, such as an overcrowded house, student residence where the case has a roommate, or a homeless shelter. Housing conditions should also be assessed, including access to potable, running water, and the state of repair of the home. Safety of the setting should also be assessed in terms of the potential occurrence of gender-based or family violence or other abuse.

Can the case access adequate supplies and necessities?

Consider whether or not the case has access to supplies and necessities for the duration of isolation, such as food, running water, drinking water, supplies for infection control (e.g., masks), and cleaning supplies. A [list of supplies](#) to have on-hand while isolating is available. Those residing in [remote and isolated communities](#) may wish to consider stockpiling the needed supplies, as well as food and medications usually taken, if it is likely that the supply chain may be interrupted or unreliable.

A case who does not have access to adequate food or necessary supplies could contact local leadership, public health or organizations that provide direct support. Guidance is available for [hand washing in the absence of running or clean water](#).

If the home or co-living setting is inadequate for home isolation based on the assessment, PHAs should collaborate with the case and their health care provider, to determine a more suitable location. This may involve relocating the case to a more suitable community setting, hospitalizing the case, or accessing additional community supports and resources where available.

Appendix 3: Recommended infection prevention and control precautions when caring for a case in the home or co-living setting

Anyone who provides care to a case of COVID-19 should wear a medical mask ^a, as well as [eye protection](#) whenever providing care. Caregivers should also frequently [wash their hands](#), especially when in direct contact with the ill person or their environment, including soiled materials and surfaces.

Advice is available to support those caring for someone with COVID-19 at home:

- [How to care for a child with COVID-19 at home: Advice for caregivers](#)
- [How to care for someone with COVID-19 at home](#)
- [How to care for a person with COVID-19 at home: Advice for caregivers](#)

Additional information may be provided to caregivers in the home related to how to appropriately put on (don) and take off (doff) eye protection and gloves.

Eye protection

Eye protection is recommended to protect the mucous membranes of the caregiver's eyes while providing care to a case of COVID-19, or during any activities likely to generate splashes or sprays of bodily fluids, including respiratory secretions.

- Eye protection should be worn over prescription eyeglasses. Prescription eyeglasses alone are not adequate protection against respiratory droplets.
- Protective eye wear should be put on after putting on a mask.
- If using gloves, they should be donned (see below) after applying eye protection.
- To remove eye protection, first remove gloves and perform hand hygiene. Then remove the eye protection by handling the arms of goggles or sides or back of face shield. The front of the goggles or face shield is considered contaminated.
- Discard the eye protection into a plastic lined waste container. If the eye protection is not intended for single use, clean it with soap and water and then disinfect it with [approved hard-surface disinfectants](#) or, if not available, a diluted bleach solution, being mindful not to contaminate the environment with the eye protection. Refer to [Clean and disinfect all high-touch surfaces](#) for instructions on diluting bleach.
- Perform [hand hygiene](#).

Gloves

Caregivers do not have to wear disposable single-use gloves when caring for someone in the home setting. Frequent hand washing is preferred.

However, caregivers may still choose to wear disposable single use gloves, when in direct contact with the ill person, cleaning contaminated surfaces, and handling items soiled with bodily fluids, including dishes, cutlery, clothing, laundry, and waste for disposal.

Gloves are not a substitute for hand hygiene; caregivers must perform hand hygiene before and after putting on and taking off gloves.

- Gloves should be removed, hand hygiene performed, and new gloves applied when they become soiled or torn during care.
- To remove gloves safely, with one of your gloved hands pull off your glove for the opposite hand from the fingertips, as you are pulling, form your glove into a ball within the palm of your gloved hand. To remove your other glove, slide your ungloved hand in under the glove at the wrist and gently roll inside out, and away from your body. Avoid touching the outside of the gloves with your bare hands.
- Discard the gloves in a plastic-lined waste container.
- Perform hand hygiene.
- Double-gloving is not necessary.

Acknowledgments

The Public Health Measures (PHM) technical guidance is developed and approved in collaboration with federal, provincial and territorial partners, via the Technical Advisory Committee (TAC) and/or the Special Advisory Committee (SAC). In its guidance development process, PHM also works closely with: multilateral partners; other government departments; First Nations, Inuit and Métis stakeholders (through the Public Health Working Group on Remote and Isolated Communities); Sex and Gender-based Analysis (SGBA) experts at Public Health Agency of Canada; and other external stakeholders with a vested interest or a stake in the guidance.

This current iteration was prepared by: Lynn Cochrane, Lisa Paddle, Corey Green, Abraham Abood and Harunya Sivanesan

Previous iterations prepared by: Nicole Winters, Jill Sciberras, Jill Williams, Lynn Cochrane, Corey Green, Sharon E. Smith, Angela Sinilaite, Alexandra Nunn, Fanie Lalonde and Lisa Paddle

and supported by: Canadian Pandemic Influenza Preparedness (CPIP) Task Group Members, an external expert group: Bonnie Henry, Susy Hota, Brian Schwartz, Carolina Alfieri, Ian Gemmill, Kim Daly (ISC), Pamela Wolfe-Roberge, Todd Hatchette, Erin Henry, Nadine Sicard, Michelle Murti and Eleni Galanis

Footnotes

- a In situations where a medical mask is recommended but not available, the individual should properly wear a well-constructed and well-fitting non-medical mask.
- b COVID-19 guidance for acute care settings: <https://www.canada.ca/en/public-health/services/diseases/2019-novel-coronavirus-infection/health-professionals/infection-prevention-control-covid-19-second-interim-guidance.html> COVID-19 guidance for long-term care settings: <https://www.canada.ca/en/public-health/services/diseases/2019-novel-coronavirus-infection/prevention-control-covid-19-long-term-care-homes.html#a22>
- c This guidance is focused on community settings, and does not replace point-of-care risk assessments by health care providers in health care settings, or a risk assessment conducted by PHAs to determine the exposure risk for a health care worker (HCW).
Guidance related to the appropriate use of personal protective equipment (PPE) and infection prevention and control for HCWs and laboratory workers is available. See the following guidance documents:
- [Infection prevention and control for COVID-19: Second interim guidance for acute health care settings](#)
 - [Infection prevention and control for COVID-19: Interim guidance for home care settings](#)
 - [Infection prevention and control for COVID-19: Interim guidance for long term care homes](#)
 - [Routine practices and additional precautions for preventing the transmission of infection in health care settings](#)
 - Instructions on handling specimens: [Biosafety advisory: SARS-CoV-2 \(Severe acute respiratory syndrome-related coronavirus 2\)](#).
- d There is insufficient evidence available to define risk in terms of the length of exposure time required for transmission. For public health contact identification and management purposes only, a period of 15 cumulative minutes over 24 hours has been selected to distinguish between brief and prolonged exposure. This same period has been used in other countries ^{14 25 26}. This parameter should not replace the conclusions derived from a risk assessment, conducted by the public health authority, that addresses a variety of factors (i.e. infectiousness of the case at time of exposure, exposure is to a VOC, likely route of transmission, risk factors, etc.) that will more precisely inform risk.
- e The high and low risk exposure categories in Table 1 offer a simple guide for assessing a contact's risk of exposure to COVID-19 during contact tracing. In reality, there is a spectrum of risk, where adherence to public health risk mitigation measures helps to decrease the chance of infection. A risk assessment conducted by the PHA may further inform personalized recommendations.
Individual-level risk mitigation measures for consideration in the risk assessment include adherence to [personal preventive practices](#) (e.g., mask wearing, hand hygiene, physical distancing, etc.) by both the case and the contact. It should also include whether or not the contact avoids settings or activities where they may be exposed, including closed spaces and crowded places, as well as settings where these factors overlap and/or involve activities such as close-range conversations, singing, shouting, or heavy breathing. Setting-specific considerations include those places where a contact was potentially exposed, including whether the exposure was indoors (higher risk) or outdoors (lower risk), ventilation quality, the size and number of people in the setting, and risk mitigation measures in place in the setting (e.g., requirements for wearing masks, physical distancing, cleaning high-touch surfaces, etc.) ²⁷.
Although outdoor settings are not generally considered high risk, the potential for transmission still exists under certain circumstances, such as close conversations or rigorous exercise when participants are in close proximity and are not wearing masks; therefore, public health authorities should consider these risks when classifying contacts based on risk ²⁷.

- f The quarantine period typically aligns with the period of communicability. However, PTs may opt to implement a reduced quarantine period in combination with testing protocols, depending on the risk assessment and local circumstances.
- In general, quarantine means that a contact stays in their home and does not go out, and avoids in-person interactions with others, including their household members.
- A contact who does not live with a case should quarantine away from other household members or occupants, as directed by their PHA. It is recommended the contact quarantine in a separate room for sleeping with access to a separate washroom from other household members or occupants, if possible. When feasible and as directed by the PHA, a contact who does not live with the case could quarantine in an alternate dwelling such a hotel or self-containing unit.
- A contact who does not live with a case should wear a non-medical mask when in shared spaces (e.g., kitchen, washroom, hallway) in the home or co-living setting, regardless if others are present.
- For contacts in quarantine who are living with a case, it is recommended they wear a medical mask or a well-fitted, well-constructed and properly worn non-medical mask when in a shared space (e.g., the same room) as the case. Jurisdictions may adjust mask recommendations depending on local circumstances (e.g., if VOCs are circulating in the community; if the case and household contacts are living in a overcrowded or poorly ventilated setting).
- For contacts in quarantine who are living with a case, the PHA will determine when their quarantine period begins by assessing the characteristics of the setting. If it is determined that there is adequate separation between the case and their household members, the PHA may advise that household members' quarantine period begins the day the case goes into isolation. If there is inadequate separation (e.g., shared sleeping quarters, shared washroom, etc.), the PHA may require household members to quarantine for the duration of the case's isolation period, plus up to an additional 14 days afterwards.
- If additional members of a household with a case become ill, the PHA should assess whether other asymptomatic household members need to extend their period of quarantine based on their last exposure to the new case.
- g Jurisdictional specific testing policies/capacity could have implications on individual quarantine recommendations within that jurisdiction
- h The 2-metre parameter should not replace the conclusions derived from a risk assessment conducted by the PHA that addresses a variety of factors (e.g., infectiousness to the case at time of exposure, exposure is to a VOC, the likely route of transmission, increased risk of more severe disease or outcomes) that will more precisely inform risk.
- i For operational purposes, an appropriate physical distance is at least 2 metres. In general, if in-person interactions must take place, individuals should be encouraged to interact from the greatest distance possible, and with other personal preventive practices in place for a layered approach.

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Editor: L. Leibovici

To the Editor,

On January 29, 2020, two Chinese spouses (patient 1, female; patient 2, male), coming to Italy as tourists from Hubei province, were hospitalized at the National Institute for Infectious Diseases “L. Spallanzani”, Rome, with fever and respiratory symptoms. SARS-CoV-2 diagnosis was accomplished using real-time RT-PCR [1] on a nasopharyngeal swab and sputum for patient 1 and on a nasopharyngeal swab for patient 2, collected 1 day after symptom onset. Partial sequencing confirmed both patients to be infected with SARS-CoV-2.

A virus isolate was obtained (in a Vero E6 cell line) from the sputum of patient 1, with cytopathic effects evident 24 h post-inoculation. At the time of writing, virus isolation from the nasopharyngeal swab sample collected from patient 2 was not successful, likely due to the lower viral load (higher cycle threshold value, 24.56 in the real-time RT-PCR), therefore no further analysis was performed on the virus detected in patient 2. Next-generation sequencing (NGS) was performed on the respiratory samples from patient 1 and on the primary isolate, prior to any further passage, by using the Ion Torrent S5 platform (ThermoFisher). The mean count of sequencing reads obtained per sample was 44 000 000 (minimum 41.6×10^6 to maximum 49.7×10^6). The reads from the

two respiratory samples of patient 1 were merged to obtain a better coverage along the virus genome, and in this paper are referred to as data from the clinical sample. Details of sequencing and bioinformatic analyses are available upon request.

The number of SARS-CoV-2 reads obtained varied from 4079 to $>14 \times 10^6$. By using *de novo* assembly, two contigs of 29 867 nt (mean coverage: 81 324 reads; range: 26–510 718 reads) and 29 792 nt (mean coverage: 80 reads; range: 5–599 reads) were obtained for the isolate and clinical sample of patient 1, respectively, and referred to as consensus sequences. Further analysis was dedicated to identifying the variants present at any nucleotide position for the variability analysis.

Considering the consensus sequences, two non-synonymous changes with respect to the Wuhan-Hu-1 NCBI Reference Genome (Accession number: MN908947.3) [2] were observed in the sequence from the clinical sample from patient 1: G11083T, leading to L3606F change in Orf1a, and G26144T, leading to G251V change in Orf3a. One additional synonymous substitution in Orf1a (A2269T) was detected in the isolate but not in the corresponding clinical sample. All variants were confirmed by Sanger sequencing.

Considering the analysis of genomic variability, several intra-sample variants were observed in both the isolate and the clinical sample, but only the positions with a minimum coverage of 20 reads were considered. Intra-sample assessment of overall virus genome variability resulted in 1.27×10^{-4} and 1.02×10^{-4} nucleotide substitutions per site for the isolate and the clinical sample, respectively. Only two variable positions were observed with a frequency $>10\%$ in the clinical sample, both in Orf1a: A2269T (13.73%, coverage: 51x), synonymous for amino acid A668, and G7388A (13.21%, coverage: 53x), leading to amino acid change (A2375T). Interestingly, the frequency of variants at position 2269 was different in the isolate, being T dominant over A in 72% of reads (coverage: 119 582x), accounting for the difference resulting in the consensus sequences.

For the phylogenetic analysis, 87 full-genome SARS-CoV-2 sequences were retrieved from the Global Initiative on Sharing All Influenza Data (GISAID), along with WH-01_MN908947.3 from GenBank. The G26144T substitution observed in the isolate from Italy was also present in five sequences from cases occurring

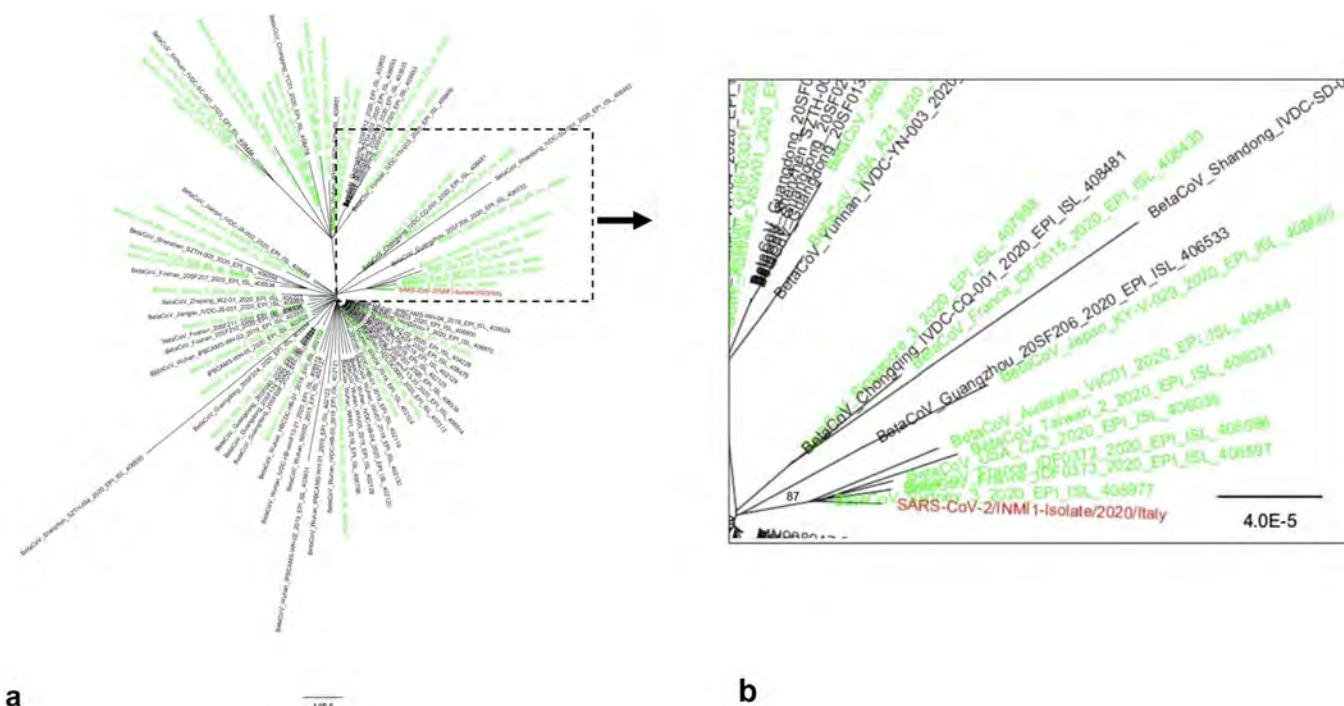

Fig. 1. (a) Unrooted phylogenetic tree based on SARS-CoV-2 full genome database from the Global Initiative on Sharing All Influenza Data (GISAID). Genomes collected outside China are highlighted in green. (b) Enlargement of clade reporting SARS-CoV-2/INMI1-Isolate/2020/Italy (in red). Maximum likelihood phylogeny was reconstructed under Hasegawa-Kishino-Yano plus proportion of invariable sites (HKY + I), inferred by model test function.

outside of China: EPI_ISL_406596 and EPI_ISL_406597 from France, EPI_ISL_406031 from Taiwan, EPI_ISL_406036 from USA, EPI_ISL_406844 and EPI_ISL_408977 from Australia. All the genomes carrying this mutation are included in a significant phylogenetic cluster (bootstrap 87%), suggesting a common origin (Fig. 1); in fact, the G251V substitution in Orf3a has recently been defined as the marker variant of the 'V' clade (GISAID).

The presence of quasispecies has previously been reported for SARS-CoV and MERS-CoV [3,4], suggesting that these betacoronaviruses may consist of complex and dynamic distributions of closely related variants *in vivo*, similarly to other RNA viruses. When applied to SARS-CoV-2 in this study, the analysis of sequence variability supported the presence of viral quasispecies in the clinical sample as well as in the primary isolate. Namely, two positions with variant frequency >10% were observed in the biological sample, both in Orf1a: A2269T, synonymous, and G7388A, corresponding to amino acid change A2375T. The synonymous variant A2269T, representing a minority variant in the clinical sample, was the dominant one in the isolate. Although low coverage may have affected the precise calculation of minority variant frequency in the clinical sample, the data are consistent with variant selection occurring during the isolation procedure, as previously shown for other respiratory viruses. In the respiratory sample neither mutations nor intra-sample variants were found at positions 8782 and 28 144, recently identified as hotspots of hypervariability (coverage: 61x and 76x respectively) [5].

Full-genome characterization of new viruses is instrumental for updating diagnostics and assessing viral evolution. On the other hand, virus variability, leading to the development of quasispecies within infected patients, may provide the background for virus evolution and adaptation to new hosts; more studies are necessary

to unravel the importance of intra-patient variability in the SARS-CoV-2 evolutionary trajectory.

Genome sequences described on this manuscript are available from GISAID and from GenBank (Acc. Numb: MT008022, MT008023, MT066156 and MT077125).

This case series describes COVID-19 symptoms persisting a mean of 60 days after onset among Italian patients previously discharged from COVID-19 hospitalization.

In Italy, a large proportion of patients with coronavirus disease 2019 (COVID-19) presented with symptoms (71.4% of 31 845 confirmed cases as of June 3, 2020).¹ Common symptoms include cough, fever, dyspnea, musculoskeletal symptoms (myalgia, joint pain, fatigue), gastrointestinal symptoms, and anosmia/dysgeusia.^{2,3,4} However, information is lacking on symptoms that persist after recovery. We assessed persistent symptoms in patients who were discharged from the hospital after recovery from COVID-19.

Methods

In the waning phase of the pandemic, beginning on April 21, 2020, the Fondazione Policlinico Universitario Agostino Gemelli IRCCS in Rome, Italy, established a postacute outpatient service for individuals discharged from the hospital after recovery from COVID-19. All patients who met World Health Organization criteria for discontinuation of quarantine (no fever for 3 consecutive days, improvement in other symptoms, and 2 negative test results for severe acute respiratory syndrome coronavirus 2 [SARS-CoV-2] 24 hours apart) were followed up. At enrollment in the study, real-time reverse transcriptase–polymerase chain reaction for SARS-CoV-2 was performed and patients with a negative test result were included.

Patients were offered a comprehensive medical assessment with detailed history and physical examination. Data on all clinical characteristics, including clinical and pharmacological history, lifestyle factors, vaccination status, and body measurements, were collected in a structured electronic data collection system. The COVID-19 postacute outpatient service is currently active, and further details about the patient evaluation protocol are described elsewhere.⁵

In particular, data on specific symptoms potentially correlated with COVID-19 were obtained using a standardized questionnaire administered at enrollment. Patients were asked to retrospectively recount the presence or absence of symptoms during the acute phase of COVID-19 and whether each symptom persisted at the time of the visit. More than 1 symptom could be reported. The EuroQol visual analog scale was used to ask patients to score their quality of life from 0 (worst imaginable health) to 100 (best imaginable health) before COVID-19 and at the time of the visit. A difference of 10 points defined worsened quality of life. All analyses were performed using R version 3.6.3 (R Foundation).

This study was approved by the Università Cattolica and Fondazione Policlinico Gemelli IRCCS Institutional Ethics Committee. Written informed consent was obtained from all participants.

Results

From April 21 to May 29, 2020, 179 patients were potentially eligible for the follow-up post-acute care assessment; 14 individuals (8%) refused to participate and 22 had a positive test result. Thus, 143 patients were included. The mean age was 56.5 (SD, 14.6) years (range, 19–84 years), and 53 (37%) were women. During hospitalization, 72.7% of participants had evidence of interstitial pneumonia. The mean length of hospital stay was 13.5 (SD, 9.7) days; 21 patients (15%) received noninvasive ventilation and 7 patients (5%) received invasive ventilation. The characteristics of the study population are summarized in the [Table](#).

Patients were assessed a mean of 60.3 (SD, 13.6) days after onset of the first COVID-19 symptom; at the time of the evaluation, only 18 (12.6%) were completely free of any COVID-19–related symptom, while 32% had 1 or 2 symptoms and 55% had 3 or more. None of the patients had fever or any signs or symptoms of acute illness. Worsened quality of life was observed among 44.1% of patients. The [Figure](#) shows that a high proportion of individuals still reported fatigue (53.1%), dyspnea (43.4%), joint pain, (27.3%) and chest pain (21.7%).

Discussion

This study found that in patients who had recovered from COVID-19, 87.4% reported persistence of at least 1 symptom, particularly fatigue and dyspnea. Limitations of the study include the lack of information on symptom history before acute COVID-19 illness and the lack of details on symptom severity. Furthermore, this is a single-center study with a relatively small number of patients and without a control group of patients discharged for other reasons. Patients with community-acquired pneumonia can also have persistent symptoms, suggesting that these findings may not be exclusive to COVID-19.⁶

Clinicians and researchers have focused on the acute phase of COVID-19, but continued monitoring after discharge for long-lasting effects is needed.

The figure shows percentages of patients presenting with specific coronavirus disease 2019 (COVID-19)–related symptoms during the acute phase of the disease (left) and at the time of the follow-up visit (right).

Coronavirus Disease 2019 in Children — United States, February 12–April 2, 2020

CDC COVID-19 Response Team

On April 6, 2020, this report was posted as an MMWR Early Release on the MMWR website (<https://www.cdc.gov/mmwr>).

As of April 2, 2020, the coronavirus disease 2019 (COVID-19) pandemic has resulted in >890,000 cases and >45,000 deaths worldwide, including 239,279 cases and 5,443 deaths in the United States (1,2). In the United States, 22% of the population is made up of infants, children, and adolescents aged <18 years (children) (3). Data from China suggest that pediatric COVID-19 cases might be less severe than cases in adults and that children might experience different symptoms than do adults (4,5); however, disease characteristics among pediatric patients in the United States have not been described. Data from 149,760 laboratory-confirmed COVID-19 cases in the United States occurring during February 12–April 2, 2020 were analyzed. Among 149,082 (99.6%) reported cases for which age was known, 2,572 (1.7%) were among children aged <18 years. Data were available for a small proportion of patients on many important variables, including symptoms (9.4%), underlying conditions (13%), and hospitalization status (33%). Among those with available information, 73% of pediatric patients had symptoms of fever, cough, or shortness of breath compared with 93% of adults aged 18–64 years during the same period; 5.7% of all pediatric patients, or 20% of those for whom hospitalization status was known, were hospitalized, lower than the percentages hospitalized among all adults aged 18–64 years (10%) or those with known hospitalization status (33%). Three deaths were reported among the pediatric cases included in this analysis. These data support previous findings that children with COVID-19 might not have reported fever or cough as often as do adults (4). Whereas most COVID-19 cases in children are not severe, serious COVID-19 illness resulting in hospitalization still occurs in this age group. Social distancing and everyday preventive behaviors remain important for all age groups as patients with less serious illness and those without symptoms likely play an important role in disease transmission (6,7).

Data on COVID-19 cases were reported to CDC from 50 states, the District of Columbia, New York City, and four U.S. territories. Jurisdictions voluntarily report data on laboratory-confirmed cases using a standardized case report form.* Data on cases occurring during February 12–April 2, 2020 and submitted through an electronic case-based COVID-19

surveillance database were reviewed for this report. Data submitted to CDC are preliminary and can be updated by health departments as more data become available. At the time of this analysis, characteristics of interest were available for only a minority of cases, including hospitalization status (33%), presence of preexisting underlying medical conditions (13%), and symptoms (9.4%). Because of the high percentage of cases with missing data and because cases with severe outcomes are more likely to have hospitalization or intensive care unit (ICU) status reported, percentages of patients hospitalized, including those admitted to the ICU, were estimated as a range, for which the denominator for the lower bound included cases with both known and unknown hospitalization or ICU status, and the upper bound included only cases with known hospitalization or ICU status. For other characteristics, percentages were calculated from among the number of cases with known information for that characteristic. Demographics of COVID-19 cases were assessed among cases in children aged <18 years and adults aged ≥18 years. Because clinical severity of COVID-19 is higher among adults aged ≥65 years than in younger age groups (8), clinical features including symptoms and hospitalizations were assessed among adults aged 18–64 years and compared with those among the pediatric cases. Statistical comparisons were not performed because of the high percentage of missing data.

As of April 2, 2020, data on 149,760 laboratory-confirmed U.S. COVID-19 cases were available for analysis. Among 149,082 (99.6%) cases for which patient age was known, 2,572 (1.7%) occurred in children aged <18 years and 146,510 (98%) in adults aged ≥18 years, including 113,985 (76%) aged 18–64 years. Among the 2,572 pediatric cases, 850 (33%) were reported from New York City; 584 (23%) from the rest of New York state; 393 (15%) from New Jersey; and the remaining 745 (29%) from other jurisdictions. The distribution of reporting jurisdictions for pediatric cases was similar to that of reporting jurisdictions for cases among adults aged ≥18 years, except that a lower percentage of adult cases was reported from New York state (14%). The first pediatric U.S. COVID-19 case was reported to CDC on March 2, 2020; since March 5, pediatric cases have been reported daily (Figure 1).

Among all 2,572 COVID-19 cases in children aged <18 years, the median age was 11 years (range 0–17 years). Nearly one third of reported pediatric cases (813; 32%) occurred in children aged 15–17 years, followed by those in children aged 10–14 years (682; 27%). Among younger

FIGURE 1. COVID-19 cases in children* aged <18 years, by date reported to CDC (N = 2,549)[†] — United States, February 24–April 2, 2020[§]

* Includes infants, children, and adolescents.

[†] Excludes 23 cases in children aged <18 years with missing report date.

[§] Date of report available starting February 24, 2020; reported cases include any with onset on or after February 12, 2020.

children, 398 (15%) occurred in children aged <1 year, 291 (11%) in children aged 1–4 years, and 388 (15%) in children aged 5–9 years. Among 2,490 pediatric COVID-19 cases for which sex was known, 1,408 (57%) occurred in males; among cases in adults aged ≥18 years for which sex was known, 53% (75,450 of 143,414) were in males. Among 184 (7.2%) cases in children aged <18 years with known exposure information, 16 (9%) were associated with travel and 168 (91%) had exposure to a COVID-19 patient in the household or community.

Data on signs and symptoms of COVID-19 were available for 291 of 2,572 (11%) pediatric cases and 10,944 of 113,985 (9.6%) cases among adults aged 18–64 years (Table). Whereas fever (subjective or documented), cough, and shortness of breath were commonly reported among adult patients aged 18–64 years (93% reported at least one of these), these signs and symptoms were less frequently reported among pediatric patients (73%). Among those with known information on each symptom, 56% of pediatric patients reported fever, 54% reported cough, and 13% reported shortness of breath, compared with 71%, 80%, and 43%, respectively, reporting these signs and symptoms among patients aged 18–64 years. Myalgia, sore throat, headache, and diarrhea were also less commonly reported by pediatric patients. Fifty-three (68%) of the 78 pediatric cases reported not to have fever, cough, or shortness of breath had no symptoms reported, but could not be classified as asymptomatic because of incomplete symptom information. One (1.3%) additional pediatric patient with a positive test result for SARS-CoV-2 was reported to be asymptomatic.

Information on hospitalization status was available for 745 (29%) cases in children aged <18 years and 35,061 (31%) cases in adults aged 18–64 years. Among children with COVID-19, 147 (estimated range = 5.7%–20%) were reported to be hospitalized, with 15 (0.58%–2.0%) admitted to an ICU (Figure 2). Among adults aged 18–64 years, the percentages of patients who were hospitalized (10%–33%), including those admitted to an ICU (1.4%–4.5%), were higher. Children aged <1 year accounted for the highest percentage (15%–62%) of hospitalization among pediatric patients with COVID-19. Among 95 children aged <1 year with known hospitalization status, 59 (62%) were hospitalized, including five who were admitted to an ICU. The percentage of patients hospitalized among those aged 1–17 years was lower (estimated range = 4.1%–14%), with little variation among age groups (Figure 2).

Among 345 pediatric cases with information on underlying conditions, 80 (23%) had at least one underlying condition. The most common underlying conditions were chronic lung disease (including asthma) (40), cardiovascular disease (25), and immunosuppression (10). Among the 295 pediatric cases for which information on both hospitalization status and underlying medical conditions was available, 28 of 37 (77%) hospitalized patients, including all six patients admitted to an ICU, had one or more underlying medical condition; among 258 patients who were not hospitalized, 30 (12%) patients had underlying conditions. Three deaths were reported among the pediatric cases included in this analysis; however, review of these cases is ongoing to confirm COVID-19 as the likely cause of death.

TABLE. Signs and symptoms among 291 pediatric (age <18 years) and 10,944 adult (age 18–64 years) patients* with laboratory-confirmed COVID-19 — United States, February 12–April 2, 2020

Sign/Symptom	No. (%) with sign/symptom	
	Pediatric	Adult
Fever, cough, or shortness of breath [†]	213 (73)	10,167 (93)
Fever [§]	163 (56)	7,794 (71)
Cough	158 (54)	8,775 (80)
Shortness of breath	39 (13)	4,674 (43)
Myalgia	66 (23)	6,713 (61)
Runny nose [¶]	21 (7.2)	757 (6.9)
Sore throat	71 (24)	3,795 (35)
Headache	81 (28)	6,335 (58)
Nausea/Vomiting	31 (11)	1,746 (16)
Abdominal pain [¶]	17 (5.8)	1,329 (12)
Diarrhea	37 (13)	3,353 (31)

* Cases were included in the denominator if they had a known symptom status for fever, cough, shortness of breath, nausea/vomiting, and diarrhea. Total number of patients by age group: <18 years (N = 2,572), 18–64 years (N = 113,985).

[†] Includes all cases with one or more of these symptoms.

[§] Patients were included if they had information for either measured or subjective fever variables and were considered to have a fever if “yes” was indicated for either variable.

[¶] Runny nose and abdominal pain were less frequently completed than other symptoms; therefore, percentages with these symptoms are likely underestimates.

Discussion

Among 149,082 U.S. cases of COVID-19 reported as of April 2, 2020, for which age was known, 2,572 (1.7%) occurred in patients aged <18 years. In comparison, persons aged <18 years account for 22% of the U.S. population (3). Although infants <1 year accounted for 15% of pediatric COVID-19 cases, they remain underrepresented among COVID-19 cases in patients of all ages (393 of 149,082; 0.27%) compared with the percentage of the U.S. population aged <1 year (1.2%) (3). Relatively few pediatric COVID-19 cases were hospitalized (5.7%–20%; including 0.58%–2.0% admitted to an ICU), consistent with previous reports that COVID-19 illness often might have a mild course among younger patients (4,5). Hospitalization was most common among pediatric patients aged <1 year and those with underlying conditions. In addition, 73% of children for whom symptom information was known reported the characteristic COVID-19 signs and symptoms of fever, cough, or shortness of breath.

These findings are largely consistent with a report on pediatric COVID-19 patients aged <16 years in China, which found that only 41.5% of pediatric patients had fever, 48.5% had cough, and 1.8% were admitted to an ICU (4). A second report suggested that although pediatric COVID-19 patients infrequently have severe outcomes, the infection might be more severe among infants (5). In the current analysis, 59 of 147 pediatric hospitalizations, including five of 15 pediatric ICU admissions, were among children aged <1 year; however, most reported U.S. cases in infants had unknown hospitalization status.

FIGURE 2. COVID-19 cases among children* aged <18 years, among those with known hospitalization status (N = 745),[†] by age group and hospitalization status — United States, February 12–April 2, 2020

Abbreviation: ICU = intensive care unit.

* Includes infants, children, and adolescents.

[†] Number of children missing hospitalization status by age group: <1 year (303 of 398; 76%); 1–4 years (189 of 291; 65%); 5–9 years (275 of 388; 71%); 10–14 years (466 of 682; 68%); 15–17 years (594 of 813; 73%).

Summary

What is already known about this topic?

Data from China suggest that pediatric coronavirus disease 2019 (COVID-19) cases might be less severe than cases in adults and that children (persons aged <18 years) might experience different symptoms than adults.

What is added by this report?

In this preliminary description of pediatric U.S. COVID-19 cases, relatively few children with COVID-19 are hospitalized, and fewer children than adults experience fever, cough, or shortness of breath. Severe outcomes have been reported in children, including three deaths.

What are the implications for public health practice?

Pediatric COVID-19 patients might not have fever or cough. Social distancing and everyday preventive behaviors remain important for all age groups because patients with less serious illness and those without symptoms likely play an important role in disease transmission.

In this preliminary analysis of U.S. pediatric COVID-19 cases, a majority (57%) of patients were males. Several studies have reported a majority of COVID-19 cases among males (4,9), and an analysis of 44,000 COVID-19 cases in patients of all ages in China reported a higher case-fatality rate among men than among women (10). However, the same report, as well as a separate analysis of 2,143 pediatric COVID-19 cases from China, detected no substantial difference in the number of cases among males and females (5,10). Reasons for any potential difference in COVID-19 incidence or severity between males and females are unknown. In the present analysis, the predominance of males in all pediatric age groups, including patients aged <1 year, suggests that biologic factors might play a role in any differences in COVID-19 susceptibility by sex.

The findings in this report are subject to at least four limitations. First, because of the high workload associated with COVID-19 response activities on local, state, and territorial public health personnel, a majority of pediatric cases were missing data on disease symptoms, severity, or underlying conditions. Data for many variables are unlikely to be missing at random, and as such, these results must be interpreted with caution. Because of the high percentage of missing data, statistical comparisons could not be conducted. Second, because many cases occurred only days before publication of this report, the outcome for many patients is unknown, and this analysis might underestimate severity of disease or symptoms that manifested later in the course of illness. Third, COVID-19 testing practices differ across jurisdictions and might also differ across age groups. In many areas, prioritization of testing for severely

ill patients likely occurs, which would result in overestimation of the percentage of patients with COVID-19 infection who are hospitalized (including those treated in an ICU) among all age groups. Finally, this analysis compares clinical characteristics of pediatric cases (persons aged <18 years) with those of cases among adults aged 18–64 years. Severe COVID-19 disease appears to be more common among adults at the high end of this age range (6), and therefore cases in young adults might be more similar to those among children than suggested by the current analysis.

As the number of COVID-19 cases continues to increase in many parts of the United States, it will be important to adapt COVID-19 surveillance strategies to maintain collection of critical case information without overburdening jurisdiction health departments. National surveillance will increasingly be complemented by focused surveillance systems collecting comprehensive case information on a subset of cases across various health care settings. These systems will provide detailed information on the evolving COVID-19 incidence and risk factors for infection and severe disease. More systematic and detailed collection of underlying condition data among pediatric patients would be helpful to understand which children might be at highest risk for severe COVID-19 illness.

This preliminary examination of characteristics of COVID-19 disease among children in the United States suggests that children do not always have fever or cough as reported signs and symptoms. Although most cases reported among children to date have not been severe, clinicians should maintain a high index of suspicion for COVID-19 infection in children and monitor for progression of illness, particularly among infants and children with underlying conditions. However, these findings must be interpreted with caution because of the high percentage of cases missing data on important characteristics. Because persons with asymptomatic and mild disease, including children, are likely playing a role in transmission and spread of COVID-19 in the community, social distancing and everyday preventive behaviors are recommended for persons of all ages to slow the spread of the virus, protect the health care system from being overloaded, and protect older adults and persons of any age with serious underlying medical conditions. Recommendations for reducing the spread of COVID-19 by staying at home and practicing strategies such as respiratory hygiene, wearing cloth face coverings when around others, and others are available on CDC's coronavirus website at <https://www.cdc.gov/coronavirus/2019-ncov/prevent-getting-sick/prevention.html>.

CLINICAL UPDATE

Virology, transmission, and pathogenesis of SARS-CoV-2

Muge Cevik,^{1,2} Krutika Kuppalli,³ Jason Kindrachuk,⁴ Malik Peiris⁵

What you need to know

- SARS-CoV-2 is genetically similar to SARS-CoV-1, but characteristics of SARS-CoV-2—eg, structural differences in its surface proteins and viral load kinetics—may help explain its enhanced rate of transmission
- In the respiratory tract, peak SARS-CoV-2 load is observed at the time of symptom onset or in the first week of illness, with subsequent decline thereafter, indicating the highest infectiousness potential just before or within the first five days of symptom onset
- Reverse transcription polymerase chain reaction (RT-PCR) tests can detect viral SARS-CoV-2 RNA in the upper respiratory tract for a mean of 17 days; however, detection of viral RNA does not necessarily equate to infectiousness, and viral culture from PCR positive upper respiratory tract samples has been rarely positive beyond nine days of illness
- Symptomatic and pre-symptomatic transmission (1–2 days before symptom onset), is likely to play a greater role in the spread of SARS-CoV-2 than asymptomatic transmission
- A wide range of virus-neutralising antibodies have been reported, and emerging evidence suggests that these may correlate with severity of illness but wane over time

Since the emergence of SARS-CoV-2 in December 2019, there has been an unparalleled global effort to characterise the virus and the clinical course of disease. Coronavirus disease 2019 (covid-19), caused by SARS-CoV-2, follows a biphasic pattern of illness that likely results from the combination of an early

viral response phase and an inflammatory second phase. Most clinical presentations are mild, and the typical pattern of covid-19 more resembles an influenza-like illness—which includes fever, cough, malaise, myalgia, headache, and taste and smell disturbance—rather than severe pneumonia (although emerging evidence about long term consequences is yet to be understood in detail).¹ In this review, we provide a broad update on the emerging understanding of SARS-CoV-2 pathophysiology, including virology, transmission dynamics, and the immune response to the virus. Any of the mechanisms and assumptions discussed in the article and in our understanding of covid-19 may be revised as further evidence emerges.

What we know about the virus

SARS-CoV-2 is an enveloped β -coronavirus, with a genetic sequence very similar to SARS-CoV-1 (80%) and bat coronavirus RaTG13 (96.2%).² The viral envelope is coated by spike (S) glycoprotein, envelope (E), and membrane (M) proteins (fig 1). Host cell binding and entry are mediated by the S protein. The first step in infection is virus binding to a host cell through its target receptor. The S1 sub-unit of the S protein contains the receptor binding domain that binds to the peptidase domain of angiotensin-converting enzyme 2 (ACE 2). In SARS-CoV-2 the S2 sub-unit is highly preserved and is considered a potential antiviral target. The virus structure and replication cycle are described in figure 1.

Published: 23 October 2020

Fig 1 | (1) The virus binds to ACE 2 as the host target cell receptor in synergy with the host's transmembrane serine protease 2 (cell surface protein), which is principally expressed in the airway epithelial cells and vascular endothelial cells. This leads to membrane fusion and releases the viral genome into the host cytoplasm (2). Stages (3-7) show the remaining steps of viral replication, leading to viral assembly, maturation, and virus release

Coronaviruses have the capacity for proofreading during replication, and therefore mutation rates are lower than in other RNA viruses. As SARS-CoV-2 has spread globally it has, like other viruses, accumulated some mutations in the viral genome, which contains geographic signatures. Researchers have examined these mutations to study virus characterisation and understand epidemiology and transmission patterns. In general, the mutations have not been attributed to phenotypic changes affecting viral transmissibility or pathogenicity. The G614 variant in the S protein has been postulated to increase infectivity and transmissibility of the virus.³ Higher viral loads were reported in clinical samples with virus containing G614 than previously circulating variant D614, although no association was made with severity of illness as measured by hospitalisation outcomes.³ These findings have yet to be confirmed with regards to natural infection.

Why is SARS-CoV-2 more infectious than SARS-CoV-1?

SARS-CoV-2 has a higher reproductive number (R_0) than SARS-CoV-1, indicating much more efficient spread.¹ Several characteristics of SARS-CoV-2 may help explain this enhanced

transmission. While both SARS-CoV-1 and SARS-CoV-2 preferentially interact with the angiotensin-converting enzyme 2 (ACE 2) receptor, SARS-CoV-2 has structural differences in its surface proteins that enable stronger binding to the ACE 2 receptor⁴ and greater efficiency at invading host cells.¹ SARS-CoV-2 also has greater affinity (or bonding) for the upper respiratory tract and conjunctiva,⁵ thus can infect the upper respiratory tract and can conduct airways more easily.⁶

Viral load dynamics and duration of infectiousness

Viral load kinetics could also explain some of the differences between SARS-CoV-2 and SARS-CoV-1. In the respiratory tract, peak SARS-CoV-2 load is observed at the time of symptom onset or in the first week of illness, with subsequent decline thereafter, which indicates the highest infectiousness potential just before or within the first five days of symptom onset (fig 2).⁷ In contrast, in SARS-CoV-1 the highest viral loads were detected in the upper respiratory tract in the second week of illness, which explains its minimal contagiousness in the first week after symptom onset, enabling early case detection in the community.⁷

Fig 2 | After the initial exposure, patients typically develop symptoms within 5-6 days (incubation period). SARS-CoV-2 generates a diverse range of clinical manifestations, ranging from mild infection to severe disease accompanied by high mortality. In patients with mild infection, initial host immune response is capable of controlling the infection. In severe disease, excessive immune response leads to organ damage, intensive care admission, or death. The viral load peaks in the first week of infection, declines thereafter gradually, while the antibody response gradually increases and is often detectable by day 14 (figure adapted with permission from <https://www.sciencedirect.com/science/article/pii/S009286742030475X>; [https://www.thelancet.com/journals/lanres/article/PIIS2213-2600\(20\)30230-7/fulltext](https://www.thelancet.com/journals/lanres/article/PIIS2213-2600(20)30230-7/fulltext))

Quantitative reverse transcription polymerase chain reaction (qRT-PCR) technology can detect viral SARS-CoV-2 RNA in the upper respiratory tract for a mean of 17 days (maximum 83 days) after symptom onset.⁷ However, detection of viral RNA by qRT-PCR does not necessarily equate to infectiousness, and viral culture from PCR positive upper respiratory tract samples has been rarely positive beyond nine days of illness.⁵ This corresponds to what is known about transmission based on contact tracing studies, which is that transmission capacity is maximal in the first week of illness, and that transmission after this period has not been documented.⁸ Severely ill or immune-compromised patients may have relatively prolonged virus shedding, and some patients may have intermittent RNA shedding; however, low level results close to the detection limit may not constitute infectious viral particles. While asymptomatic individuals (those with no symptoms throughout the infection) can transmit the infection, their relative degree of infectiousness seems to be limited.⁹⁻¹¹ People with mild symptoms (paucisymptomatic) and those whose symptom have not yet appeared still carry large amounts of virus in the upper respiratory tract, which might contribute to the easy and rapid spread of SARS-CoV-2.⁷ Symptomatic and pre-symptomatic transmission (one to two days before symptom onset) is likely to play a greater role in the spread of SARS-CoV-2.^{10,12} A combination of preventive measures, such as physical distancing and testing, tracing, and self-isolation, continue to be needed.

Route of transmission and transmission dynamics

Like other coronaviruses, the primary mechanism of transmission of SARS-CoV-2 is via infected respiratory droplets, with viral

infection occurring by direct or indirect contact with nasal, conjunctival, or oral mucosa, when respiratory particles are inhaled or deposited on these mucous membranes.⁶ Target host receptors are found mainly in the human respiratory tract epithelium, including the oropharynx and upper airway. The conjunctiva and gastrointestinal tracts are also susceptible to infection and may serve as transmission portals.⁶

Transmission risk depends on factors such as contact pattern, environment, infectiousness of the host, and socioeconomic factors, as described elsewhere.¹² Most transmission occurs through close range contact (such as 15 minutes face to face and within 2 m),¹³ and spread is especially efficient within households and through gatherings of family and friends.¹² Household secondary attack rates (the proportion of susceptible individuals who become infected within a group of susceptible contacts with a primary case) ranges from 4% to 35%.¹² Sleeping in the same room as, or being a spouse of an infected individual increases the risk of infection, but isolation of the infected person away from the family is related to lower risk of infection.¹² Other activities identified as high risk include dining in close proximity with the infected person, sharing food, and taking part in group activities.¹² The risk of infection substantially increases in enclosed environments compared with outdoor settings.¹² For example, a systematic review of transmission clusters found that most superspreading events occurred indoors.¹¹ Aerosol transmission can still factor during prolonged stay in crowded, poorly ventilated indoor settings (meaning transmission could occur at a distance > 2 m).^{12,14-17}

The role of faecal shedding in SARS-CoV-2 transmission and the extent of fomite (through inanimate surfaces) transmission also remain to be fully understood. Both SARS-CoV-2 and SARS-CoV-1 remain viable for many days on smooth surfaces (stainless steel, plastic, glass) and at lower temperature and humidity (eg, air conditioned environments).^{18 19} Thus, transferring infection from contaminated surfaces to the mucosa of eyes, nose, and mouth via unwashed hands is a possible route of transmission. This route of transmission may contribute especially in facilities with communal areas, with increased likelihood of environmental contamination. However, both SARS-CoV-1 and SARS-CoV-2 are readily inactivated by commonly used disinfectants, emphasising the potential value of surface cleaning and handwashing. SARS-CoV-2 RNA has been found in stool samples and RNA shedding often persists for longer than in respiratory samples⁷; however, virus isolation has rarely been successful from the stool.^{5 7} No published reports describe faecal-oral transmission. In SARS-CoV-1, faecal-oral transmission was not considered to occur in most circumstances; but, one explosive outbreak was attributed to aerosolisation and spread of the virus across an apartment block via a faulty sewage system.²⁰ It remains to be seen if similar transmission may occur with SARS-CoV-2.

Pathogenesis

Viral entry and interaction with target cells

SARS-CoV-2 binds to ACE 2, the host target cell receptor.¹ Active replication and release of the virus in the lung cells lead to non-specific symptoms such as fever, myalgia, headache, and respiratory symptoms.¹ In an experimental hamster model, the virus causes transient damage to the cells in the olfactory epithelium, leading to olfactory dysfunction, which may explain temporary loss of taste and smell commonly seen in covid-19.²¹ The distribution of ACE 2 receptors in different tissues may explain the sites of infection and patient symptoms. For example, the ACE 2 receptor is found on the epithelium of other organs such as the intestine and endothelial cells in the kidney and blood vessels, which may explain gastrointestinal symptoms and cardiovascular complications.²² Lymphocytic endotheliitis has been observed in postmortem pathology examination of the lung, heart, kidney, and liver as well as liver cell necrosis and myocardial infarction in patients who died of covid-19.^{1 23} These findings indicate that the virus directly affects many organs, as was seen in SARS-CoV-1 and influenzae.

Much remains unknown. Are the pathological changes in the respiratory tract or endothelial dysfunction the result of direct viral infection, cytokine dysregulation, coagulopathy, or are they multifactorial? And does direct viral invasion or coagulopathy directly contribute to some of the ischaemic complications such as ischaemic infarcts? These and more, will require further work to elucidate.

Immune response and disease spectrum (figure 2)

After viral entry, the initial inflammatory response attracts virus-specific T cells to the site of infection, where the infected cells are eliminated before the virus spreads, leading to recovery in most people.²⁴ In patients who develop severe disease, SARS-CoV-2 elicits an aberrant host immune response.^{24 25} For example, postmortem histology of lung tissues of patients who died of covid-19 have confirmed the inflammatory nature of the injury, with features of bilateral diffuse alveolar damage, hyaline-membrane formation, interstitial mononuclear inflammatory infiltrates, and desquamation consistent with acute respiratory distress syndrome (ARDS), and is similar to the lung pathology seen in severe Middle East respiratory

syndrome (MERS) and severe acute respiratory syndrome (SARS).^{26 27} A distinctive feature of covid-19 is the presence of mucus plugs with fibrinous exudate in the respiratory tract, which may explain the severity of covid-19 even in young adults.²⁸ This is potentially caused by the overproduction of pro-inflammatory cytokines that accumulate in the lungs, eventually damaging the lung parenchyma.²⁴

Some patients also experience septic shock and multi-organ dysfunction.²⁴ For example, the cardiovascular system is often involved early in covid-19 disease and is reflected in the release of highly sensitive troponin and natriuretic peptides.²⁹ Consistent with the clinical context of coagulopathy, focal intra-alveolar haemorrhage and presence of platelet-fibrin thrombi in small arterial vessels is also seen.²⁷ Cytokines normally mediate and regulate immunity, inflammation, and haematopoiesis; however, further exacerbation of immune reaction and accumulation of cytokines in other organs in some patients may cause extensive tissue damage, or a cytokine release syndrome (cytokine storm), resulting in capillary leak, thrombus formation, and organ dysfunction.^{24 30}

Mechanisms underlying the diverse clinical outcomes

Clinical outcomes are influenced by host factors such as older age, male sex, and underlying medical conditions,¹ as well as factors related to the virus (such as viral load kinetics), host-immune response, and potential cross-reactive immune memory from previous exposure to seasonal coronaviruses (box 1).

Box 1: Risk factors associated with the development of severe disease, admission to intensive care unit, and mortality

Underlying condition

- Older age
- Hypertension
- Cardiovascular disease
- Chronic obstructive pulmonary disease
- Diabetes
- Obesity
- Malignancy

Presentation

- Higher fever ($\geq 39^{\circ}\text{C}$ on admission)
- Dyspnoea on admission
- Higher qSOFA score

Laboratory markers

- Neutrophilia/lymphopenia
- Raised lactate and lactate dehydrogenase
- Raised C reactive protein
- Raised ferritin
- Raised IL-6
- Raised ACE2
- D-dimer $>1 \mu\text{g/mL}$

Sex-related differences in immune response have been reported, revealing that men had higher plasma innate immune cytokines and chemokines at baseline than women.³¹ In contrast, women had notably more robust T cell activation than men, and among male participants T cell activation declined with age, which was sustained among female patients. These findings suggest that adaptive immune response may be important in defining the clinical outcome

as older age and male sex is associated with increased risk of severe disease and mortality.

Increased levels of pro-inflammatory cytokines correlate with severe pneumonia and increased ground glass opacities within the lungs.^{30 32} In people with severe illness, increased plasma concentrations of inflammatory cytokines and biomarkers were observed compared with people with non-severe illness.^{30 33 34}

Emerging evidence suggests a correlation between viral dynamics, the severity of illness, and disease outcome.⁷ Longitudinal characteristics of immune response show a correlation between the severity of illness, viral load, and IFN- α , IFN- γ , and TNF- α

response.³⁴ In the same study many interferons, cytokines, and chemokines were elevated early in disease for patients who had severe disease and higher viral loads. This emphasises that viral load may drive these cytokines and the possible pathological roles associated with the host defence factors. This is in keeping with the pathogenesis of influenza, SARS, and MERS whereby prolonged viral shedding was also associated with severity of illness.^{7 35}

Given the substantial role of the immune response in determining clinical outcomes, several immunosuppressive therapies aimed at limiting immune-mediated damage are currently in various phases of development (table 1).

Table 1 | Therapeutics currently under investigation

Entry to the cell	Viral replication	Host immune response
ACE receptor inhibitors	RNA polymerase inhibitors	Immunomodulators
Angiotensin II receptor blockers	Remdesivir	Tocilizumab
Fusion inhibitors	Ribavirin	Sarilumab
Uminefovir	Favipiravir	Adalimumab (TNF inhibitor)
Baricitinib	Protease inhibitors	IFN
Monoclonal antibodies	Lopinavir	Corticosteroids
	Darunavir	

Immune response to the virus and its role in protection

Covid-19 leads to an antibody response to a range of viral proteins, but the spike (S) protein and nucleocapsid are those most often used in serological diagnosis. Few antibodies are detectable in the first four days of illness, but patients progressively develop them, with most achieving a detectable response after four weeks.³⁶ A wide range of virus-neutralising antibodies have been reported, and emerging evidence suggests that these may correlate with severity but wane over time.³⁷ The duration and protectivity of antibody and T cell responses remain to be defined through studies with longer follow-up. CD-4 T cell responses to endemic human coronaviruses appear to manifest cross-reactivity with SARS-CoV-2, but their role in protection remains unclear.³⁸

Unanswered questions

Further understanding of the pathogenesis for SARS-CoV-2 will be vital in developing therapeutics, vaccines, and supportive care modalities in the treatment of covid-19. More data are needed to understand the determinants of healthy versus dysfunctional response and immune markers for protection and the severity of disease. Neutralising antibodies are potential correlates of protection, but other protective antibody mechanisms may exist. Similarly, the protective role of T cell immunity and duration of both antibody and T cell responses and the correlates of protection need to be defined. In addition, we need optimal testing systems and technologies to support and inform early detection and clinical management of infection. Greater understanding is needed regarding the long term consequences following acute illness and multisystem inflammatory disease, especially in children.

Education into practice

How would you describe SARS-CoV-2 transmission routes and ways to prevent infection?

How would you describe to a patient why cough, anosmia, and fever occur in covid-19?

Questions for future research

- What is the role of the cytokine storm and how could it inform the development of therapeutics, vaccines, and supportive care modalities?
- What is the window period when patients are most infectious?
- Why do some patients develop severe disease while others, especially children, remain mildly symptomatic or do not develop symptoms?
- What are the determinants of healthy versus dysfunctional response, and the biomarkers to define immune correlates of protection and disease severity for the effective triage of patients?
- What is the protective role of T cell immunity and duration of both antibody and T cell responses, and how would you define the correlates of protection?

How patients were involved in the creation of this article

No patients were directly involved in the creation of this article.

How this article was created

We searched PubMed from 2000 to 18 September 2020, limited to publications in English. Our search strategy used a combination of key words including "COVID-19," "SARS-CoV-2," "SARS," "MERS," "Coronavirus," "Novel Coronavirus," "Pathogenesis," "Transmission," "Cytokine Release," "immune response," "antibody response." These sources were supplemented with systematic reviews. We also reviewed technical documents produced by the Centers for Disease Control and Prevention and World Health Organization technical documents.

Author contributions: MC, KK, JK, MP drafted the first and subsequent versions of the manuscript and all authors provided critical feedback and contributed to the manuscript.

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

SARS-CoV-2, SARS-CoV, and MERS-CoV viral load dynamics, duration of viral shedding, and infectiousness: a systematic review and meta-analysis

Muge Cevik, Matthew Tate, Ollie Lloyd, Alberto Enrico Maraolo, Jenna Schafers, Antonia Ho

Summary

Background Viral load kinetics and duration of viral shedding are important determinants for disease transmission. We aimed to characterise viral load dynamics, duration of viral RNA shedding, and viable virus shedding of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) in various body fluids, and to compare SARS-CoV-2, SARS-CoV, and Middle East respiratory syndrome coronavirus (MERS-CoV) viral dynamics.

Methods In this systematic review and meta-analysis, we searched databases, including MEDLINE, Embase, Europe PubMed Central, *medRxiv*, and *bioRxiv*, and the grey literature, for research articles published between Jan 1, 2003, and June 6, 2020. We included case series (with five or more participants), cohort studies, and randomised controlled trials that reported SARS-CoV-2, SARS-CoV, or MERS-CoV infection, and reported viral load kinetics, duration of viral shedding, or viable virus. Two authors independently extracted data from published studies, or contacted authors to request data, and assessed study quality and risk of bias using the Joanna Briggs Institute Critical Appraisal Checklist tools. We calculated the mean duration of viral shedding and 95% CIs for every study included and applied the random-effects model to estimate a pooled effect size. We used a weighted meta-regression with an unrestricted maximum likelihood model to assess the effect of potential moderators on the pooled effect size. This study is registered with PROSPERO, CRD42020181914.

Findings 79 studies (5340 individuals) on SARS-CoV-2, eight studies (1858 individuals) on SARS-CoV, and 11 studies (799 individuals) on MERS-CoV were included. Mean duration of SARS-CoV-2 RNA shedding was 17·0 days (95% CI 15·5–18·6; 43 studies, 3229 individuals) in upper respiratory tract, 14·6 days (9·3–20·0; seven studies, 260 individuals) in lower respiratory tract, 17·2 days (14·4–20·1; 13 studies, 586 individuals) in stool, and 16·6 days (3·6–29·7; two studies, 108 individuals) in serum samples. Maximum shedding duration was 83 days in the upper respiratory tract, 59 days in the lower respiratory tract, 126 days in stools, and 60 days in serum. Pooled mean SARS-CoV-2 shedding duration was positively associated with age (slope 0·304 [95% CI 0·115–0·493]; $p=0·0016$). No study detected live virus beyond day 9 of illness, despite persistently high viral loads, which were inferred from cycle threshold values. SARS-CoV-2 viral load in the upper respiratory tract appeared to peak in the first week of illness, whereas that of SARS-CoV peaked at days 10–14 and that of MERS-CoV peaked at days 7–10.

Interpretation Although SARS-CoV-2 RNA shedding in respiratory and stool samples can be prolonged, duration of viable virus is relatively short-lived. SARS-CoV-2 titres in the upper respiratory tract peak in the first week of illness. Early case finding and isolation, and public education on the spectrum of illness and period of infectiousness are key to the effective containment of SARS-CoV-2.

Introduction

Viral load kinetics and the duration of viral shedding are important determinants for disease transmission. They determine the duration of infectiousness, which is a critical parameter to inform effective control measures and disease modelling. Although several studies have evaluated severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) shedding, viral load dynamics and duration of viral shedding reported across studies so far have been heterogeneous.¹ In several case series with serial respiratory sampling, peak viral load was observed just

before, or at the time of, symptom onset.^{2–4} Viral RNA shedding was reported to be persistent in the upper respiratory tract and in faeces for more than 1 month after illness onset.¹ However, the duration of SARS-CoV-2 RNA detection has not been well characterised. A comprehensive understanding of viral load dynamics, length of viral shedding, and how these measures relate to other factors, such as age and disease severity, is lacking.

We aimed to characterise the viral load dynamics of SARS-CoV-2, duration of viral RNA shedding by RT-PCR, and viable virus shedding in various body fluids,

Research in context

Evidence before this study

Understanding when patients are most infectious and the duration of infectiousness are of critical importance to controlling the COVID-19 pandemic. The duration of RNA detection across human coronaviruses has not been well characterised, and comprehensive understanding about viral load dynamics and the duration of viral shedding in severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is lacking. We retrieved all articles reporting the dynamics and the duration of SARS-CoV-2, SARS-CoV, and Middle East respiratory syndrome coronavirus (MERS-CoV) shedding in various specimens through systematic searches of major databases. Our research identified publications that included terms related to viral dynamics and viral shedding. We included case series, cohort studies, and randomised controlled trials in which the viral dynamics or the duration of viral shedding was reported. We excluded case reports, case series with fewer than five patients, and studies that did not have a clear time of symptom onset.

Added value of this study

To our knowledge, this is the first systematic review and meta-analysis that has examined and compared the viral dynamics of the three highly pathogenic human coronaviruses: SARS-CoV-2, SARS-CoV, and MERS-CoV. The results provide a comprehensive understanding regarding their viral kinetics and duration of shedding. Mean SARS-CoV-2 RNA shedding duration was 17.0 days (maximum shedding duration 83 days) in upper respiratory tract, 14.6 days (maximum 59 days) in lower respiratory tract, 17.2 days (maximum 35 days) in stool, and 16.6 days (maximum 60 days) in serum samples. Pooled mean SARS-CoV-2 shedding duration was positively associated with

age. No study detected live virus beyond day 9 of illness, despite persistently high viral loads. SARS-CoV-2 viral load in the upper respiratory tract appeared to peak in the first week of illness, whereas SARS-CoV and MERS-CoV peaked later. Several studies reported similar viral loads at the start of infection among asymptomatic and symptomatic patients infected with SARS-CoV-2; however, most studies demonstrated faster viral clearance in asymptomatic individuals, as also seen in MERS-CoV, suggesting a shorter infectious period but with similar potential transmissibility at the onset of infection.

Implications of all the available evidence

Our study shows that despite evidence of prolonged SARS-CoV-2 RNA shedding in respiratory and stool samples, viable virus appears to be short-lived. Therefore, RNA detection cannot be used to infer infectiousness. High titres of SARS-CoV-2 are detected early in the disease course, with an early peak observed at the time of symptom onset to day 5 of illness; this finding probably explains the efficient spread of SARS-CoV-2 compared with SARS-CoV and MERS-CoV. This has important implications for SARS-CoV-2 transmission in the community and hospital setting, emphasising the importance of early case finding and prompt isolation as well as public education about the spectrum of illness. Our study shows that isolation practices should be commenced with the start of first symptoms, which can include mild and atypical symptoms, preceding typical symptoms of COVID-19 such as cough and fever. However, given the potential delays in isolation of patients, even the early detection and isolation strategy might not be fully effective in containing SARS-CoV-2.

and to compare SARS-CoV-2 viral dynamics with those of SARS-CoV and Middle East respiratory syndrome coronavirus (MERS-CoV).

Methods

Search strategy and selection criteria

We retrieved all English-language research articles reporting viral dynamics or the duration of shedding of SARS-CoV-2, SARS-CoV, or MERS-CoV in various specimens through systematic searches of major databases, including MEDLINE, Embase, Europe PubMed Central, *medRxiv*, and *bioRxiv*, and the grey literature from Jan 1, 2003, to June 6, 2020, using medical subject headings terms (appendix p 14). We also manually screened the references of included original studies to obtain additional studies. Studies published before 2003 were excluded because the first recognised case of SARS-CoV was identified in March, 2003.

Studies were eligible if they met the following inclusion criteria: report on SARS-CoV-2, SARS-CoV, or MERS-CoV

infection, and report viral load kinetics, duration of viral shedding, or viable virus shedding. We excluded review papers; animal studies; studies on environmental sampling; case reports and case series with less than five participants, due to likely reporting bias; papers in which the starting point of viral shedding was not clear or reported from post hospital discharge; and modelling studies with no original data.

Data extraction

Two authors (MT and OL) screened and retrieved articles according to the eligibility criteria. Four reviewers (MT, OL, JS, and MC) reviewed full-text articles and selected articles to be included. From each study, the following variables were extracted as a minimum: name of first author, year of publication, city and country, sample size, median age, sex ratio, time from symptom onset to viral clearance detected by RT-PCR and culture in different specimens, and longest reported time to viral clearance. If these data were not reported, we also contacted the

See Online for appendix

authors to request the data. If available, we extracted data on peak viral load, clinical outcome, and reported factors associated with duration of viral shedding.

Two authors (OL and JS) independently assessed study quality and risk of bias using the Joanna Briggs Institute Critical Appraisal Checklist tools,⁵ which comprise standardised checklists, for the different study designs included in this review. Any disagreements regarding grading of quality were resolved through discussion with a third author (MC).

Data analysis

For every study included, we calculated the mean duration of viral shedding and 95% CIs. We applied the random-effects model to estimate a pooled effect size. We generated forest plots to show the detailed representation of all studies based on the effect size and 95% CI. If not reported, we derived means and SDs from sample size, and median, IQR, minimum, and maximum values.⁶ Heterogeneity between studies was quantified by the *I*² index and Cochran's *Q* test. We did not assess publication bias because usual appraisal methods are uninformative when meta-analysed studies do not include a test of significance. We used a weighted meta-regression with an unrestricted maximum likelihood model to assess the effect of potential moderators on the pooled effect size ($p < 0.05$ was considered to be significant). The eligibility criterion for meta-regression was the presence of at least ten studies (referring to one virus) for each covariate. All statistical analyses were done with Comprehensive Meta-Analysis (version 3) software (Biostat, Englewood, NJ, USA).

This systematic review is registered with PROSPERO, CRD42020181914, and will be updated periodically.

Role of the funding source

There was no funding source for this study. The corresponding author and senior author (AH) had full access to all the data in the study and had final responsibility for the decision to submit for publication.

Results

The systematic search identified 1486 potentially relevant articles. 350 articles were retrieved for full-text review. After reviewing the eligibility criteria, 79 studies (5340 individuals) on SARS-CoV-2,^{2,4,7–82} eight (1858 individuals) on SARS-CoV,^{83–90} and 11 (799 individuals) on MERS-CoV^{91–101} were included (figure 1).

Of the 79 papers included, 58 studies were done in China (appendix pp 1–4).^{2,10–12,14–17,19–21,23–28,35–41,43,44,48–50,52–63,65–73,75–82} 73 studies included only patients who were admitted to hospital.^{3,4,7–29,31,32,34–49,52–54,56–82} Six studies reported viral load dynamics exclusively in children (age younger than 16 years).^{7–12} Two additional studies included children, but data on viral load dynamics were presented in aggregate with adults.^{13,14}

61 studies reported median or maximum viral RNA shedding in at least one body fluid and were eligible

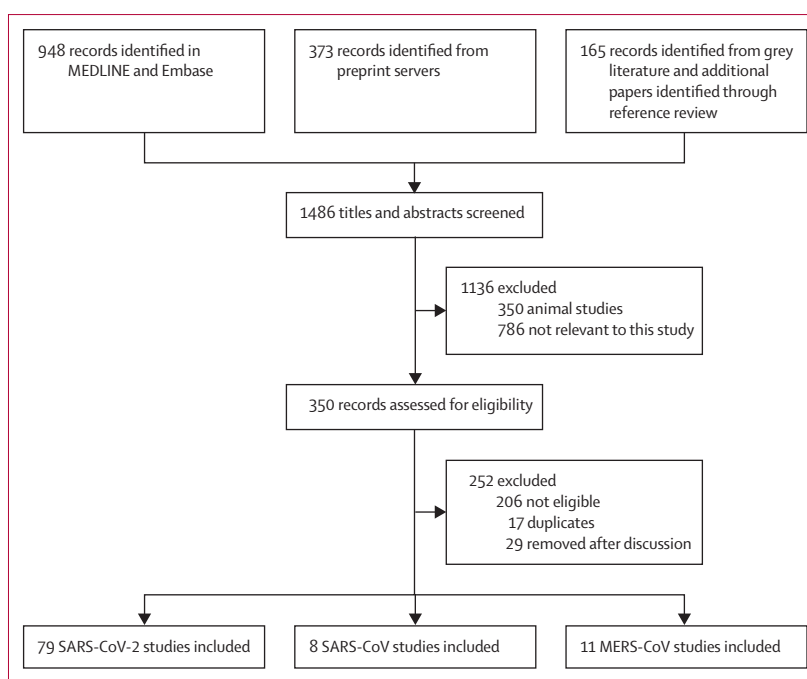

Figure 1: Study selection

MERS-CoV=Middle East respiratory syndrome coronavirus. SARS-CoV=severe acute respiratory syndrome coronavirus. SARS-CoV-2=severe acute respiratory syndrome coronavirus 2.

for quantitative analysis,^{3,4,7,9–12,14–17,19–22,24,25,27–30,34–43,45,47,48,50,51,53,54,57–65,}

^{67–76,78–80,82} and six studies provided duration of shedding stratified by illness severity only.^{13,39,52,55,77,81} Of those studies, 43 (including 3229 individuals) reported duration of shedding in the upper respiratory tract (mean viral shedding duration 17.0 days [95% CI 15.5–18.6]; figure 2), seven (260 individuals) in the lower respiratory tract (14.6 days [9.3–20.0]; appendix p 6), 13 (586 individuals) in stool samples (17.2 days [14.4–20.1]; appendix p 7), and two (108 individuals) in serum samples (16.6 days [3.6–29.7]; appendix p 6). Maximum duration of RNA shedding reported was 83 days in the upper respiratory tract,³⁵ 59 days in the lower respiratory tract,²⁷ 126 days in stool samples,⁸⁸ and 60 days in serum samples.⁷⁸

Studies reporting duration of viral shedding in upper respiratory tract and stool samples were eligible for meta-regression analysis. Pooled mean viral shedding duration was positively associated with age (slope 0.304 [95% CI 0.115–0.493]; $p=0.0016$), but not sex ($p=0.28$; appendix pp 7–8). When adjusted for the proportion of males in a multivariable analysis, mean age was positively associated with the mean duration of viral shedding in upper respiratory tract specimens ($p=0.0029$). There was a positive but non-significant association between mean age and duration of shedding in stool samples ($p=0.37$; appendix p 8).

Eight of 13 studies evaluating SARS-CoV-2 viral load in serial upper respiratory tract samples showed peak viral loads inferred from cycle threshold values within the first week of symptom onset.^{2–4,8,15–23} The highest viral loads were

Figure 2: Pooled mean duration (days) of SARS-CoV-2 shedding from the upper respiratory tract (random-effects model)
SARS-CoV-2=severe acute respiratory syndrome coronavirus 2.

reported soon after or at the time of symptom onset,^{2,8,15,21,23} or at day 3–5 of illness,^{3,4,20} followed by a consistent decline.

Five studies that evaluated viral load dynamics in lower respiratory tract samples observed a peak viral load in the second week of illness.^{3,4,17,21,23} By contrast, the dynamics of SARS-CoV-2 shedding in stool samples was erratic, with highest viral loads reported on day 7,¹⁷ 2–3 weeks,^{22,23} and up

to 5–6 weeks after symptom onset.²¹ Although two studies reported significantly higher viral titres in stool samples than in respiratory samples,^{8,23} one study reported lower viral load in stool samples than in both lower and upper respiratory tract samples at the time of symptom onset.²¹

20 studies evaluated duration of viral RNA shedding based on disease severity. 13 of these studies reported

longer duration of viral shedding in patients with severe illness than in those with non-severe illness,^{17,23–34} whereas five studies in upper respiratory tract samples^{16,18,35–37} and one study in stool samples³⁸ reported similar shedding durations according to disease severity. One study reported shorter duration of viral shedding in moderate to severe illness than in mild to moderate illness.³⁹ Six studies compared viral shedding among individuals with severe illness versus non-severe illness:^{17,23,25,26,36,37} five studies showed significantly longer duration of shedding among those with severe illness than among those with non-severe illness,^{17,23,25,26,36} and one study observed no difference³⁷ (table 1).

All but one study⁴⁰ that examined the effect of age on SARS-CoV-2 shedding identified an association between older age (older than 60 years) and prolonged viral RNA shedding.^{23,24,26,31,35–37,41–43} Three studies identified age as an independent risk factor for delayed viral clearance.^{23,24,36} Male sex was also associated with prolonged shedding,^{23,36,44} and the association remained significant even when patients were stratified based on illness severity.^{23,36} Corticosteroid treatment was associated with delayed viral clearance in four studies,^{31,36,45,46} and one study that recruited 120 patients with critical illness found no difference between corticosteroid and control groups.⁴⁷

A randomised, placebo-controlled trial of remdesivir in adults with severe COVID-19 found a similar decline in viral load over time in remdesivir and control groups, as well as similar proportions of patients with undetectable viral RNA at 28 days.¹⁰² In a phase 2, open-label study evaluating interferon beta-1b, lopinavir–ritonavir, and ribavirin, a shorter duration of viral shedding was seen with combination treatment than with the control.⁴⁸ None of the antiviral regimens (chloroquine, oseltamivir, arbidol, and lopinavir–ritonavir) independently improved viral RNA clearance.^{26,49} In a retrospective study of 284 patients, lopinavir–ritonavir use was associated with delayed viral clearance even after adjusting for confounders.²⁶

12 studies reported viral load dynamics or duration of viral shedding among individuals with asymptomatic SARS-CoV-2 infection (table 2); two demonstrated lower viral loads among asymptomatic individuals than among symptomatic individuals,^{8,50} and four found similar initial viral loads.^{13,14,51,52} However, Chau and colleagues reported significantly lower viral load in asymptomatic individuals during the follow-up than in symptomatic individuals.⁵¹ Faster viral clearance was observed in asymptomatic individuals in five of six studies.^{13,26,51,53,54} The exception, Yongchen and colleagues, found longer shedding duration among asymptomatic cases, but the difference was not significant.³⁴

We identified 11 studies that attempted to isolate live virus. All eight studies that attempted virus isolation in respiratory samples successfully cultured viable virus within the first week of illness.^{3,9,16,52,55–58} No live virus was

Table 1: Severity of illness and viral dynamics

isolated from any respiratory samples taken after day 8 of symptoms in three studies,^{3,55,56} or beyond day 9 in two studies^{16,52} despite persistently high viral RNA loads. One study demonstrated the highest probability of positive culture on day 3 of symptoms.⁵⁵ Arons and colleagues cultured viable virus 6 days before typical symptom onset; however, onset of symptoms was unclear.⁵²

The success of viral isolation correlated with viral load quantified by RT-PCR. No successful viral culture was obtained from samples with a viral load below 1×10^6 copies per mL in one study,³ cycle threshold values higher than 24 in another study,⁵⁵ or higher than 34 in other studies,^{52,56} with culture positivity declining with increasing cycle threshold values.⁵⁶ Several other studies cultured live virus from RT-PCR-positive specimens; however, they did not correlate these results with viral load titres.^{9,57,58}

One study reported the duration of viable virus shedding in respiratory samples; time to clearance from symptom onset was 3–12 days in upper respiratory tract samples and 5–13 days in lower respiratory tract samples, and no positive viral culture was obtained after day 4 in upper respiratory tract infection and day 8 in lower respiratory tract infection.³ Arons and colleagues cultured viable virus from the respiratory tract in one of three asymptomatic cases.⁵²

Viral culture was successful in two of three RT-PCR-positive patients in one study, but the timepoints

SARS-CoV-2=severe acute respiratory syndrome coronavirus 2. *IQR, if available, unless otherwise stated.

Table 2: SARS-CoV-2 viral dynamics in asymptomatic individuals compared with symptomatic individuals

from symptom onset were not reported.⁵⁹ Andersson and colleagues were unable to culture virus from 27 RT-PCR-positive serum samples.⁶⁰

Of eight studies on SARS-CoV, none reported mean or median duration of viral shedding and thus were not eligible for quantitative analysis. The maximum duration of viral shedding reported was 8 weeks in upper respiratory tract,^{83,84} 52 days in lower respiratory tract,^{83,85} 6–7 weeks in serum,⁸⁶ and 126 days in stool samples.^{83,85,87–89} Studies that evaluated SARS-CoV kinetics found low viral load in the initial days of illness, increasing after the

first week of illness in upper respiratory tract samples, peaking at day 10,⁹⁰ or days 12–14,⁸⁷ and declining after weeks 3–4.⁸⁴ High viral loads correlated with severity of illness and poor survival.⁸⁴ Although Chen and colleagues identified an association between younger age and lower viral titres,⁸⁴ Leong and colleagues found no difference.⁸⁹ Viable SARS-CoV was isolated from stool and respiratory samples up to 4 weeks, and urine specimens up to day 36 from symptom onset.^{83,86} All attempts to isolate virus from RT-PCR-positive stool specimens collected more than 6 weeks after disease onset failed.⁸⁵ The isolation probability for stool samples was approximately five to ten times lower than for respiratory specimens.⁸³

We identified 11 studies on MERS-CoV. Three studies (324 participants) reporting MERS-CoV shedding in the upper respiratory tract^{99–101} and four studies (93 participants) reporting MERS-CoV shedding in the lower respiratory tract^{91,92,96,101} were included in the quantitative analysis. The mean shedding duration was 15.3 days (95% CI 11.6–19.0) in the upper respiratory tract and 16.3 days (13.8–18.9) in the lower respiratory tract (figures 3, 4). Only one study reported duration of viral shedding in serum with a maximum of 34 days.⁹¹ In a small study, mortality was higher in patients with viraemia (viral RNA in blood).⁹² In upper and lower respiratory tract specimens, prolonged shedding was associated with illness severity^{93,94} and survival,⁹⁵ with the shortest duration observed in asymptomatic individuals.⁹³ Peak viral loads were observed between days 7 and 10, and higher viral loads were observed among patients with severe illness and fatal outcome.^{91,93,94,96,97} Differences in viral loads between survivors and fatal cases was more pronounced in the second week of illness (p=0.0006).⁹⁷ The proportion of successful viable culture was 6% in respiratory samples, with a viral load value below 1×10⁷ copies per mL.⁹⁸

All but 11 studies (six cohort studies, two cross-sectional studies, and one randomised controlled trial on SARS-CoV-2 and two cohort studies on MERS-CoV) were case series, the majority of which recruited non-consecutive patients and were therefore prone to possible selection bias (appendix pp 9–13).

Discussion

This systematic review and meta-analysis provides comprehensive data on the viral dynamics of SARS-CoV-2, including the duration of RNA shedding and viable virus isolation. Our findings suggest that, although patients with SARS-CoV-2 infection might have prolonged RNA shedding of up to 83 days in upper respiratory tract infection, no live virus was isolated from culture beyond day 9 of symptoms despite persistently high viral RNA loads. This finding is supported by several studies demonstrating an association between viral load and viability of virus, with no successful culture from samples below a certain viral load threshold. These findings indicate that, in clinical practice, repeat testing might not

be indicated to deem patients no longer infectious. Duration of infectiousness and subsequent isolation timelines could reflect viral load dynamics and could be counted from symptom onset for 10 days in non-severe cases.

SARS-CoV-2 viral load appeared to peak in the upper respiratory tract within the first week after symptom onset, and later in the lower respiratory tract. By contrast, the viral load of SARS-CoV peaked at days 10–14 of illness and that of MERS-CoV peaked at 7–10 days of illness. Combined with isolation of viable virus in respiratory samples primarily within the first week of illness, patients with SARS-CoV-2 infection are likely to be most infectious in the first week of illness, emphasising the importance of immediate isolation with symptom onset early in the course of illness. Several studies report viral load peaks during the prodromal phase of illness or at the time of symptom onset.^{2–4,8,15–21} providing a rationale for the efficient spread of SARS-CoV-2. This finding is supported by the observation in contact-tracing studies that the highest risk of transmission occurs very early in the disease course (a few days before and within the first 5 days after symptom onset).^{103,104} Although modelling studies estimated potential viral load peak before symptom onset, we did not identify any study that confirms pre-symptomatic viral load peak.¹⁵

Similar to SARS-CoV, SARS-CoV-2 can be detected in stool samples for prolonged periods, with high viral loads detected even after 3 weeks of illness. In SARS-CoV, RNA prevalence in stool samples was high, with almost all studies reporting shedding in stools. Although viable SARS-CoV was isolated during up to 4 weeks of illness, faecal–oral transmission was not considered to be a primary driver of infection. By contrast, none of the studies in MERS-CoV reported duration of viral shedding in stool samples and RNA detection was low.^{97,105} So far, only a few studies have demonstrated viable SARS-CoV-2 in stool samples.^{59,106} Thus, the role of faecal shedding in viral transmission remains unclear.

Viral loads appear to be similar between asymptomatic and symptomatic individuals infected with SARS-CoV-2. Nevertheless, most studies demonstrate faster viral clearance among asymptomatic individuals than those who are symptomatic. This finding is in keeping with viral kinetics observed with other respiratory viruses such as influenza and MERS-CoV, in which people with asymptomatic infection have a shorter duration of viral shedding than symptomatic individuals.^{93,107} However, data on the shedding of infectious virus in asymptomatic individuals are too scarce to quantify their transmission potential in order to inform policy on quarantine duration in the absence of testing.

To our knowledge, this is the first systematic review to comprehensively examine and compare SARS-CoV-2, SARS-CoV, and MERS-CoV viral dynamics, and the first meta-analysis of viral shedding duration. Our study has limitations. First, almost all patients in the included

Figure 3: Pooled mean duration (days) of MERS-CoV shedding from the upper respiratory tract (random-effects model)

MERS-CoV=Middle East respiratory syndrome coronavirus.

Figure 4: Pooled mean duration (days) of MERS-CoV shedding from the lower respiratory tract (random-effects model)

MERS-CoV=Middle East respiratory syndrome coronavirus.

studies received a range of treatments, which might have modified the shedding dynamics. Second, our meta-analysis identified substantial study heterogeneity, probably due to differences in study population, follow-up, and management approaches. Furthermore, shedding duration is reported as median with IQR for most studies, but meta-analysis necessitates conversion to mean with SD.⁶ The validity of this conversion is based on the assumption that duration of viral shedding is normally distributed, which might not apply to some studies. Last, although there is probably a broad overlap, the true clinical window of infectious shedding might not entirely align with viral culture duration.

We identified a systematic review of SARS-CoV-2 viral load kinetics that included studies published up until May 12, 2020.¹⁰⁸ This review included 26 case reports and 13 case series involving less than five individuals, which did not meet our eligibility criteria; these studies are prone to substantial selection bias, reporting atypical cases with prolonged viral shedding. Additionally, the review included studies that reported viral shedding duration from the time of hospital admission or initial PCR positivity. Furthermore, no meta-analysis of the duration of viral shedding was done.

This review provides detailed understanding about the evidence available so far on viral dynamics of SARS-CoV-2 and has implications for pandemic control strategies and infection control practices. Although SARS-CoV-2 RNA shedding can be prolonged in respiratory and stool

samples, viable virus is short-lived, with culture success associated with viral load levels. Most studies detected the SARS-CoV-2 viral load peak within the first week of illness. These findings highlight that isolation practices should be commenced with the start of first symptoms, including mild and atypical symptoms that precede more typical COVID-19 symptoms. However, given potential delays in the isolation of patients, effective containment of SARS-CoV-2 might be challenging even with an early detection and isolation strategy.¹⁰⁹

Summary:

Non-contact transmission of SARS-CoV-2 was demonstrated in a Syrian hamster model. Surgical mask partition significantly reduced the transmission of SARS-CoV-2 from challenged index hamsters to the exposed naïve hamsters via respiratory droplets and/or airborne droplet nuclei.

Accepted Manuscript

ABSTRACT

Background. Coronavirus disease 2019 (COVID-19) caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is believed to be mostly transmitted by medium-to-large sized respiratory droplets although airborne transmission is theoretically possible in healthcare settings involving aerosol-generating procedures. Exposure to respiratory droplets can theoretically be reduced by surgical mask usage. However, there is a lack of experimental evidence supporting surgical mask usage for prevention of COVID-19.

Methods. We used a well-established golden Syrian hamster SARS-CoV-2 model. We placed SARS-CoV-2-challenged index hamsters and naïve hamsters into closed system units each comprising two different cages separated by a polyvinyl chloride air porous partition with unidirectional airflow within the isolator. The effect of a surgical mask partition placed in between the cages was investigated. Besides clinical scoring, hamster specimens were tested for viral load, histopathology, and viral nucleocapsid antigen expression.

Results. Non-contact transmission was found in 66.7% (10/15) of exposed naïve hamsters. Surgical mask partition for challenged index or naïve hamsters significantly reduced transmission to 25% (6/24, $P=0.018$). Surgical mask partition for challenged index hamsters significantly reduced transmission to only 16.7% (2/12, $P=0.019$) of exposed naïve hamsters. Unlike the severe COVID-19 manifestations of challenged hamsters, infected naïve hamsters had lower clinical scores, milder histopathological changes, and lower viral nucleocapsid antigen expression in respiratory tract tissues.

Conclusions. SARS-CoV-2 could be transmitted by respiratory droplets or airborne droplet nuclei in the hamster model. Such transmission could be reduced by surgical mask usage, especially when masks were worn by infected individuals.

Keywords: coronavirus; COVID-19; SARS-CoV-2; mask; transmission.

Accepted Manuscript

The source of the 2003 severe acute respiratory syndrome (SARS) epidemic was traced to civets in live animal markets, and ultimately to Chinese horseshoe bats in the wild.¹⁻³ The epidemiological significance of the large number of bat SARS-related coronaviruses subsequently found in horseshoe and other bat species was not fully appreciated for the last 17 years.^{4, 5} In late 2019, infection due to a novel *betacoronavirus* named severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which is phylogenetically close to bat SARS-related coronaviruses, was reported in patients with epidemiological link to a market with wild mammal trade in Wuhan, China.⁶⁻⁸ SARS-CoV-2 infection causing Coronavirus Disease 2019 (COVID-19) was initially recognized as an acute febrile pneumonia with lymphopenia and multifocal peripheral ground glass changes on thoracic computerized tomography.⁹⁻¹¹ COVID-19 is often self-limiting, but may have severe manifestations such as silent (asymptomatic until sudden collapse) hypoxia, acute respiratory distress syndrome (ARDS), thrombocytopenia and disseminated intravascular coagulation with diffuse microvascular thrombosis, deep venous thrombosis with pulmonary embolism, and/or multi-organ failure.^{9, 10, 12, 13} Gastrointestinal manifestations such as diarrhea, neurological manifestations such as meningoencephalitis and Guillain-Barré syndrome, and Kawasaki syndrome-like multi-systemic inflammatory disorder in children have also been reported.¹⁴⁻¹⁶ However, most symptomatic patients have mild to moderate respiratory illness with manifestations such as rhinorrhea, sore throat, cough, conjunctivitis, anosmia, and ageusia.^{17, 18} Furthermore, a high proportion of patients with COVID-19 have subclinical infections, which is believed to enable efficient person-to-person transmission in both community and hospital settings. This renders symptom screening at borders ineffective, entails extensive testing and isolation of infected individuals, require labor-intensive contact tracing measures, and necessitates social distancing or lockdowns. As a result, the ongoing COVID-19

pandemic has already affected more than 4 million patients with over 280,000 deaths in just 5 months.¹⁹

Although COVID-19 is believed to be transmitted by respiratory droplet and direct or indirect contact, no clear experimental evidence for this has been reported. Based on *in silico* estimates of the binding affinity of angiotensin-converting enzyme 2 (ACE2) of common laboratory mammals and the receptor-binding domain of the surface spike protein of SARS-CoV-2, we recently established a golden Syrian hamster model for COVID-19.²⁰ SARS-CoV-2-infected hamsters developed clinical signs of rapid breathing, weight loss, and histopathological changes of ARDS.²⁰ Using this animal model, we showed that SARS-CoV-2-challenged index hamsters consistently infected co-housed naïve hamsters, confirming virus transmission by direct or indirect contact.²⁰ However, the controversies of whether there is transmission by respiratory droplets or airborne droplet nuclei, and whether the wearing of surgical mask by the virus shedder or by the susceptible individual is useful for the prevention of transmission, are still unsettled. In this study, using our hamster model for COVID-19, we confirmed non-contact transmission of SARS-CoV-2 which could potentially be prevented by surgical mask worn by the infected or by the susceptible host.

METHODS

Virus and biosafety

SARS-CoV-2 was isolated from the nasopharyngeal aspirate specimen of a laboratory-confirmed COVID-19 patient in Hong Kong.²¹ The plaque purified viral isolate was amplified by one additional passage in VeroE6 cells to make working stocks of the virus as described previously.²¹ All experiments involving live SARS-CoV-2 followed the approved standard operating procedures of the Biosafety Level (BSL)-3 facility of The University of Hong Kong (HKU).^{22, 23}

Animals

Approval was obtained from the HKU Committee on the Use of Live Animals in Teaching and Research. Male and female Syrian hamsters, aged 6-10 weeks old, were obtained from the Chinese University of Hong Kong Laboratory Animal Service Centre through the HKU Laboratory Animal Unit. The animals were kept in BSL-2 housing and given access to standard pellet feed and water ad libitum until virus challenge in our BSL-3 animal facility. The animal rooms were kept at 25°C and 50% humidity.

Non-contact transmission model set-up

To study the transmissibility of SARS-CoV-2 among hamsters through non-contact transmission, we housed SARS-CoV-2-challenged index hamsters and naïve hamsters together in closed systems. The closed systems were kept in isolators (Tecniplast SpA, Varese, Italy) to prevent leakage of contaminated air to the external environment (Figure 1A). Each closed system contained two cages (Marukan Co., Ltd., Osaka, Japan) separated by a polyvinyl chloride air porous partition with unidirectional airflow maintained by an electrically powered fan from the cage housing one SARS-CoV-2-challenged index hamster towards the cage housing three naïve hamsters (Figure 1B). Each system had either no surgical mask partition or a fully knitted layer of partition made of surgical mask (A. R. Medicom Inc. (Asia) Ltd., Hong Kong, China) fulfilling the ASTM F2100 Level 1 standard placed on the polyvinyl chloride air porous partition between the cages to assess the effect of the surgical mask partition in this hamster model (Figure 1C). There were two or three closed systems per isolator.

Animal challenge and transmission experiments

Three sets of experiments were conducted using our isolator non-contact transmission model. In the first experiment, no mask partition was placed between the two cages in each system to investigate whether non-contact transmission occurred among the hamsters (Figure 2). A total of five systems housing 20 hamsters were included in the first experiment. In the second experiment, to simulate the situation when surgical masks are worn by a SARS-CoV-2-infected person, a fully knitted partition layer using surgical mask was placed on the polyvinyl chloride air porous partition between the cages with the outer fluid-repellent layer (the blue side) facing the exposed-naïve hamsters to prevent emitted respiratory droplets containing SARS-CoV-2 from the challenged index hamster from reaching exposed naïve hamsters (Figure 3A). A total of four systems housing 16 hamsters were included in the second experiment. In the third experiment, to simulate the situation when close contacts of a SARS-CoV-2-infected person wear surgical masks, the surgical mask partition with the outer fluid-repellent layer (the blue side) facing the challenged index hamsters was placed on the polyvinyl chloride air porous partition between the cages to prevent droplets containing SARS-CoV-2 emitted by the challenged index hamster from reaching the exposed naïve hamsters (Figure 3B). A total of four systems housing 16 hamsters were included in the third experiment. The air velocities from the challenged index hamster's cage to the exposed naïve hamsters' cage in the three experiments were shown in Table 1.

At day 0, a challenge dose of 100µl of Dulbecco's Modified Eagle Medium (DMEM) containing 10^5 plaque-forming units of SARS-CoV-2 was intranasally inoculated to the index hamster in each system under intraperitoneal ketamine (200mg/kg) and xylazine (10mg/kg) anaesthesia as we described previously.²⁰ Twenty-four hours later, three naïve hamsters were transferred to the cage adjacent and exposed to the cage housing the virus-challenged index hamster per system. The animals were monitored daily for clinical signs of disease. Two of

the three exposed naïve hamsters in each system were sacrificed at 5 days post-inoculation (dpi) (4 days after exposure). The challenged index animal and remaining exposed naïve animal in each system were then sacrificed at 7dpi. The animals' organ tissues at necropsy were separated into two parts, one immediately fixed in 10% PBS-buffered formalin for histopathological analysis, and the other immediately frozen at -80°C until use for viral load studies as we described previously.^{20, 24, 25} Serum samples were used for neutralizing antibody detection as we described previously.²⁰ To compare the histopathological changes at 5dpi, an additional control SARS-CoV-2-challenged hamster was sacrificed at 5dpi.

Statistical analysis

All data were analysed with GraphPad Prism software (GraphPad Software, Inc). Fisher's exact test was used to compare the rate of infection between the different groups of hamsters with or without surgical mask partition. Student's t-test was used to determine significant differences in clinical scores and virus loads between different groups.²⁰ $P < 0.05$ was considered statistically significant.

RESULTS

Non-contact transmission of SARS-CoV-2 among hamsters

Consistent with our previous findings, all 13 (n=5, 4, and 4 for experiments 1, 2, and 3, respectively) SARS-CoV-2-challenged index hamsters developed clinical signs of lethargy, ruffled furs, hunched back posture, and rapid breathing starting at 2dpi, and had virological and histological evidence of infection.²⁰ In the first experiment, six of the ten (60%) exposed naïve hamsters sacrificed at 5dpi (4 days after exposure) also developed similar clinical signs. The overall mean clinical score of the 10 exposed naïve hamsters was 1.800 ± 1.687 (Table 2). The 6 naïve hamsters which developed clinical signs were confirmed to be infected with

SARS-CoV-2 as evidenced by positive RT-PCR results (Table 3). The viral loads ranged from around 0.1 to 1000 genome copies/ β -actin (nasal turbinate), 0.1 to 100 genome copies/ β -actin (trachea), and 0.02 to 10 genome copies/ β -actin (lung) (Figure 4A). At 7 dpi (6 days after exposure), the remaining 5 naïve hamsters had a mean clinical score of 2.400 ± 1.517 . Four of the five (80.0%) exposed naïve hamsters were found to be infected, with viral loads of around 100 to 1000 genome copies/ β -actin (nasal turbinate), 10 to 100 genome copies/ β -actin (trachea), and 0.1 to 100 genome copies/ β -actin (lung) (Figure 4B). None of the index and naïve hamsters died.

Non-contact transmission of SARS-CoV-2 among hamsters with surgical mask partition

Having demonstrated that non-contact transmission of SARS-CoV-2 occurred among the hamsters in our model, we next investigated the effectiveness of surgical mask partition to reduce the risk of non-contact transmission. Surgical mask partition between cages was installed with the external fluid-repelling surface facing the exposed naïve hamsters or the challenged index hamsters to mimic the situation of the mask being worn by index hamsters or by exposed naïve contact hamsters, respectively.

In the second experiment in which the external surface of the mask was facing the naïve hamsters, at 5 dpi (4 days after exposure), two of the three naïve hamsters in each system (n=8) were sacrificed. Only 1 out of 8 (12.5%) naïve hamsters was SARS-CoV-2 RT-PCR-positive (Table 3). The viral loads of this hamster were about 1 (nasal turbinate), 100 (trachea), and 10 (lung) genome copies/ β -actin (Figure 4A). At 7 dpi, the remaining exposed naïve hamster (n=4) and the SARS-CoV-2-challenged index hamster (n=4) in each system were also sacrificed. Only one of the four (25.0%) remaining naïve hamsters were RT-PCR-positive, with viral loads of around 0.5 (lung) to 100 (nasal turbinate) genome copies/ β -actin

(Figure 4B). This transmission rate (16.7%) was significantly ($P=0.019$) lower than that of the exposed naïve hamsters without surgical mask partition (66.7%).

In the third experiment, the external surface of the mask was facing the challenged index hamsters. At 5 dpi (4 days after exposure), two of the three naïve hamsters in each system ($n=8$) were sacrificed. Three out of 8 (37.5%) exposed naïve hamsters developed clinical signs and were SARS-CoV-2 RT-PCR positive (Table 3). The viral loads ranged from around 1 to 10 genome copies/ β -actin (nasal turbinate), 0.01 to 100 (trachea) genome copies/ β -actin, and 1 to 1000 genome copies/ β -actin (lung) (Figure 4A). At 7 dpi, the remaining exposed naïve hamster ($n=4$) and the challenged index hamster ($n=4$) in each system were also sacrificed. One of the four (25.0%) remaining naïve hamsters were RT-PCR positive, with viral loads of around 1 (lung) to 100 (nasal turbinate) genome copies/ β -actin (Figure 4B). This transmission rate (33.3%) was also lower than that of the exposed naïve hamsters without surgical mask partition (66.7%), although not reaching statistical significance ($P=0.128$).

Immunological response in hamsters infected by SARS-CoV-2 through non-contact transmission

At 7 dpi (6 days after exposure of the naïve hamsters to the challenged index hamsters), all challenged index hamsters ($n=13$) exhibited high titers of serum neutralizing antibodies, ranging from 1:320 to $\geq 1:640$, which is consistent with our previous observation (Figure 5). Interestingly, three of the five exposed (60%) naïve hamsters without surgical mask partition sacrificed at 7 dpi also developed serum neutralizing antibody titers of 1:160 to 1:640, which suggested that these three RT-PCR-positive infected naïve hamsters likely acquired the virus very early after exposure to the challenged index hamsters as it required 5 to 7 days before serum neutralizing antibodies were detectable in this animal model. In contrast, none of the 8

exposed naïve hamsters with surgical mask partition facing either side sacrificed at 7 dpi, including the two RT-PCR-positive hamsters, developed detectable serum neutralizing antibody (all $<1:20$). These results suggested that even though these two exposed naïve hamsters were infected, they likely acquired the virus much later than the infected naïve hamsters without protection by surgical mask partition.

Histological features of hamsters infected by SARS-CoV-2 through non-contact transmission

The representative histological and immunofluorescent staining findings of the infected naïve hamsters are shown in Figure 6. At 5dpi (4 days after exposure), the histopathological changes of the infected naïve hamsters in experiments 1, 2, and 3, were generally milder than those of the challenged control hamster (Figure 6A, a to d). In the infected naïve hamsters, the nasal turbinate only showed mild degree of epithelium cells swelling and submucosal infiltration, whereas there were severe epithelial cell death, desquamation, and massive submucosal infiltration in the challenged control hamster. Similarly, the histopathological changes in the trachea (Figure 6A, e to h) and lung (Figure 6A, i to l) of the challenged control hamster were generally more severe than the infected naïve hamsters in experiments 1, 2, and 3. This was corroborated by the viral N antigen expression pattern (Figure 6B).

DISCUSSION

Following up on the demonstration of SARS-CoV-2 transmission through direct or indirect contact in our hamster model, a non-contact transmission model inside isolators was established in this study.²⁰ We showed that non-contact transmission occurred in 66.7% of unprotected naïve hamsters after exposure to SARS-CoV-2-challenged hamsters for less than 96 hours. Despite documented transmission in the exposed naïve hamsters as evident by positive viral loads in the upper and lower respiratory tract at 4 days after exposure or serum neutralizing antibody titre at 6 days after exposure, these hamsters had less severe histopathological changes and lower amount of SARS-CoV-2-N antigen expression in the upper and lower respiratory tract compared to virus-challenged hamsters. Moreover, the use of surgical mask partition to prevent emission of respiratory droplets from SARS-CoV-2-challenged index hamsters significantly reduced the transmission rate to 16.7% ($P=0.019$). The use of surgical mask partition to protect naïve hamsters reduced the transmission rate to 33.3%, although this did not reach statistical significance, likely because of the relatively small number of animals ($P=0.128$). As expected, the histopathological changes and the amount of respiratory tract viral N antigen expression of these protected naïve hamsters were also significantly lower than those of the challenged index hamsters.

The finding of SARS-CoV-2 being transmitted by the non-contact route of respiratory droplets or airborne droplet nuclei is not unexpected as this is the case for other respiratory viruses. For seasonal influenza viruses, similar transmission has been demonstrated with Syrian hamster, ferret, and guinea pig models.²⁶⁻²⁸ Seasonal influenza viruses could be isolated by plaque assay from naïve hamsters by day 4 post-exposure, whereas SARS-CoV-2 could be detected by RT-PCR in our infected naïve hamsters as early as day 4 post-exposure.²⁶ However, in the case of Nipah virus which is more of a neurotropic than

respiratory virus, transmission in the Syrian hamster model was largely by direct contact, despite predominant virus shedding in nasal and oropharyngeal secretions.²⁹

The intensity of exposure may affect the severity of viral infections as has been demonstrated in outbreaks of chickenpox, measles, and poliomyelitis.³⁰⁻³² The effect of virus inoculum on the severity of COVID-19 is evident when the histopathological changes and amount of viral N antigen expression in the respiratory tracts of the infected naïve hamsters with or without protection by surgical mask partition was compared with those of the virus-challenged hamsters. Besides a virus inoculum of 10^5 plaque forming units in 100µl DMEM being instilled intranasally into the challenged hamsters, the inoculum might be aspirated directly into the lungs when the hamsters were under anaesthesia. Such large dose of deep exposure resulted in significantly more severe histopathological changes and higher amount of viral N antigen expression in the respiratory tract than the infected naïve hamsters after droplet and/or aerosol exposure. The protective effect of masking may not be just determined by the success or failure of SARS-CoV-2 transmission, but also by the severity of COVID-19 in the case of transmission. For example, in Hong Kong where the population has a mask-use compliance rate of 96.6% during local COVID-19 epidemic, both the incidence rate (1048 cases per 7.5 million population) and crude fatality rate (4 out of 1048, 0.4%) of COVID-19 were amongst the lowest in the world at the timing of writing.³³

Although we could not differentiate whether transmission occurred by respiratory droplets or airborne aerosols in this study, both types of non-contact transmission might have happened because surgical masks is most efficient in filtering out large respiratory droplets of more than 10µm, but not the airborne aerosol particles of less than 5µm. Therefore, non-contact transmission still occurred in our hamster model despite a reduction of transmission when the naïve hamsters were protected by mask partitioning. Alternatively, the filtration efficiency of the masks might have declined over time during the study period. Interestingly,

transmission to the exposed naïve hamsters was significantly reduced when surgical mask partition was placed to prevent emission from the challenged index hamsters. This was not completely unexpected because the masking of infectious patients with multidrug-resistant tuberculosis on a hospital ward in South Africa reduced airborne transmission by 56% from these patients to guinea pigs which were breathing the ward air, compared with the percentage of transmission to guinea pigs during periods when masks were not worn.³⁴ This report clearly showed that surgical masks could be partially effective in reducing the transmission of a well-known airborne pathogen *Mycobacterium tuberculosis* and corroborated with the masking experiments in our hamster model of non-contact transmission of SARS-CoV-2.

Unlike the use of surgical mask in healthcare setting, masking in the community remains controversial. The World Health Organization found no evidence that wearing a surgical mask by healthy persons can prevent acquisition of SARS-CoV-2. However, the US Centers for Disease Control and Prevention recommends the use of cloth face coverings in communities with significant community-based transmission. This shift of recommendation was based on the finding of pre-symptomatic shedding of SARS-CoV-2 and the presence of asymptomatic patients with high viral loads in the community. Face mask usage may serve as source control by preventing dispersal of droplets during talking, sneezing, and coughing, and also reduce the risk of environmental contamination by SARS-CoV-2. Our results showed that masking of the challenged index appeared to be more important than masking the exposed naïve, which is consistent with the findings in a systematic review on influenza transmission.³⁵ Masking is a continuous form of protection to stop the spreading of saliva and respiratory droplets to or from others, and to or from the environment to the susceptible individuals by hands through subconscious touching of their nose, mouth, and eyes. Hand hygiene is always the cornerstone to prevent transmission of SARS-CoV-2, but it is a one-off

discontinuous process where hand contamination may occur again easily between each episode of alcoholic hand rubbing or hand washing. Studies have also shown that wearing a mask with frequent hand hygiene significantly reduced transmission of seasonal influenza virus in the community setting.³⁶ But once the effect of the use of surgical mask was removed, the effect of hand hygiene became insignificant.³⁶

Containment public health interventions including border source control, extensive testing of cases and isolation, rapid contact tracing and quarantine, and mitigation measures of social distancing including school closures, home office, closure of food premises and public places to stop gatherings and even city lockdown, were used by every developed country at different time points and to different extents to control the COVID-19 pandemic. However, the presence of a significant proportion of asymptotically infected patients who were not aware of the need of testing, wearing mask, or isolation has markedly impaired these control measures. In the case of the Princess Diamond cruise outbreak, 6 out of 9 returnees were found to be asymptotically infected during the 14 days of quarantine and serial virological monitoring after returning to Hong Kong.³⁷ Our findings on the use of surgical mask partition for protection against non-contact transmission in this hamster model supported the use of community-wide masking to reduce the amount of virus shedding from the asymptotically infected patients and to protect susceptible individuals. This should be a reasonable approach for the epidemic control of a densely populated city like Hong Kong without resorting to city lockdown, and an important measure during the stepwise loosening of social distancing measures in the days ahead.

Our study had limitations. The speed of the unidirectional airflow could not be unified when the surgical mask partitions were installed, but that would also apply when surgical masks were worn by different individuals in real life, and this could indeed be a mechanism for protection during mask usage. We could not determine the exact timing of acquisition of

SARS-CoV-2 by the exposed naïve hamsters as we only started sampling them 4 days after exposure. Moreover, we could not determine if contact transmission has occurred among exposed naïve hamsters housed in the same cage. This might have resulted in an underestimation of the protective efficacy of masks, which would otherwise be even more significant. Further studies on the relative importance of large respiratory droplets and small airborne aerosols are warranted.

Figure legends

Figure 1. Non-contact transmission of SARS-CoV-2 in the Syrian hamster model. (A)

The closed systems housing the hamsters were placed in the isolator in a Biosafety Level-3 laboratory. **(B)** Enlarged view of the closed systems used in the non-contact transmission studies. Each system contained two cages (left and right) separated by a polyvinyl chloride air porous partition. An electrically powered fan was installed at the polyvinyl chloride air porous partition to ensure unidirectional airflow from the cage housing the challenged index hamsters to the cage housing the naïve hamsters. **(C)** Surgical mask partition with the blue external surface facing the challenged hamsters in experiment 3.

Figure 2. Non-contact transmission of SARS-CoV-2 from virus-challenged index hamsters to exposed naïve hamsters without surgical mask partition between the cages (experiment 1).

SARS-CoV-2 was intranasally inoculated to the index hamsters (n=5) at day 0. Twenty-four hours later, three naïve hamsters were transferred to the adjacent cage and exposed to the cage housing the virus-challenged index hamster. Two exposed naïve hamsters in each system were sacrificed at day 5 post-inoculation (4 days after exposure). The challenged index animal and the remaining exposed naïve animal in each system were then sacrificed at 7 dpi. A total of 5 systems (n=20) were included in experiment 1.

Figure 3. Non-contact transmission of SARS-CoV-2 from virus-challenged index hamsters to exposed naïve hamsters with surgical mask partition between the cages.

Surgical mask partition with the external surface facing (A) exposed naïve hamsters (experiment 2) to mimic the situation of the mask being worn by the challenged index hamster for preventing the emission of SARS-CoV-2 infected droplets, or (B) facing the challenged index hamsters to mimic the situation of the mask being worn by the exposed

naïve hamsters to prevent the reception of SARS-CoV-2-infected droplets from the challenged index hamsters. The timing of virus challenge and sacrifice of animals was the same as experiment 1. A total of 4 systems (n=16) were included in experiment 2 and another 4 systems (n=16) were included in experiment 3.

Figure 4. Viral loads in the respiratory tract tissues of the SARS-CoV-2 RT-PCR-positive naïve hamsters exposed to the challenged index hamsters. Naïve hamsters without surgical mask partition in experiment 1 (red squares), naïve hamsters exposed to masked challenged index hamsters in experiment 2 (black circles), and the masked naïve hamsters exposed to the challenged index hamsters in experiment 3 (blue triangles). Statistical comparison between the SARS-CoV-2 RT-PCR-positive naïve hamsters without surgical mask partition (experiment 1) and the SARS-CoV-2 RT-PCR-positive naïve hamsters with surgical mask partition (experiments 2 and 3) was performed using Student's t-test. n.s. = not significant and * = $P < 0.05$. LOD, limit of detection.

Figure 5. Reciprocal serum SARS-CoV-2-specific neutralizing antibody titers in the hamsters. The mean serum neutralizing antibody titers of the challenged index hamsters (n=13, orange diamonds), the naïve hamsters exposed to the challenged index hamsters without surgical mask partition in experiment 1 (n=5, red squares), the naïve hamsters exposed to masked challenged index hamsters in experiment 2 (n=4, black circles), and the masked naïve hamsters exposed to the challenged index hamsters in experiment 3 (n=4, blue triangles) at 7 days post-inoculation (6 days after exposure of the naïve hamsters to the index hamsters) are shown on a logarithmic scale. The dotted line indicates the lower limit of detection (<1:20). LOD, limit of detection.

Figure 6. Histopathological changes and SARS-CoV-2 nucleocapsid (N) protein expression in the upper and lower respiratory tissues of the hamsters.

(A) Hematoxylin and eosin-stained tissue sections. (a) to (d) Representative images of nasal turbinate tissue sections which showed pieces of epithelium desquamation (arrows) in all four groups of hamsters. The tissue damage was generally more severe in the challenged control hamster which exhibited massive secretion mixed with detached epithelial cells in the nasal cavity (empty arrow). (e) to (h) Representative images of the tracheal tissue sections showing various degrees of epithelial desquamation (arrows) and submucosal infiltration which was also more prominent in the challenged control hamster (empty arrows). (i) to (l) Representative images of the lung sections. (i) The lung of the challenged control hamster at 5 dpi showed bronchiolar epithelial cell death, luminal secretion and cell debris (arrow), severe alveolar infiltration, exudation and hemorrhage (empty arrows). Two blood vessels showed perivascular and intra-endothelial infiltration (arrowheads). (j) The lung of the infected naïve hamster from experiment 1 showed bronchiolar epithelial desquamation (arrows), patchy alveolar wall thickening and blood vessel congestion (arrowhead). (k) The lung of the infected naïve hamster from experiment 2 showed no apparent alveolar damage, but with bronchiolar epithelial desquamation (arrow) and mild perivascular infiltration (arrowhead). (l) The lung of the infected naïve hamster from experiment 3 showed mild alveolar wall thickening with blood vessel congestion.

(B) Immunofluorescence-stained viral N protein (green) expression in hamster respiratory tissues. (a) to (d) Representative images of the nasal turbinate of the hamsters, showing more abundant viral N antigen expression in the challenged control hamster than the infected naïve hamsters in experiments 1, 2, and 3. Viral N antigen-positive cells located in the epithelium (arrows) and viral N antigens associated with detached cells (solid arrows). (e) to (h) The tracheal tissue of the challenged control hamster showed more intense epithelial viral N

antigen expression (arrows) than the infected naïve hamsters in experiments 1, 2, and 3. (i) to (l) Viral N antigen expression in the lung tissues. The lung sections of the challenged control hamster showed diffuse viral N antigen expression in alveolar cells compared to scanty expression in the bronchiolar epithelium (thin arrows) and alveoli (solid arrows) of the infected naïve hamsters in experiments 1, 2, and 3.

Word count (abstract): 273 words

Word count (text only): 3,500 words

Background: SARS-CoV-2 shedding dynamics in the upper (URT) and lower respiratory tract (LRT) remain unclear.

Objective: To analyze SARS-CoV-2 shedding dynamics across COVID-19 severity, the respiratory tract, sex and age cohorts (aged 0 to 17 years, 18 to 59 years, and 60 years or older).

Design: Systematic review and pooled analyses.

Setting: MEDLINE, EMBASE, CENTRAL, Web of Science Core Collection, medRxiv and bioRxiv were searched up to 20 November 2020.

Participants: The systematic dataset included 1,266 adults and 136 children with COVID-19.

Measurements: Case characteristics (COVID-19 severity, age and sex) and quantitative respiratory viral loads (rVLs).

Results: In the URT, adults with severe COVID-19 had higher rVLs at 1 DFSO than adults ($P = 0.005$) or children ($P = 0.017$) with nonsevere illness. Between 1-10 DFSO, severe adults had comparable rates of SARS-CoV-2 clearance from the URT as nonsevere adults ($P = 0.479$) and nonsevere children ($P = 0.863$). In the LRT, severe adults showed higher post-symptom-onset rVLs than nonsevere adults ($P = 0.006$). In the analyzed period (4-10 DFSO), severely affected adults had no significant trend in SARS-CoV-2 clearance from LRT ($P = 0.105$), whereas

nonsevere adults showed a clear trend ($P < 0.001$). After stratifying for disease severity, sex and age (including child vs. adult) were not predictive of the duration of respiratory shedding.

Limitation: Limited data on case comorbidities and few samples in some cohorts.

Conclusion: High, persistent LRT shedding of SARS-CoV-2 characterized severe COVID-19 in adults. After symptom onset, severe cases tended to have higher URT shedding than their nonsevere counterparts. Disease severity, rather than age or sex, predicted SARS-CoV-2 kinetics. LRT specimens should more accurately prognosticate COVID-19 severity than URT specimens.

INTRODUCTION

As of 17 February 2021, the coronavirus disease 2019 (COVID-19) pandemic has caused more than 109 million infections and 2.4 million deaths globally (1). The clinical spectrum of COVID-19, caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), is wide, ranging from asymptomatic infection to fatal disease. Risk factors for severe illness and death include age, sex, smoking and comorbidities, such as obesity, hypertension, diabetes and cardiovascular disease (2-4). Emerging evidence indicates that age and sex differences in innate, cross-reactive and adaptive immunity facilitate the higher risks in older and male cases (5-8). Robust immune responses putatively mediate nonsevere illness, in part, by controlling the replication of SARS-CoV-2 (9).

As SARS-CoV-2 is a respiratory virus, its shedding dynamics in the upper (URT) and lower respiratory tract (LRT) provide insight into clinical and epidemiological factors. URT viral load has been associated with transmission risk, duration of infectiousness, disease severity and mortality (10-16). Key questions, however, remain. While chest computed tomography (CT) evidence of viral pneumonitis suggests pulmonary replication in most symptomatic cases (17), the LRT kinetics of SARS-CoV-2, especially as related to disease severity, remain unknown. The relationships between sex, age and disease severity on respiratory shedding are unclear. Moreover, whether children clear SARS-CoV-2 at similar rates as adults, and if this correlates the age-based differences in disease severity, is unknown.

For insight into these questions, we conducted a systematic review on SARS-CoV-2 quantitation from respiratory specimens and developed a large, diverse dataset of respiratory viral loads (rVLs) and individual case characteristics. Stratified pooled analyses then assessed SARS-CoV-2 shedding dynamics across the respiratory tract, age, sex and COVID-19 severity.

73

74 **METHODS**

75 Our systematic review identified studies reporting SARS-CoV-2 quantitation in respiratory
76 specimens taken during the estimated infectious period (-3 to 10 days from symptom onset
77 [DFS0]) (15, 18). The systematic review protocol was based on our previous study (19) and was
78 prospectively registered on PROSPERO (registration number, CRD42020204637). The
79 systematic review was conducted according to Cochrane methods guidance (20). Other than the
80 title of this study, we have followed PRISMA reporting guidelines (21).

81

82 **Data Sources and Searches**

83 Up to 20 November 2020, we searched, without the use of filters or language restrictions,
84 the following sources: MEDLINE (Ovid), EMBASE (Ovid), Cochrane Central Register of
85 Controlled Trials (CENTRAL, Ovid), Web of Science Core Collection, and medRxiv and
86 bioRxiv (both searched through Google Scholar via the Publish or Perish program). We also
87 gathered studies by searching through the reference lists of review articles identified by the
88 database search, by searching through the reference lists of included articles, through expert
89 recommendation (by Epic J. Topol and Akiko Iwasaki on Twitter) and by hand-searching
90 through journals. A comprehensive search was developed by a librarian (Z.P.). Additional details
91 on the search are included in the **Supplement**.

92

93 **Study selection**

94 Studies that reported SARS-CoV-2 quantitation in individual URT (nasopharyngeal swab
95 [NPS], nasopharyngeal aspirate [NPA], oropharyngeal swab [OPS] or posterior oropharyngeal

saliva [POS]) or LRT (endotracheal aspirate [ETA] or sputum [Spu]) specimens taken during the estimated infectious period (-3 to 10 DFSO) in humans were included (additional details in the **Supplement**). As semiquantitative metrics (cycle threshold [Ct] values) cannot be compared on an absolute scale between studies based on instrument and batch variation (22), studies reporting specimen measurements as Ct values, without quantitative calibration, were excluded. Two authors (P.Z.C. and N.B.) independently screened titles and abstracts and reviewed full texts. At the full-text stage, reference lists were reviewed for study inclusion. Inconsistencies were resolved by discussion and consensus.

Data Extraction and Risk-of-Bias Assessment

Two authors (P.Z.C. and N.B.) independently collected data (specimen measurements taken between -3 and 10 DFSO, specimen type, volume of transport media and case characteristics, including age, sex and disease severity) from contributing studies and assessed risk of bias using a modified Joanna Briggs Institute (JBI) critical appraisal checklist (described in the **Supplement** and shown in **Supplement Table 6**). Data were collected for individually reported specimens of known type, with known DFSO, and for COVID-19 cases with known age, sex or severity. Case characteristics were collected directly from contributing studies when reported individually or obtained via data request from the authors. Data from serially sampled asymptomatic cases were included, and the day of laboratory diagnosis was referenced as 0 DFSO (15, 23). Based on the modified JBI checklist, studies were considered to have low risk of bias if they met the majority of items and included item 1 (representative sample). Discrepancies were resolved by discussion and consensus.

Respiratory Viral Load

For analyses based on rVL (viral RNA concentration in the respiratory tract) and to account for interstudy variation in the volumes of viral transport media (VTM) used, the rVL for each collected sample was estimated based on the specimen concentration (viral RNA concentration in the specimen) and dilution factor in VTM. Typically, swabbed specimens (NPS and OPS) report the viral RNA concentration in VTM. Based on the VTM volume reported in the study along with the expected uptake volume for swabs (0.128 ± 0.031 ml, mean \pm SD) (24), we calculated the dilution factor for each respiratory specimen and then estimated the rVL. Similarly, liquid specimens (ETA, POS and Spu) are often diluted in VTM, and the rVL was estimated based on the reported collection and VTM volumes. If the diluent volume was not reported, then VTM volumes of 1 ml (NPS and OPS) or 2 ml (POS and ETA) were assumed (23, 25). Unless dilution was reported, Spu specimens were taken as undiluted (15). The non-reporting of VTM volume was noted as an element increasing risk of bias in the modified JBI critical appraisal checklist. For laboratory-confirmed COVID-19 cases, negative specimen measurements were taken at the reported assay detection limit in the respective study.

Case Definitions

As severity in the clinical manifestations of COVID-19 and case-fatality rates tend to increase among children (aged 0-17 y), younger adults (aged 18-59 y) and older adults (aged 60 y or older) (4, 26), the data were delineated based on these three age cohorts. Cases were also categorized by sex.

U.S. National Institutes of Health guidance was used to categorize disease severity as nonsevere or severe (27). The nonsevere cohort included those with asymptomatic infection

(individuals who test positive via a molecular test for SARS-CoV-2 and report no symptoms consistent with COVID-19); mild illness (individuals who report any signs or symptoms of COVID-19, including fever, cough, sore throat, malaise, headache, muscle pain, nausea, vomiting, diarrhea, loss of taste and smell, but who do not have dyspnea or abnormal chest imaging); and moderate illness (individuals with clinical or radiographic evidence of LRT disease, fever $>39.4^{\circ}\text{C}$ or $\text{SpO}_2 \geq 94\%$ on room air) disease. The severe cohort included those with severe illness (individuals who have $\text{SpO}_2 < 94\%$ on room air, $[\text{PaO}_2/\text{FiO}_2] < 300$ mmHg, respiratory rate > 30 breaths/min or lung infiltrates $> 50\%$) and critical illness (respiratory failure, septic shock or multiple organ dysfunction).

Statistical Analysis

We used regression analysis to assess the respiratory shedding of SARS-CoV-2 and compare age, sex or severity cohorts. In COVID-19 cases, rVL tends to diminish exponentially after 1 DFSO in the URT, whereas it tends to do so after 4 DFSO in the LRT (15, 17, 19). Hence, rVLs (in units of \log_{10} copies/ml) between 1-10 DFSO for the URT, or 4-10 DFSO for the LRT, were fitted using general linear regression with interaction:

$$V = \alpha + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_1 X_2, \quad (1)$$

where V represents the rVL, α represents the estimated mean rVL (at 1 DFSO for URT or 4 DFSO for LRT) for the reference cohort, X_1 represents DFSO for the reference cohort, X_2 represents the comparison cohort, β_1 represents the effect of DFSO on rVL for the reference cohort, β_2 represents the effect of the comparison cohort on the intercept and β_3 represents the interaction between DFSO and cohorts. Regression analyses were offset by DFSO such that mean rVLs at 1 DFSO for URT, or 4 DFSO for LRT, were compared between cohorts by the

effect on the intercept (regression t -test for β_2). Shedding dynamics were compared between cohorts by interaction (regression t -test for β_3). The statistical significance of viral clearance for each cohort was analyzed using simple linear regression (regression t -test on the slope). Regression models were extrapolated (to 0 log₁₀ copies/ml, rather than an assay detection limit) to estimate the duration of shedding.

To assess heterogeneity in shedding, rVL data were fitted to Weibull distributions (19), and the rVL at a case percentile was estimated using the Weibull quantile function. Each cohort in statistical analyses included all rVLs for which the relevant characteristic (LRT or URT, age cohort, sex or disease severity) was ascertained at the individual level. Cohorts with small sample sizes were not compared, as these analyses are more sensitive to potential sampling error. Statistical analyses were performed using OriginPro 2019b (OriginLab) and the General Linear regression app or Matlab R2019b (MathWorks) and the Distribution Fitter app. P values below 0.05 were considered statistically significant.

Role of the Funding Source

This study was funded by the Natural Science Research Council of Canada (NSERC). The funder had no role in study design, collection or interpretation of the data, preparation of the manuscript, or the decision to submit the manuscript for publication.

RESULTS

Overview of Contributing Studies

After screening and full-text review, 26 studies met the inclusion criteria and contributed to the systematic dataset (**Figure 1**) (15, 16, 23, 25, 26, 28-48). We collected 1,915 quantitative

specimen measurements of SARS-CoV-2 from 1,402 COVID-19 cases (**Table 1**, rVL data summarized in **Appendix Figure**). For pediatric cases, the search found only nonsevere infections and URT specimen measurements. **Appendix Table 1** summarizes the characteristics of contributing studies, of which 18 had low risk of bias according to the modified JBI critical appraisal checklist. Studies at high or unclear risk of bias typically included samples that were not representative of the target population; did not report the VTM volume used; had non-consecutive inclusion for case series and cohort studies or did not use probability-based sampling for cross-sectional studies; and did not report the response rate (**Appendix Table 2**).

URT Shedding of SARS-CoV-2 for Adult COVID-19

In the adult URT, regression analysis showed that, at 1 DFSO, the mean rVL for severe COVID-19 (8.28 [95% CI, 7.71-8.84] log₁₀ copies/ml) was significantly greater (*P* for intercept = 0.005) than that of nonsevere COVID-19 (7.45 [95% CI, 7.26-7.65] log₁₀ copies/ml) (**Figure 2A**). Meanwhile, these cohorts showed comparable rates of SARS-CoV-2 clearance from the URT (*P* for interaction = 0.479). For severe cases, the estimated mean duration of URT shedding (down to 0 log₁₀ copies/ml) was 27.5 (95% CI, 21.2-33.8) DFSO; it was 27.9 (95% CI, 24.4-31.3) DFSO for nonsevere cases.

While regression analysis compared mean shedding levels and dynamics, we fitted rVLs to Weibull distributions to assess heterogeneity in shedding. Both severe and nonsevere adult COVID-19 showed comparably broad heterogeneity in URT shedding throughout disease course (**Figure 2B**). For severe disease, the standard deviation (SD) of rVL was 1.86, 2.34, 1.89 and 1.90 log₁₀ copies/ml at 2, 4, 7 and 10 DFSO, respectively. For nonsevere illness, these SDs were 2.08, 1.90, 1.89 and 1.96 log₁₀ copies/ml, respectively.

Based on our data, the distinction in rVL between severity cohorts was greater near symptom onset. Based on distribution fitting (**Figure 2B**), at 2 DFSO, the estimated rVL at the 80th case percentile (cp) for severe disease was 9.54 (95% CI, 8.78-10.4) log₁₀ copies/ml, while it was 8.84 (95% CI, 8.49-9.20) log₁₀ copies/ml for nonsevere illness. By 10 DFSO, this difference reduced: the 80th-cp estimates were 6.86 (95% CI, 6.20-7.59) and 6.45 (95% CI, 5.91-7.04) log₁₀ copies/ml for severe and nonsevere disease, respectively.

After stratifying adults for disease severity, our analyses showed nonsignificant differences in URT shedding based on sex and age. For nonsevere illness, male and female cases had no significant difference in mean rVL at 1 DFSO (P for intercept = 0.085) or rate of viral clearance (P for interaction = 0.644) (**Figure 2C**). Similarly, for severe disease, male and female cases had comparable mean rVLs at 1 DFSO (P for intercept = 0.326) and URT dynamics (P for interaction = 0.280) (**Figure 2D**). For nonsevere illness, younger and older adults had no significant difference in URT shedding levels at 1 DFSO (P for intercept = 0.294) or post-symptom-onset dynamics (P for interaction = 0.100) (**Figure 2E**). For severe disease, the adult age cohorts showed similar mean rVLs at 1 DFSO (P for intercept = 0.915) and rates of viral clearance (P for interaction = 0.359) (**Figure 2F**).

LRT Shedding of SARS-CoV-2 for Adult COVID-19

Our analyses showed that high, persistent LRT shedding of SARS-CoV-2 was associated with severe COVID-19, but not nonsevere illness, in adults (**Figure 3A**). At the initial day in our analyzed period (4 DFSO), the mean rVL in the LRT of severe cases (8.42 [95% CI, 7.67-9.17] log₁₀ copies/ml) was significantly greater (P for intercept = 0.006) than that of nonsevere cases (6.82 [95% CI, 5.95-7.69] log₁₀ copies/ml). Between severities, the difference in LRT clearance

rates was marginally above the threshold for statistical significance (P for interaction = 0.053). However, severe cases had persistent LRT shedding, with no significant trend in SARS-CoV-2 clearance in the analyzed period (-0.14 [95% CI, -0.32 to 0.030] \log_{10} copies/ml day⁻¹, P = 0.105), whereas nonsevere cases rapidly cleared the virus from the LRT (-0.41 [95% CI, -0.64 to -0.19] \log_{10} copies/ml day⁻¹, P < 0.001). For nonsevere cases, the estimated mean duration of LRT shedding (down to 0 \log_{10} copies/ml) was 20.4 (95% CI, 13.2-27.7) DFSO.

Accordingly, the distributions of severe and nonsevere LRT shedding bifurcated along disease course (**Figure 3B**). At 6 DFSO, the 80th cp estimate of LRT rVL was 9.40 (95% CI, 8.67-10.20) \log_{10} copies/ml for severe COVID-19, while it was 7.66 (95% CI, 6.65-8.83) \log_{10} copies/ml for nonsevere illness. At 10 DFSO, the difference between 80th-cp estimates expanded, as they were 8.63 (95% CI, 8.04-9.26) and 6.01 (95% CI, 4.65-7.78) \log_{10} copies/ml for severe and nonsevere disease, respectively.

Our data indicated that nonsevere illness yielded greater skewing in LRT shedding than severe disease in the analyzed period (**Figure 3B**). For nonsevere COVID-19, the SD of rVL was 1.92, 2.01 and 2.09 \log_{10} copies/ml at 6, 8 and 10 DFSO, respectively. For severe disease, it was lesser 1.25, 1.37 and 1.61 \log_{10} copies/ml at 6, 8 and 10 DFSO, respectively.

For severe COVID-19, regression analysis showed, in the LRT, comparable mean rVLs at 4 DFSO between younger and older adults (P for intercept = 0.745) (**Figure 3C**). Both severe age cohorts also showed persistent LRT shedding in the analyzed period: younger adults (-0.20 [95% CI, -0.32 to 0.042] \log_{10} copies/ml day⁻¹, P = 0.105) and older adults (-0.13 [95% CI, -0.39 to 0.13] \log_{10} copies/ml day⁻¹, P = 0.316) both had no significant trend in SARS-CoV-2 clearance. Likewise, severely affected male cases had no significant trend in LRT shedding (0.001 [95%

CI, -0.16 to 0.19] \log_{10} copies/ml day⁻¹, $P = 0.988$). The female cohort included few samples, and statistically analyses were not conducted (**Appendix Table 3**).

Interestingly, nonsevere cases showed similar SARS-CoV-2 shedding between the URT and LRT, whereas severe cases shed greater and longer in the LRT than the URT (**Figure 3, D and E**). At 4 DFSO, the URT rVL of nonsevere adults was 6.62 (95% CI, 6.50-6.74) \log_{10} copies/ml, which was not different from the LRT rVL of nonsevere adults (P for intercept = 0.651). In contrast, at 4 DFSO, the URT rVL of severe adults (7.34 [95% CI, 7.01-7.68] \log_{10} copies/ml) was significantly lower than the LRT rVL of severe adults (P for intercept = 0.031).

Comparison of URT Shedding between Adult and Pediatric COVID-19

For the pediatric cohort, regression estimated, in the URT, the mean rVL at 1 DFSO to be 7.32 (95% CI, 6.78-7.86) \log_{10} copies/ml and SARS-CoV-2 clearance rate as -0.32 (95% CI, -0.42 to -0.22) \log_{10} copies/ml day⁻¹ (**Figure 4A**). Both estimates were comparable between the sexes for children (**Figure 4D**). The estimated mean duration of URT shedding (down to 0 \log_{10} copies/ml) was 22.6 (95% CI, 17.0-28.1) DFSO for children with COVID-19.

Between pediatric cases, who had nonsevere illness in our dataset, and adults with nonsevere illness, both URT shedding at 1 DFSO (P for intercept = 0.653) and URT dynamics (P for interaction = 0.400) were similar (**Figure 4A**). Distributions of rVL were also comparable between these cohorts (**Figure 4B**). Conversely, URT shedding at 1 DFSO was greater for severely affected adults when compared to nonsevere pediatric cases (P for intercept = 0.017), but URT dynamics remained similar (P for interaction = 0.863) (**Figure 4C**).

DISCUSSION

Our study systematically developed a dataset of COVID-19 case characteristics and rVLs and conducted stratified analyses on SARS-CoV-2 shedding post-symptom onset. In the URT, we found that adults with severe COVID-19 showed higher rVLs shortly after symptom onset, but similar SARS-CoV-2 clearance rates, when compared with their nonsevere counterparts. In the LRT, we found that high, persistent shedding was associated with severe COVID-19, but not nonsevere illness, in adults. Interestingly, in the analyzed periods, adults with severe disease tended to have higher rVLs in the LRT than the URT.

After stratifying for disease severity, we found that sex and age had nonsignificant effects on post-symptom-onset SARS-CoV-2 shedding levels and dynamics for each included analysis (summarized in **Table 2**). Thus, while sex and age influence the tendency to develop severe COVID-19 (2-4), we find no such sex dimorphism or age distinction in URT shedding among cases of similar severity. This includes children, who had nonsevere illness in our study and show similar URT shedding post-symptom onset as adults with nonsevere illness.

Notably, our analyses indicate that high, persistent LRT shedding of SARS-CoV-2 characterizes severe COVID-19 in adults. This suggests that the effective immune responses associated with milder COVID-19, including innate, cross-reactive and coordinated adaptive immunity (5-9), do not significantly inhibit early, or prolonged, SARS-CoV-2 replication in the LRT of severely affected adults. Hence, uncontrolled LRT replication tends to continue, at least, to 10 DFSO, coinciding with the timing of clinical deterioration (median, 10 DFSO) (2, 49). Furthermore, the bifurcated profiles of LRT shedding concur with the observed severity-associated differences in lung pathology, in which severe cases show hyperinflammation and progressive loss of epithelial-endothelial integrity (50-52).

Our results suggest that rVL may be a key prognostic indicator in SARS-CoV-2 infection. They reinforce that severe COVID-19 is associated with greater rVLs than nonsevere illness (12-14), and suggest that sex and age may not significantly influence prognostic thresholds. In the URT, both nonsevere and severe cases tend to clear SARS-CoV-2 at comparable rates. Thus, time course of disease (e.g., DFSO) should be considered alongside rVL, rather than simply employing rVL at admission. LRT shedding, however, bifurcates considerably between nonsevere and severe COVID-19, meaning that SARS-CoV-2 quantitation from the LRT may more accurately predict severity. While URT specimens are typically used to diagnose COVID-19, LRT specimens (our study predominantly analyzed sputum) may be collected from high-risk patients for severity prognostication.

While our analyses did not account for virus infectivity, higher SARS-CoV-2 rVL is associated with a higher likelihood of culture positivity, from adults (15, 16) as well as children (36), and higher transmission risk (10). Hence, our results suggest that infectiousness increases with COVID-19 severity, concurring with epidemiological analyses (53, 54). They also suggest that adult and pediatric infections of similar severity have comparable infectiousness, reflecting epidemiological findings on age-based infectiousness (54-56). Moreover, since respiratory aerosols are typically produced from the LRT (57), severe SARS-CoV-2 infections may have increased, and extended, risk for aerosol transmission. As severe cases tend to be hospitalized, this provides one possible explanation for the elevated risk of COVID-19 among healthcare workers in inpatient settings (58); airborne precautions, such as the use of N95 or air-purifying respirators, should be implemented around patients with COVID-19.

Our study has limitations. First, while our study design systematically developed a large, diverse dataset, there were few severe female cases with LRT specimens and no severe pediatric

cases included. Statistical comparisons involving these cohorts were not conducted based on increased sensitivity to sampling bias, as COVID-19 presents broad heterogeneity in rVL. Additional studies should permit these remaining comparisons. Second, our analyses did not assess the influence of therapies or additional case characteristics, including comorbidities. While the relationships between some comorbidities and SARS-CoV-2 kinetics remain unclear, recent studies indicate many potential therapies (e.g., remdesivir, hydroxychloroquine, lopinavir, ritonavir, low-dose monoclonal antibodies and ivermectin) have no significant anti-SARS-CoV-2 effects in patients (59-64). Third, the systematic dataset consisted largely of hospitalized patients, and our results may not generalize to asymptomatic infections.

In summary, our findings provide insight into SARS-CoV-2 kinetics and describe virological factors that distinguish severe COVID-19 from nonsevere illness. They show that high, persistent LRT shedding characterizes severe disease in adults, highlighting the potential prognostic utility of SARS-CoV-2 quantitation from LRT specimens. Lastly, each study identified by our systematic review collected specimens before October 2020. As widespread transmission of the emerging variants of concern likely occurred after this date (65, 66), our study presents a quantitative resource to assess the effects of their mutations on respiratory shedding levels and dynamics.

541 **Table 1.** Characteristics of adult and pediatric COVID-19 cases

	Adult	Pediatric
Cases, <i>n</i>	1 266	136
URT specimens, <i>n</i>	1 513	192
LRT specimens, <i>n</i>	210	0
Mean age (SD), <i>y</i>	51.8 (18.0)	8.7 (5.3)
Male, <i>n</i> (%)	528 (44.0)	63 (52.5)
Disease severity, <i>n</i> (%)		
Asymptomatic	2 (0.2)	5 (3.7)
Mild	710 (57.5)	112 (83.6)
Moderate	178 (14.4)	17 (12.7)
Severe	167 (13.5)	0 (0.0)
Critical	178 (14.4)	0 (0.0)

542 LRT = lower respiratory tract; URT = upper respiratory tract.

543 The table summarizes collected case characteristics in the systematic dataset. Adult cases were

544 those aged 18 y or older, while pediatric cases were those aged younger than 18 y.

Table 2. Summary of statistical comparisons on SARS-CoV-2 shedding, across the respiratory tract, COVID-19 severity, sex and age cohorts

Group 1	Group 2	P value*	
		Intercept†	Interaction‡
URT, ≥18 y			
Nonsevere	Severe	0.005*	0.479
Female (nonsevere)	Male (nonsevere)	0.085	0.644
Female (severe)	Male (severe)	0.326	0.280
Nonsevere (18-59 y)	Nonsevere (≥60 y)	0.294	0.100
Severe (18-59 y)	Severe (≥60 y)	0.915	0.359
LRT, ≥18 y §			
Nonsevere	Severe	0.006*	0.053
Severe (18-59 y)	Severe (≥60 y)	0.745	0.716
URT vs. LRT, ≥18 y			
Nonsevere (URT, ≥18 y)	Nonsevere (LRT, ≥18 y)	0.651	0.231
Severe (URT, ≥18 y)	Severe (LRT, ≥18 y)	0.031*	0.151
URT, 0-17 y			
Nonsevere (0-17 y)	Nonsevere (≥18 y)	0.653	0.400
Nonsevere (0-17 y)	Severe (≥18 y)	0.017*	0.863
Female (nonsevere)	Male (nonsevere)	0.667	0.333

COVID-19 = coronavirus disease 2019; DFSO = days from symptom onset; LRT = lower

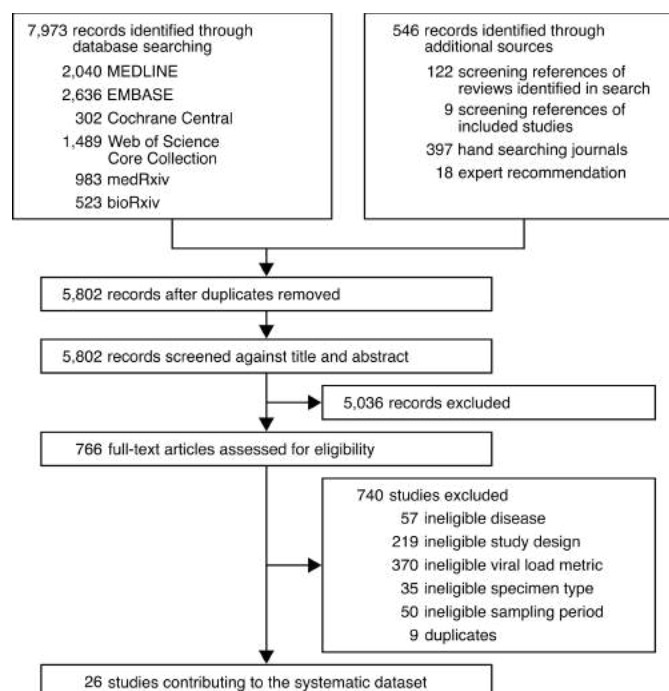

respiratory tract; nonsevere = asymptomatic, mild and moderate COVID-19; rVL = respiratory viral load; severe = severe and critical COVID-19; URT = upper respiratory tract.

* $P < 0.05$. Each regression analysis was shown in **Figures 2 to 4**.

† P value for the intercept in regression analysis compares the mean rVLs at 1 DFSO for the URT or, for any analyses including the LRT, at 4 DFSO.

‡ P value for interaction in regression analysis describes the difference in respiratory shedding dynamics along the time course of disease.

§ There were small sample sizes in the nonsevere cohorts and female (LRT, severe, ≥18 y) cohort, and these analyses were not included.

558

559 **Figure 1.** Study selection.

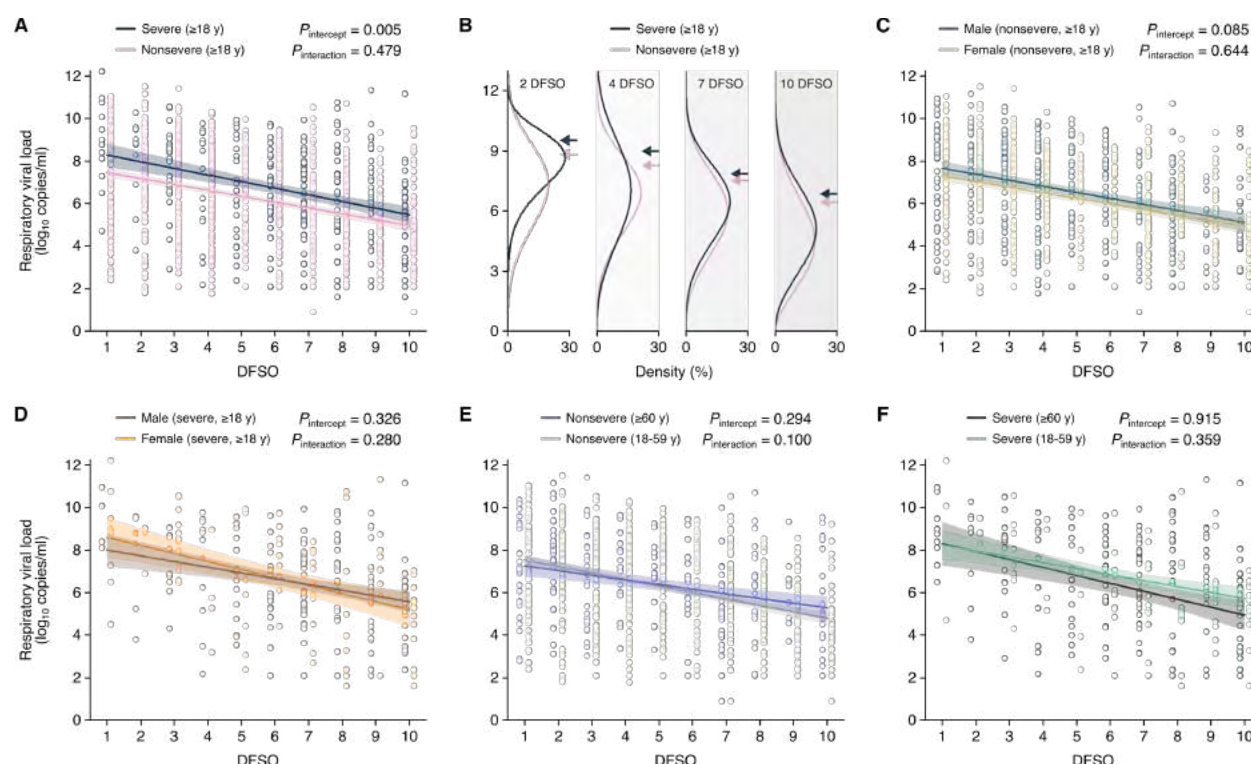

Figure 2. Comparison of SARS-CoV-2 shedding in the adult URT, across disease severity, sex and age cohorts.

COVID-19 = coronavirus disease 2019; DFSO = days from symptom onset; nonsevere = asymptomatic, mild and moderate COVID-19; rVL = respiratory viral load; SARS-CoV-2 = severe acute respiratory syndrome coronavirus 2; severe = severe and critical COVID-19; URT = upper respiratory tract.

A and B. Regression analysis (A) and estimated distributions at 2, 4, 7 and 10 DFSO (B) of URT shedding for severe and nonsevere adult (aged 18 y or older) COVID-19. Arrows denote rVLs for the 80th case percentiles, in terms of rVL, for each age group. **C and D.** Regression analyses comparing URT shedding between sexes for nonsevere (C) and severe (D) adult COVID-19. **E and F.** Regression analyses comparing URT shedding between age cohorts (aged 18-59 y and 60

574 y or older) for nonsevere (E) and severe (F) adult COVID-19. Open circles represent rVL data
 575 and were offset from their DFSO for visualization. Lines and bands show regressions and their
 576 95% CIs, respectively. *P* values for the intercept compare the rVLs at 1 DFSO. *P* values for
 577 interaction compare shedding dynamics.

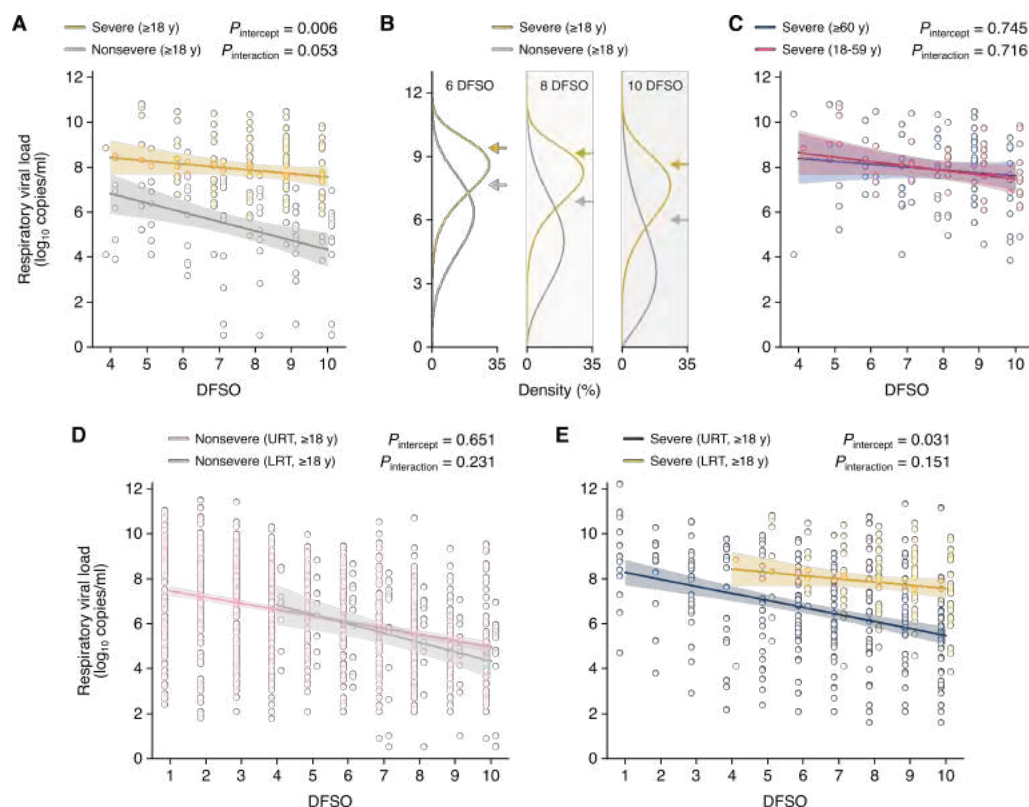

Figure 3. Comparison of SARS-CoV-2 shedding in the adult LRT, across disease severity, age and with shedding in the adult URT.

COVID-19 = coronavirus disease 2019; DFSO = days from symptom onset; LRT = lower respiratory tract; nonsevere = asymptomatic, mild and moderate COVID-19; rVL = respiratory viral load; SARS-CoV-2 = severe acute respiratory syndrome coronavirus 2; severe = severe and critical COVID-19; URT = upper respiratory tract.

A and B. Regression analysis (A) and estimated distributions at 6, 8 and 10 DFSO (B) of LRT shedding for severe and nonsevere adult (aged 18 y or older) COVID-19. Arrows denote rVLs for the 80th case percentiles, in terms of rVL, for each age group. **C.** Regression analyses comparing LRT shedding between age cohorts (aged 18-59 y and 60 y or older) for severe adult

591 COVID-19. **D** and **E**. Regression analyses comparing URT and LRT shedding for nonsevere (D)
 592 and severe (E) adult COVID-19. Open circles represent rVL data and were offset from their
 593 DFSO for visualization. Lines and bands show regressions and their 95% CIs, respectively. *P*
 594 values for the intercept compare the rVLs at 4 DFSO. *P* values for interaction compare shedding
 595 dynamics.

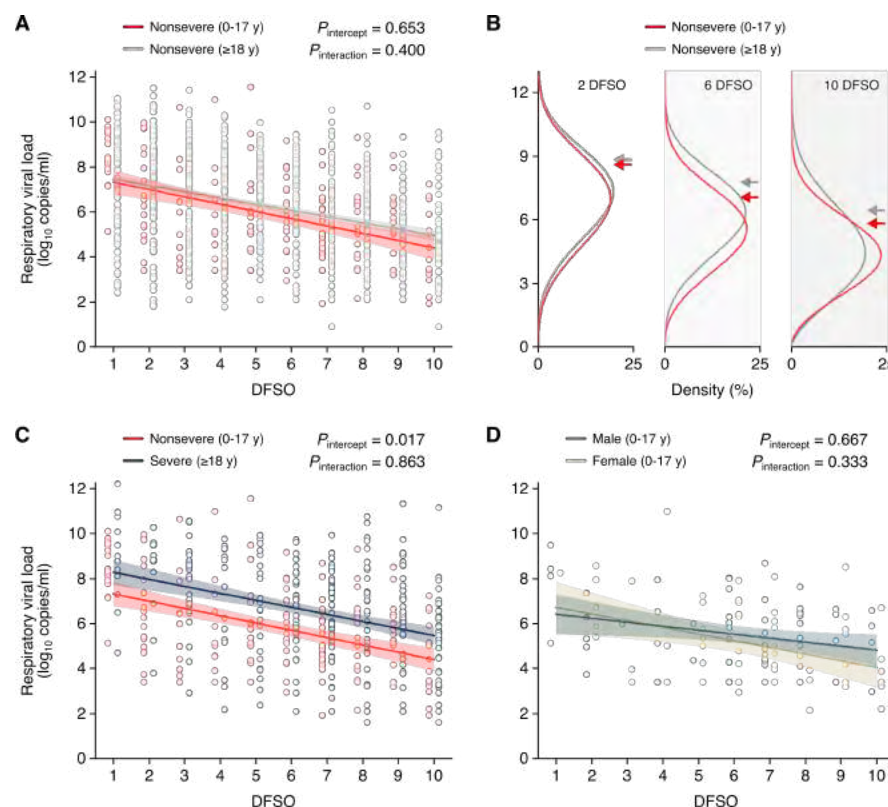

Figure 4. URT shedding of SARS-CoV-2 in pediatric COVID-19, compared with adults and across sex.

COVID-19 = coronavirus disease 2019; DFSO = days from symptom onset; nonsevere = asymptomatic, mild and moderate COVID-19; rVL = respiratory viral load; SARS-CoV-2 = severe acute respiratory syndrome coronavirus 2; severe = severe and critical COVID-19; URT = upper respiratory tract.

A and B. Regression analysis (A) and estimated distributions at 2, 6, and 10 DFSO (B) of URT shedding for children (aged 0-17 y) with nonsevere COVID-19 and adults (aged 18 y or older) with nonsevere illness. Arrows denote rVLs for the 80th case percentiles, in terms of rVL, for each cohort. **C.** Regression analysis comparing URT shedding between nonsevere pediatric and

609 severe adult COVID-19. **D.** Regression analysis comparing URT shedding between sexes for
 610 pediatric cases. Open circles represent rVL data and were offset from their DFSO for
 611 visualization. Lines and bands show regressions and their 95% CIs, respectively. *P* values for the
 612 intercept compare the rVLs at 1 DFSO. *P* values for interaction compare shedding dynamics.

Article Information

Group Information: A complete list of the members of the Taiwan COVID-19 Outbreak Investigation Team appears at the end of this article.

Accepted for Publication: April 21, 2020.

Published Online: May 1, 2020. doi:10.1001/jamainternmed.2020.2020

Correction: This article was corrected on September 8, 2020, to fix transposed numbers of men and women study participants in the Abstract and in the Results section; an error in the definition of serial interval in the Introduction; the misspelling of 2 names in the Group Information section; and typographical data errors in the Supplement.

Open Access: This is an open access article distributed under the terms of the [CC-BY License](#). © 2020 Cheng H-Y et al. *JAMA Internal Medicine*.

Corresponding Author: Hsien-Ho Lin, MD, ScD, National Taiwan University, 17 Xuzhou Rd, Taipei 100, Taiwan (hsienho@ntu.edu.tw).

Author Contributions: Drs Cheng and Lin had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis.

Concept and design: Cheng, Jian, Huang, Lin.

Acquisition, analysis, or interpretation of data: All authors.

Drafting of the manuscript: Cheng, Jian, Ng, Lin.

Critical revision of the manuscript for important intellectual content: Cheng, Jian, Liu, Huang, Lin.

Statistical analysis: Cheng, Jian, Ng, Lin.

Obtained funding: Lin.

Administrative, technical, or material support: Jian, Liu, Ng, Huang, Lin.

Supervision: Liu, Huang, Lin.

Conflict of Interest Disclosures: None reported.

Funding/Support: The study was funded by Taiwan Ministry of Science and Technology (MOST 107-2314-B-002-187-MY2 and MOST 108-2628-B-002-022).

Role of the Funder/Sponsor: The funder had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication.

Group Information: The Taiwan COVID-19 Outbreak Investigation Team members include the following: Taiwan CDC: Office of Preventive Medicine and Taiwan Field Epidemiology Training Program: Wan-Ting Huang, Wan-Chin Chen, Angela Song-En Huang, Chia-Ping Su, Pin-Hui Lee, Pei-Chun Chan, Hao-Hsin Wu, Shih-Tse Huang, Tsung-Pei Tsou, Ying-Shih Su, and Yang Li. Taipei Regional Control Center: Hsin-Yi Wei, Meng-Yu Chen, Shiao-Ping Tung, Yu-Fang Tsai, Xiang-Ting Huang, and Chien-Yu Chou. North Regional Control Center: Pei-Yuan Wu, Fang-Tzu Chang, Chia-Ying Yen, Hsueh-Mei Chiang, Ju-Hui Lin, and Ming-Chu Tai. Central Regional Control Center: Kung-Chin Wang, Ching-Fen Ko, Pei-Fang Lai, Du-Ling Lin, Min-Tsung Lin, and Zhi-Jie Ding. South Regional Control Center: Huai-Te Tsai, Ping-Jung Liu, Pei-Yi Lin, Shu-Chen Chang, and Yi-Ying Lin. Kao-Ping Regional Control Center: Hsin-Chun Lee, Chi-Nan Hung, Ching-Li Lin, Chi-Mei Lai, and Hsiao-Mei Liu.

Additional Contributions: We thank the Taiwan COVID-19 Outbreak Investigation Team, the staffs of regional control centers of the Taiwan Centers for Disease Control (CDC), and partners from other public health bureaus (Taipei City, New Taipei City, Taoyuan City, Taichung City, Tainan City, Kaohsiung City, Changhua, Nantou, Hsinchu, Miaoli, Yunlin, and Ilan County) for their dedicated outbreak investigation and meticulous data collection. Our study could not have been done without their efforts. We also thank Chia-Lin Lee, MSc, and Yu-Lun Liu, MD, MSc, for the development of electronic contact tracing system (Epidemic Intelligence Center, Taiwan CDC); Ching-Hung Wang (TonyQ) for the consultation of system development; Angela Song-En Huang, MD, MPH (Office of Preventive Medicine, Taiwan CDC), for writing assistance. They did not receive compensation outside of their salary.

Key Points

Question

What is the transmissibility of coronavirus disease 2019 (COVID-19) to close contacts?

Findings

In this case-ascertained study of 100 cases of confirmed COVID-19 and 2761 close contacts, the overall secondary clinical attack rate was 0.7%. The attack rate was higher among contacts whose exposure to the index case started within 5 days of symptom onset than those who were exposed later.

Meaning

High transmissibility of COVID-19 before and immediately after symptom onset suggests that finding and isolating symptomatic patients alone may not suffice to interrupt transmission, and that more generalized measures might be required, such as social distancing.

Abstract

Importance

The dynamics of coronavirus disease 2019 (COVID-19) transmissibility are yet to be fully understood. Better understanding of the transmission dynamics is important for the development and evaluation of effective control policies.

Objective

To delineate the transmission dynamics of COVID-19 and evaluate the transmission risk at different exposure window periods before and after symptom onset.

Design, Setting, and Participants

This prospective case-ascertained study in Taiwan included laboratory-confirmed cases of COVID-19 and their contacts. The study period was from January 15 to March 18, 2020. All close contacts were quarantined at home for 14 days after their last exposure to the index case. During the quarantine period, any relevant symptoms (fever, cough, or other respiratory symptoms) of contacts triggered a COVID-19 test. The final follow-up date was April 2, 2020.

Main Outcomes and Measures

Secondary clinical attack rate (considering symptomatic cases only) for different exposure time windows of the index cases and for different exposure settings (such as household, family, and health care).

Results

We enrolled 100 confirmed patients, with a median age of 44 years (range, 11-88 years), including 44 men and 56 women. Among their 2761 close contacts, there were 22 paired index-secondary cases. The overall secondary clinical attack rate was 0.7% (95% CI, 0.4%-1.0%). The attack rate was higher among the 1818 contacts whose exposure to index cases started within 5 days of symptom onset (1.0% [95% CI, 0.6%-1.6%]) compared with those who were exposed later (0 cases from 852 contacts; 95% CI, 0%-0.4%). The 299 contacts with exclusive presymptomatic exposures were also at risk (attack rate, 0.7% [95% CI, 0.2%-2.4%]). The attack rate was higher among household (4.6% [95% CI, 2.3%-9.3%]) and nonhousehold (5.3% [95% CI, 2.1%-12.8%]) family contacts than that in health care or other settings. The attack rates were higher among those aged 40 to 59 years (1.1% [95% CI, 0.6%-2.1%]) and those aged 60 years and older (0.9% [95% CI, 0.3%-2.6%]).

Conclusions and Relevance

In this study, high transmissibility of COVID-19 before and immediately after symptom onset suggests that finding and isolating symptomatic patients alone may not suffice to contain the epidemic, and more generalized measures may be required, such as social distancing.

Introduction

The coronavirus disease 2019 (COVID-19) outbreak that originated in Wuhan, China, spread to more than 100 countries within 2 months of when the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) was identified in January 2020.^{1,2} Following the Wuhan lockdown and other extreme social-distancing

measures conducted by the Chinese government, several countries with widespread outbreaks implemented similar measures, including shutting down entire cities or communities, banning international or domestic travel, conducting border control with symptom screening, and implementing isolation and quarantine.

The unknown epidemiologic characteristics and transmission dynamics of a novel pathogen, such as SARS-CoV-2, complicate the development and evaluation of effective control policies.³ The serial interval of COVID-19, defined as the interval between the symptom onset of the index case and that of the secondary case, was found to be short (4-5 days) and was similar to the estimated incubation period.⁴ The short serial interval of COVID-19 and results from viral shedding studies suggested that most transmission occurred near or even before the time of symptom onset.^{4,5,6} On the other hand, prolonged viral shedding raised concerns about prolonged infectiousness of patients and the need for extended isolation. A few preliminary contact-tracing studies showed that the highest-risk exposure setting of COVID-19 transmission was the household.^{7,8,9} Nevertheless, it is not known when and how long a patient with COVID-19 should be isolated or whether close contacts should be quarantined. Additional information is needed about the transmission risk at different time points before and after symptom onset and with different types of exposures, such as through the household or a health care facility.

In Taiwan, the first COVID-19 case was confirmed on January 21, 2020.¹⁰ With proactive containment efforts and comprehensive contact tracing, the number of COVID-19 cases remained low, as compared with other countries that had widespread outbreaks.^{11,12} Using the contact tracing data in Taiwan, we aimed to delineate the transmission dynamics of COVID-19, evaluate the infection risk at different exposure windows, and estimate the infectious period.

Methods

Study Population

On January 15, 2020, in response to the outbreak in Wuhan, the Taiwan Centers for Disease Control (Taiwan CDC) made COVID-19 a notifiable disease. We conducted a prospective case-ascertained study that enrolled all the initial 100 confirmed cases in Taiwan between January 15 and March 18, 2020, and their close contacts. All contacts were followed up until 14 days after the last exposure to the index case. The last follow-up date was April 2, 2020.

The study followed the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) reporting guideline.¹³ Information was collected according to the pronouncement of the Central Epidemic Command Center and in accordance with Article 17 of the Communicable Disease Control Act.¹⁴ As part of the public health response functions of the Central Epidemic Command Center for surveillance purposes, institutional review board approval of this study and informed consent were waived. Prior to analysis, the data were deidentified.

Ascertainment of Cases

A confirmed case met the criteria of notification for COVID-19 in Taiwan and tested positive by real-time reverse transcriptase–polymerase chain reaction (RT-PCR) test.¹⁵ Detailed information, including demographic and clinical data, was reported to the National Notifiable Disease Surveillance System.¹⁶ The investigation team determined the clinical severity of the confirmed patients following the World Health Organization (WHO) interim guidance.¹⁷

Contact Tracing for COVID-19

When a patient was laboratory-confirmed to have SARS-CoV-2 infection, a thorough epidemiological investigation, including contact tracing, was implemented by the outbreak investigation team of the Taiwan CDC and local health authorities. The period of investigation started at the date at symptom onset (and could be extended to up to 4 days before symptom onset when epidemiologically indicated) and ended at the date at COVID-19 confirmation. For asymptomatic confirmed cases, the period of investigation was based on the date at confirmation (instead of date at onset) and was determined according to epidemiological investigation. The definition of a close contact was a person who did not wear appropriate personal protection equipment (PPE) while having face-to-face contact with a confirmed case for more than 15 minutes during the investigation period. A contact was listed as a household contact if he or she lived in the same household with the index case. Those listed as family contacts were family members not living in the same household.

For health care settings, medical staff, hospital workers, and other patients in the same setting were included; close contact was defined by contacting an index case within 2 m without appropriate PPE and without a minimal requirement of exposure time. Whether the PPE was regarded as “appropriate” depended on the exposure setting and the procedures performed. For example, for physicians who performed aerosol-generating procedures, such as intubation, an N95 respirator was required. For such procedures, a surgical mask would not be appropriate PPE. Accordingly, the medical staff would be listed as a close contact.

All close contacts were quarantined at home for 14 days after their last exposure to the index case. During the quarantine period, any relevant symptoms (fever, cough, or other respiratory symptoms) of close contacts would trigger RT-PCR testing for COVID-19. For high-risk populations, including household and hospital contacts, RT-PCR was performed regardless of symptoms. Essentially, these high-risk contacts were tested once when they were listed as a close contact. If the initial COVID-19 test result was negative, further testing would only be performed if a close contact developed symptoms during quarantine. The Taiwan CDC used an electronic tracing system (Infectious Disease Contact Tracing Platform and Management System) to follow and record the daily health status of those quarantined contacts.¹⁸ The information collected included age, sex, the index case, date at exposure, and the exposure setting.

Data Processing and Analysis

Paired data of index case and close contacts were extracted from the contact tracing database and outbreak investigation reports. For a family cluster, the index case was determined based on the temporality of symptom onset and review of the epidemiological link. A secondary case was excluded from the paired data if the beginning of exposure was after symptom onset of the secondary case (only applied when the secondary case was symptomatic). For health care contacts, the date at exposure would be the date at admission of the case if the exact date at exposure was not recorded.

Incubation period and serial interval were estimated using the contact tracing data in Taiwan and publicly available data sets globally (eMethods in the [Supplement](#)). We used the Bayesian hierarchical model to increase the stability in small-sample estimation. The exposure window period was defined as the period between the first and last day of reported exposure to the index case based on contact investigation. Following the WHO, we defined the secondary clinical attack rate as the ratio of symptomatic confirmed cases among the close contacts.¹⁹ We analyzed the dynamic change of secondary clinical attack rate in relation to symptom onset of the index case (days <0, 0-3, 4-5, 6-7, 8-9, or >9).

The percentage of missing information was small (7.0% for age, 6.1% for sex, and 3.3% for time from onset to exposure; [Table 1](#)). In the univariable analysis of secondary clinical attack rate by different exposure characteristics (eg, age), close contacts with missing information in that particular exposure

attribute were excluded. All statistical tests were 2-sided with an α level of .05. All confidence intervals (CIs) were 95%. R software (R Foundation for Statistical Computing) and RStan (Stan Development Team) were used for data management and analysis.

Results

As of March 18, 2020, there were 100 patients with laboratory-confirmed COVID-19 in Taiwan, including 10 clusters of patients and 9 asymptomatic patients. The median age of the 100 patients was 44 years old (range, 11-88 years); 44 were men and 56 were women. Of the 2761 close contacts that were identified, 5.5% were household contacts, 2.8% were non-household family contacts, and 25.3% were health care contacts ([Table 1](#)). Through contact tracing, 23 secondary cases were found. One of the 23 cases was excluded from subsequent transmission-pair analysis because the documented day at exposure occurred after symptom onset of the secondary case. None of the 9 asymptomatic case patients transmitted a secondary case. Using the data on the 22 paired cases, we estimated that the median incubation period was 4.1 days (95% credible interval [CrI], 0.4-15.8), and the median serial interval was 4.1 days (95% CrI, 0.1-27.8) (eTables 1-5 and eFigures 1-5 in the [Supplement](#)).

Among the 2761 close contacts, 22 secondary cases of COVID-19 infection (including 4 asymptomatic infections) were detected, with an infection risk of 0.8% (95% CI, 0.5%-1.2%). The secondary clinical attack rate was 18 of 2761, or 0.7% (95% CI, 0.4%-1.0%). [Figure 1](#) shows the exposure window of all contacts. All of the 22 secondary cases had their first exposure before the sixth day of the index case's symptom onset. By comparison, only 68% of noncase contacts had their first exposure before day 6 ([Table 1](#)). The secondary clinical attack rate was higher among those whose initial exposure to the index case was within 5 days of symptom onset than those who were exposed after day 6 (zero transmission of 852 contacts [95% CI, 0%-0.4%]) ([Table 2](#) and [Figure 2A](#)). The 735 contacts whose initial exposure occurred before symptom onset of the index case were also at risk, with a secondary clinical attack rate of 1.0% (95% CI, 0.5%-2.0%). A subgroup of 299 contacts with exclusive presymptomatic exposures were also at risk (secondary clinical attack rate, 0.7% [95% CI, 0.2%-2.4%]).

The secondary clinical attack rate was 4.6% (95% CI, 2.3%-9.3%) among 151 household contacts and 5.3% (95% CI, 2.1%-12.8%) in 76 nonhousehold family contacts ([Table 2](#)). The high attack rate from early exposure remained when the analysis was restricted to household and nonhousehold family contacts ([Table 3](#) and [Figure 2B](#)). The attack rates were higher among those aged 40 to 59 years (1.1% [95% CI, 0.6%-2.1%]) and those aged 60 years and older (0.9% [95% CI, 0.3%-2.6%]). The 786 close contacts of the 6 confirmed cases presenting with severe disease were at a higher risk compared with the 1097 close contacts of the 56 cases presenting with mild disease (risk ratio, 3.76 [95% CI, 1.10-12.76] and 3.99 [95% CI, 1.00-15.84] for severe pneumonia and acute respiratory distress syndrome/sepsis, respectively). Among the 91 close contacts of the 9 asymptomatic cases, no secondary transmission was observed. The secondary attack rate among contacts of cases with infection acquired in Taiwan was higher than that among contacts of cases with infection acquired outside of Taiwan ([Table 2](#)).

Discussion

Our analysis of close contacts to confirmed COVID-19 cases revealed a relatively short infectious period of COVID-19 and a higher transmission risk around the time of symptom onset of the index case, followed by a lower transmission risk at the later stage of disease. The observed decreasing transmission risk over time for COVID-19 was in striking contrast to the transmission pattern of severe acute respiratory syndrome (SARS), in which the transmission risk remained low until after day 5 of symptom onset in the index cases.²⁰ Our study and the study by Nishiura et al⁴ revealed a short serial interval of COVID-19, with a median of 4 to 5 days. In contrast, the mean serial interval of SARS was estimated to be 8.4 days in Singapore.²⁰ The present contact tracing analysis suggested that the shorter serial interval of COVID-19 was due to the combination of early-stage transmission and a short period of infectiousness.

The observed pattern of the secondary clinical attack rate over time was also consistent with the quantitative data of the SARS-CoV-2 viral shedding in upper respiratory specimens, which has been found in China to be a high viral load around the time of symptom onset, followed by a gradual decrease in viral shedding to a low level after 10 days.⁵ The viral load was similar among asymptomatic, minimally symptomatic, and symptomatic patients. Another virological study in patients with COVID-19 in Germany also found no viable isolates of the virus after the first week of symptoms.²¹ Our findings agree with the virological data on high transmissibility of COVID-19 in the first week after the onset of symptoms and decreased risk afterwards.²¹ We also documented and quantified the transmission potential of COVID-19 in a subgroup of contacts whose exposure occurred exclusively during the presymptomatic period of the index case. Our analysis revealed a similar clinical attack rate between the contacts who only had presymptomatic exposure and those who had postsymptomatic exposure.

To summarize the evidence, the decreasing risk for secondary infection over time in our study, the observed short serial interval, and the trend of decreasing viral shedding and viability after symptom onset strongly suggested high transmissibility of the disease near or even before the day of symptom onset. Because the onset of overt clinical symptoms, such as fever, dyspnea, and signs of pneumonia, usually occurred 5 to 7 days after initial symptom onset, the infection might well have been transmitted at or before the time of detection.^{22,23} This characteristic makes containment efforts challenging. In a modeling study, Hellewell et al²⁴ found that the possibility of controlling COVID-19 through isolation and contact tracing decreased with increasing proportion of transmission that occurred before symptom onset. The findings of this modeling study, when viewed in the context of our findings, might help to explain the difficult situation in such areas and countries as China, South Korea, Iran, and Italy. Aggressive social distancing and proactive contact tracing might be necessary to block the transmission chain of COVID-19 and to keep presumptive patients away from susceptible populations with a high risk for severe disease.

The observed short duration of infectiousness with lower risk of transmission 1 week after symptom onset has important implications for redirecting the efforts to control COVID-19. Given the nonspecific and mostly mild symptoms of COVID-19 at presentation, patients are often identified and hospitalized at a later stage of disease when the transmissibility of infection has started to decrease. In this case, hospitalization would not be helpful for isolation and reducing transmission, and should be only for patients whose clinical course is sufficiently severe. When the number of confirmed cases rapidly increases, home care for patients with mild illness may be preferred.²⁵ In Taiwan (where patients with COVID-19 have been routinely hospitalized), the most prolonged duration of hospital isolation for the 100 confirmed cases was more than 2 months. If every patient with mild illness is to be isolated in the hospital or other isolation facilities for such a prolonged period during a large epidemic, the health care system would soon be overwhelmed, and the case-fatality rate may increase, as observed in Wuhan.^{26,27} Similarly, better understanding of the potential duration of transmission could help direct containment strategies. For example, contact tracing could focus on the contacts near or even before symptom onset of the index cases when the number of index cases or contacts is too large for all contacts to be traced, given the available resources.

Several patients in our study were initially considered to have pneumonia of unknown etiology and had multiple contacts in the health care setting before being diagnosed. However, the number of health care contacts that led to nosocomial transmission was low. Besides the basic PPE used by medical staffs, this finding might be due to the late admissions of these patients and their lower risk of transmitting COVID-19 by the time of hospitalization. This pattern is compatible with the observations in China and Hong Kong. In China, the number of nosocomial infections might be lower than reported because some health care workers acquired infections in their households rather than in the health care facility.⁹ In Hong Kong, most hospitalization was also delayed to at least 5 days after disease onset.²⁸ In closed settings such as a hospital or a cruise ship,^{29,30} fomite transmission might play an important role, amplifying the risk of

transmission and making the temporality of transmission less identifiable.^{30,31,32} Better understanding of the dynamic change of transmissibility of COVID-19 over time and how health care workers are most likely to be infected could allow for better targeting of control measures, including the use of appropriate PPE.

In the contact tracing cohort, we observed a relatively low transmission rate of COVID-19. During the study period (January to early March 2020), the major containment measures in Taiwan were travel alerts with restriction to affected countries (principally China), home quarantine for travelers entering Taiwan, and comprehensive contact tracing for confirmed cases.¹¹ In response to a possible shortage of face masks, the government proactively initiated a name-based rationing system for mask purchase and boosted the production of face masks to ensure the availability for both N95 respirators and face masks to both health care professionals and the general public. A general recommendation on social distancing from the government was not in place, but spontaneous behavioral changes that reduced community mobility were observed.³³

Limitations

Our study has limitations. First, we did not completely examine contacts before the symptom onset of the index cases. Therefore, we might have underestimated the importance of early transmission. Thus, the actual contribution of early transmission to new infections could be greater than our estimates suggests. Our findings agree with the recommendation from the WHO to use 4 days before symptom onset as the starting date for contact tracing.¹⁹ This modification may help to further understand the pattern of early transmission in COVID-19. Second, we could not completely separate out the effect of close household contact and early contact given the strong correlation of the 2. The increased transmissibility in the early stage of COVID-19 may be partially attributed to the effect of household and nonhousehold family contacts rather than increased infectiousness at the early stage. When we stratified by type of exposure, however, the pattern of early transmission remained.

Conclusions

In summary, the findings of this study suggest that most transmission of COVID-19 occurred at the very early stage of the disease or even before the onset of symptoms, and the secondary clinical attack rate among contacts decreased over time as symptoms developed and progressed. The pattern of high transmissibility near and before symptom onset and the likely short infectious period of the virus could inform control strategies for COVID-19, as well as additional studies to fully elucidate the transmission dynamics of the virus.

Abstract

Background: Influenza results in up to 500,000 deaths annually. Seasonal influenza vaccines have an estimated 60% effectiveness, but provide little or no protection against novel subtypes, and may be less protective in high-risk groups. Neuraminidase inhibitors are recommended for the treatment of severe influenza infection, but are not proven to reduce mortality in severe disease. Preclinical models of severe influenza infection that closely correlate to human disease are needed to assess efficacy of new vaccines and therapeutics.

Methods: We developed a nonhuman primate model of influenza and bacterial co-infection that re-capitulates severe pneumonia in humans. Animals were infected with influenza A virus via intra-bronchial or small-particle aerosol inoculation, methicillin-resistant *Staphylococcus aureus*, or co-infected with influenza and methicillin-resistant *S. aureus* combined. We assessed the severity of disease in animals over the course of our study using tools available to evaluate critically ill human patients including high-resolution computed tomography imaging of the lungs, arterial blood gas analyses, and bronchoalveolar lavage.

Results: Using an intra-bronchial route of inoculation we successfully induced severe pneumonia following influenza infection alone and following influenza and bacterial co-infection. Peak illness was observed at day 6 post-influenza infection, manifested by bilateral pulmonary infiltrates and

Appendix A. Supplementary data

Supplementary data related to this article can be found at <http://dx.doi.org/10.1016/j.antiviral.2016.02.013>.

hypoxemia. The timing of radiographic and physiologic manifestations of disease in our model closely match those observed in severe human influenza infection.

Discussion: This was the first nonhuman primate study of influenza and bacterial co-infection where high-resolution computed tomography scanning of the lungs was used to quantitatively assess pneumonia over the course of illness and where hypoxemia was correlated with pneumonia severity. With additional validation this model may serve as a pathway for regulatory approval of vaccines and therapeutics for the prevention and treatment of severe influenza pneumonia.

Keywords

Influenza; Co-infection; Pneumonia; Vaccines; Therapies

1. Introduction

An estimated 5–10% of adults and 20–30% of children are infected with influenza globally each year. Severe illness occurs predominantly in high-risk groups (the very young, elderly, and those with premorbid conditions) affecting an estimated 3–5 million people resulting in an estimated 250,000–500,000 deaths annually (World Health Organization, 2015). The 1918 influenza pandemic caused an estimated 50 million deaths worldwide, disproportionately affecting young adults (World Health Organization, 2015). Zoonotic avian influenza (e.g., H5N1 and H7N9) causes infrequent although highly lethal human infections and poses risk for a severe pandemic (Su et al., 2015).

Seasonal influenza vaccines have an estimated 60% effectiveness, but provide little or no protection against novel influenza subtypes, and may be less protective in high-risk groups. Neuraminidase inhibitors (NAIs) are recommended for the treatment of severe influenza infection, but are not proven to reduce mortality in severe disease. Recent meta-analysis of observational data suggest early initiation of NAI therapy, within 5-days of symptom onset, is associated with reduced mortality (Muthuri et al., 2014). However, patients with severe influenza infection typically present to the hospital after 5-days of symptoms and experience high case-fatality (Rice et al., 2012).

New vaccines and therapies are needed to prevent and treat severe influenza illness. Efficacy of interventions must be assessed accounting for the impact of bacterial co-infection that commonly contributes to mortality (Morens et al., 2008). Clinical trials of influenza vaccine or therapeutic efficacy do not typically evaluate severe disease as a clinical endpoint, largely due to the expense required to adequately power such studies. Highly pathogenic strains of influenza and severe disease cannot be assessed in human challenge experiments for obvious ethical reasons. Preclinical models of severe influenza infection that closely correlate with the natural history of disease in humans are needed to assess efficacy of vaccines and therapeutics. Showing benefit of interventions in permissive small animals (mice and ferrets) that are genetically and phenotypically distinct from humans may not adequately translate to benefit in humans.

Nonhuman primates are naturally, and may be experimentally, infected with human influenza viruses (Davis et al., 2015). Seasonal influenza infection in most nonhuman

primate species results in mild or subclinical illness, reflective of self-limited disease observed in otherwise healthy humans. Inoculation of influenza into the lower airways of nonhuman primates induces more severe disease than upper airway inoculation or exposure via small particle aerosol (Davis et al., 2015). Bacterial infection following intra-tracheal influenza infection has been evaluated in four nonhuman primate studies since 1954 (Berendt, 1974; Berendt et al., 1975; Kobayashi et al., 2013; Miyake et al., 2010). In three of the four studies co-infection resulted in more severe bronchopneumonia than viral infection alone.

We sought to develop a nonhuman primate model of influenza and bacterial co-infection that recapitulates severe disease in humans. Severe influenza infection in humans is typically manifested by bilateral bronchopneumonia resulting in hypoxemia. Animals were infected with influenza inoculated directly into bilateral main-stem bronchi, to maximize lower respiratory tract disease. Decades of experimental observations show that intra-nasal inoculation induces only mild illness in both otherwise healthy nonhuman primate and human subjects. Co-infected animals were inoculated with bacteria into the lower airways at four days post-influenza infection. The timing of co-infection in our study closely approximates estimated timing of co-infection in human cases of severe influenza infection (Rice et al., 2012). Influenza A/Swine/Iowa/31 (Sw31) was selected as a surrogate for the 1918 pandemic influenza virus in this study based on close genetic homology and similar pathogenesis in mice and ferrets (Memoli et al., 2009). Methicillin-resistant *Staphylococcus aureus* (MRSA) was selected as a clinically relevant bacterial co-pathogen.

We also evaluated the role of aerosolized influenza with and without bacterial co-infection in this study. Few historical data exist to inform the impact of aerosolized influenza on the development of severe pneumonia in the setting of bacterial co-infection. We sought to fill this knowledge gap. We assessed the severity of disease in animals over the course of our study using tools available to evaluate critically ill human patients. These included high-resolution computed tomography (CT) imaging of the lungs, arterial blood gas analyses, and bronchoalveolar lavage (BAL).

2. Methods

2.1. Inoculations

Eighteen male juvenile rhesus macaques (4–8 kg) of Indian origin without detectable pre-existing influenza A antibody titers were randomly assigned to one of six study groups (see Table 1, Supplementary Table 1). Staff that assigned animals to groups were blinded to the intervention (i.e., pathogen and inoculation route) designated for that group. Viral stocks of Influenza A/Swine/Iowa/31 (Sw31) were grown in Madin–Darby canine kidney (MDCK) cells, harvested, purified on a sucrose cushion, and stored at -80°C . Viral titers were assessed by plaque assay technique (Qi et al., 2009). MRSA (strain USA300) was grown in tryptic soy broth (TSB) from frozen glycerol stocks until mid-log phase growth was achieved. The desired number of bacteria were pelleted, washed, and diluted in 4 mL of sterile saline immediately prior to inoculation. Bacterial titers were confirmed by serial dilution of samples on TSB agar plates Table 1.

Intra-bronchial (IB) inoculations were performed under ketamine anesthesia using a pediatric bronchoscope advanced into the airway of seated upright animals (see experimental timeline, Fig. 1). A target IB viral inoculum of 5×10^6 plaque forming units (pfu) was diluted in 4 mL of saline and administered in equal proportions into the right and left main stem bronchus. A target IB bacterial inoculum of 1×10^9 colony forming units (cfu) was similarly administered. A target aerosol viral inoculum of 5×10^6 pfu was administered as previously described (Johnson et al., 2015). All animal procedures were approved by the National Institute of Allergy and Infectious Diseases (NIAID) Division of Clinical Research Animal Care and Use Committee, and adhered to National Institutes of Health (NIH) policies. The experiments were carried out at the NIAID Integrated Research Facility, an AAALAC and AALAS accredited facility.

2.2. Procedures

Physical exams, vital sign measurements, and venous and arterial blood draws were performed every other day and BALs were performed every fourth day under ketamine anesthesia. Arterial blood was collected by puncture of the femoral artery under direct ultrasound guidance at atmospheric pressure and samples were immediately loaded onto the iSTAT® (Abbott laboratories) for bedside blood gas analysis. BALs were performed by advancing a sterile pediatric bronchoscope into the right lower lobe of an upright animal, instilling four 10 mL aliquots (40 mL total) of sterile saline into the distal lung segment, and aspirating BAL fluid into a sterile trap.

2.3. Laboratory testing

Complete blood counts (CBC) with differentials and comprehensive blood chemistries were performed on venous blood samples collected in ethylenediaminetetraacetic acid (EDTA)-coated blood tubes using a Sysmex XT2000V™ (Sysmex America, IL USA) and the Piccolo Xpress® (Abbott laboratories).

Quantitative real-time PCR (RT-PCR) was used to determine the viral copy numbers in BAL samples from all groups. Total RNA was extracted from 100 µL aliquots of BAL using standard TRIzol chloroform extraction. Reverse transcription of total RNA was performed with primers specific for swine H1N1 HA sequence using the Superscript III first-strand cDNA synthesis kit (Invitrogen, Carlsbad, CA). TaqMan primers and probes were designed using Primer Express 3.0 software (Applied Biosystems, Foster City, CA) and generated the following primers and probe: Swine-691F, 5' CAGGAGGTTCACTCCAGAAATAG 3'; Swine-787R, 5' GTGTCTCCGGTCTAGTAATG 3'; Probe, 5' FAM-AGGTCAGGCAGGGAGGATGAACTA-TAMRA 3'. RT-PCR was performed on an Applied Biosystems QuantStudio 6 Flex Real-Time PCR System and each sample was run in duplicate with TaqMan 2X PCR Universal Master Mix (Applied Biosystems) and a 25 µL total reaction volume. Quantification of viral copy number was accomplished by comparison of RT-PCR results to an established external standard of viral copy number.

Cells from BAL were pelleted by centrifugation and re-suspended in 100 µl phosphate buffered saline (PBS) + 2% fetal bovine serum (FBS). Cell aliquots were exposed to a myeloid or lymphoid antibody panel. The myeloid panel contained markers for CD14, Live/

Dead Fixable Yellow dead cell stain (Thermo Fisher Scientific, MA, USA), CD3, CD45, HLA-DR, CD11c (BD Biosciences, CA, USA), CD20 (eBioscience Inc. CA, USA), CD66abce (Miltenyi Biotech Inc. CA, USA), and CD163 (Biolegend, CA, USA). The lymphoid panel contained markers for CD3, CD8, CD20, CD16 (BD Biosciences, CA, USA), CD4 (Biolegend, CA, USA), CD14, Live/Dead Fixable Yellow dead cell stain (Thermo Fisher Scientific, MA, USA) and CD 159(NKG2a) (Beckman Coulter, CA, USA). Samples were then fixed and permeabilized using BD Cytotfix/Cytoperm solution (BD Biosciences CA, USA) and analyzed on the BD LSR II Fortessa Flow Cytometer. Data were analyzed using FlowJo Software (FlowJo LLC, OR, USA). All cells were gated first as live cells (viability dye negative) and CD45⁺ and then analyzed further. Myeloid cells were gated by forward and side scatter and monocytes were defined as CD3⁻CD20⁻HLA-DR⁺CD163⁺. CD3⁻CD20⁻CD163⁻ cells were separated by CD66abce⁺ (neutrophils) or CD11c⁺ (dendritic cells). Lymphoid cells were gated by forward and side scatter and CD14⁻. B cells were defined as CD3⁻CD20⁺ and NK cells were defined as CD3⁻NKG2a⁺. T cells were defined as CD20⁻ and CD4⁺CD8⁻ or CD4⁻CD8⁺. Percentage of each cell type was determined based on all live CD45⁺ cells.

2.4. High-resolution computed tomography scanning

Animal were intubated, deeply sedated with propofol, and mechanically ventilated on an assist-control volume-cycled ventilator mode. A standard breath-hold maneuver normalizing tidal volume to 8 cc/kg actual body weight was performed immediately prior to CT imaging of lungs using a Philips Gemini 16 slice PET/CT scanner. Lung hyper-intensity and percent change from baseline over time was determined using previously published methods (Solomon et al., 2014).

2.5. Pathology

Detailed necropsies were performed on all animals following euthanasia. Tissues were collected from major organs including multiple lung lobes, preserved in 10% normal-buffered formalin, embedded in paraffin, and 5-μm sections applied to positively charged slides for hematoxylin and eosin staining. Lung lobes were sampled for a qualitative assessment of histopathology. Both “affected” and “unaffected” regions, based upon gross pathologic evaluation, were sampled.

2.6. Statistical analysis

GraphPad Prism 6 was used for all statistical analysis including mean and standard error of the mean (SEM) calculations. Two-way ANOVA was used to detect differences in dependent variables between groups on multiple study days. Tukey’s test was used to assess for significant differences between means with $p < 0.05$, $p < 0.01$, $p < 0.001$, or $p < 0.0001$.

3. Results

3.1. Influenza and MRSA infection induced mild clinical or subclinical illness

Animals were inoculated with Sw31 or saline on day 0 and MRSA or saline on day +4 (Fig. 1). Viral and bacterial inoculation doses were confirmed by back-titration (Table 1). Group 3 (Sw31 IB) animals had the highest peak viral RNA in lung-lining fluid at day +2 that

significantly declined by day +6 (Fig. 1). MRSA was cultured from lung-lining fluid of all 3 animals from Group 4 (Sw31 IB + MRSA) on day +6 but not at later time-points and not from animals in other MRSA-infected groups (Groups 2 and 6).

Clinical scoring to quantify disease severity and early euthanasia criteria are summarized in Supplementary Tables 2 and 3. Animals in groups 3 (Sw31 IB), 4 (Sw31 IB + MRSA), and 6 (Sw31 aero + MRSA) developed self-limited fever to greater $>39.7^{\circ}\text{C}$. One animal each from Groups 3 and 4 developed mild cough on day +6 and +7 and two animals from Group 4 developed mild depressed activity on day +6. Less than 5% weight loss was observed in all animals. No clinically significant abnormalities were observed in CBC with differentials or serum chemistries.

3.2. CT imaging of lungs characterized timing and extent of influenza or MRSA pneumonia

Radiographic evidence of pneumonia with focal or multifocal infiltrates was observed in all infected animals in Groups 2 (MRSA), 3 (Sw31 IB), 4 (Sw31 IB + MRSA), and 6 (Sw31 aero + MRSA) but not in animals from Groups 1 (saline IB) or 5 (Sw31 aero) (Fig. 2A). No statistically significant difference was observed in density of radiographic infiltrates on day +2, as measured by percent change in lung hyper-intensity (PCLH) between groups (Fig. 2B). On day +6, PCLH was significantly increased in Group 4 animals (Sw31 IB + MRSA) relative to animals in all other groups, and in group 3 (Sw31 IB) and 6 (Sw31 aero + MRSA) animals relative to animals in Groups 1 (saline) and 5 (Sw31 aero) (Fig. 2B). On day +10, PCLH was significantly increased in Group 4 animals (SW31 IB + MRSA) relative to animals in Groups 1 (saline), 2 (MRSA), and 5 (Sw31 aero) (Fig. 2B). No statistically significant differences in PCLH were observed between groups on day +14 (Fig. 2B).

3.3. IB influenza with or without MRSA co-infection induced acute lung injury by clinical criteria

The clinical criteria for acute lung injury (ALI) include an arterial partial pressure of oxygen to fraction of inspired oxygen (P: F) ratio <300 in the setting of bilateral pulmonary infiltrates (Bernard et al., 1994). Three animals from Group 3 (Sw31 IB) and two animals from Group 4 (Sw31 IB + MRSA) met clinical criteria for ALI on day +6 (Fig. 2C). Clinical criteria for ALI were not met on other study days or in other groups. Timing of ALI in animals from Groups 3 and 4 correlated with timing of peak radiographic infiltrates (Fig. 2B and C).

3.4. Cellular immune responses in BAL were distinct between groups

Animals from Group 1 (saline) had no significant changes in the number or distribution of immune cell populations in BAL (Figs. 3 and 4 A–G) over the course of the study. Group 2 (MRSA) animals had significant elevations of NK cells ($\text{CD14}^{-}\text{CD3}^{-}\text{NKG2A}^{+}$), dendritic cells ($\text{CD3}^{-}\text{CD20}^{-}\text{CD163}^{-}\text{CD66}^{-}\text{HLA-DR}^{+/-}\text{CD11c}^{+}$), neutrophils ($\text{CD3}^{-}\text{CD20}^{-}\text{CD163}^{-}\text{CD11c}^{-}\text{CD66}^{+}$), monocytes ($\text{CD3}^{-}\text{CD20}^{-}\text{HLA-DR}^{+}\text{CD163}^{+}$), and B-cells ($\text{CD14}^{-}\text{CD3}^{-}\text{CD20}^{+}$) (Fig. 4A, C, D, E, and G) on day +6 and all cell populations returned to baseline by day +10. Group 3 (Sw31 IB) animals showed significant elevation of neutrophils on day +6 (Fig. 4D) and cytotoxic T-cells ($\text{CD14}^{-}\text{CD20}^{-}\text{CD3}^{+}\text{CD4}^{-}\text{CD8}^{+}$) and

dendritic cells on day +14 (Fig. 4 B and C). Group 4 (Sw31 IB + MRSA) animals had significant elevations of neutrophils, monocytes, and B-cells on day +6 (Fig. 4D, E, and G) and significant elevations of cytotoxic T-cells and dendritic cells on day +10 (Fig. 4B and C). CD4⁺ T-cell populations (CD14⁻CD20⁻CD3⁺CD8⁻CD4⁺) were significantly elevated on day +6 and +10 (Fig. 4F). Group 5 (SW31 aero) animals had significant elevation in NK cells on day +6 (Fig. 4A). Group 6 (Sw31 aero + MRSA) animals had significant elevations of NK cells on days +2, +6, and +10 (Fig. 4A); of neutrophils on days +2 and +6 (Fig. 4D); of monocytes on days +6 and +10 (Fig. 4E); of B-cells on day +6 (Fig. 4G); and of cytotoxic T-cells, dendritic cells, and CD4⁺ T-cells on day +10 (Fig. 4B, C, and F).

3.5. Pneumonia and pathologic lung injury were most severe following IB influenza and MRSA co-infection

Histopathologic examination was performed on tissues sampled on day +14. Group 1 (saline) animals had no abnormal histopathology in the respiratory epithelium of the trachea, main-stem bronchi (Fig. 5A), bronchioles (Fig. 5B), or lung parenchyma (Fig. 5C). Group 2 (MRSA) animals had focal chronic bronchiolitis (Fig. 5D), often with reparative changes (Fig. 5E), and very rarely with bacteria morphologically consistent with *Staphylococcus* associated with small amounts of necrotic luminal debris (Fig. 5F; arrow). Group 3 (Sw31 IB) animals had few foci of acute exudative DAD (Fig. 5G; left half) characterized by prominent alveolar edema and vascular congestion (Fig. 5H), surrounded by multifocal areas of proliferative organizing DAD (Fig. 5G; right half) characterized by interstitial fibrosis (Fig. 5I; arrow) and type II alveolar cell hyperplasia (Fig. 5J; arrow). Multifocal chronic bronchiolitis was also observed (Fig. 5K; arrow) with several foci of bronchiolitis obliterans (Fig. 5L, arrow). Group 4 (Sw31 IB + MRSA) animals had extensive pathology with widespread consolidation in most lung lobes. Organizing pneumonia with extensive organizing DAD (Fig. 6A–C), with multifocal bronchiolitis obliterans (Fig. 6A–C arrows), chronic bronchiolitis with transmural infiltrates of inflammatory cells and loss of epithelial cell integrity (Fig. 6D) were observed. The key features of the areas of organizing DAD included interstitial fibrosis (Fig. 6E; arrows) and type II alveolar cell hyperplasia (Fig. 6F; arrow). Group 5 (Sw31 aerosol) (Fig. 6G–I) and 6 (Sw31 aero + MRSA) (Fig. 6J–L) animals had similar histopathology features with multifocal areas of interstitial inflammatory infiltrates producing an interstitial pneumonia pattern (Fig. 6G and J) with multifocal areas of chronic bronchiolitis often with prominent submucosal lymphoid nodules (Fig. 6H & KL; arrows). Areas with organizing DAD features were noted (Fig. 6I) with interstitial fibrosis and type II hyperplasia (Fig. 6L) but were much less prominent than observed in groups 3 and 4.

4. Discussion

We developed a model of severe pneumonia following influenza and bacterial co-infection in nonhuman primates. This was the first nonhuman primate study of influenza and bacterial co-infection where high-resolution CT scanning of the lungs was used to quantitatively assess pneumonia over the course of illness and where hypoxemia was correlated with pneumonia severity. This was also the first nonhuman primate study of influenza and bacterial co-infection where immune cell responses in BAL were serially evaluated in

animals over the course of illness. Using an IB route of inoculation we successfully induced severe pneumonia following influenza infection alone and following influenza and bacterial co-infection. Peak illness was observed at day 6 post-influenza infection, manifested by bilateral pulmonary infiltrates and hypoxemia. The timing of radiographic and physiologic manifestations of disease in our model closely match those observed in severe human influenza infection (Chertow, 2012).

We observed that influenza and bacterial co-infection resulted in more severe lung histopathology than influenza infection alone. This same observation has been made in three of four prior nonhuman primate studies of influenza and bacterial co-infection where influenza was inoculated into the lower airways (Berendt, 1974; Berendt et al., 1975; Kobayashi et al., 2013; Miyake et al., 2010). In the most recent study by Kobayashi et al., no difference in lung histopathology was observed following influenza infection alone versus influenza and bacterial co-infection (Kobayashi et al., 2013). However, the MRSA inoculating dose employed by these authors was 1×10^6 CFU, 3 logs lower than the dose used in our study and lung histopathology was assessed at day 9 post-influenza infection, likely past the peak of illness.

Pneumonia in our model did not progress to refractory hypoxic respiratory failure or death. We postulate that the underlying normal health status of the animals protected them from more severe disease, similar to most healthy humans infected with influenza. A recent influenza A challenge study in humans showed that a dose of 10^7 tissue culture infectious dose 50 was needed to induce mild illness in 69% of individuals (Memoli et al., 2015). These data suggest that high-dose influenza A exposure is likely needed to induce more than mild illness in healthy hosts. Despite this, development of pneumonia was reproducible in our model. Severity of influenza pneumonia is dependent upon the viral and bacterial strain used, pathogen dose, and route of infection. We selected Sw31 because it is well characterized in mice and ferrets to cause severe pneumonia, and is genetically similar to 1918 influenza, that causes severe pneumonia in nonhuman primates (Kobasa et al., 2007). Viral dose of 5×10^6 pfu was selected as the highest dose that could be reasonably achieved and matched across routes of delivery. MRSA was selected given its high prevalence among adult and pediatric patients with severe influenza infection (Rice et al., 2012; Randolph et al., 2011). While MRSA is known to induce pneumonia in nonhuman primates, Pantone-Valentine leukocidin (PVL) does not appear to significantly contribute to pathogenesis (Olsen et al., 2010). While PVL is known to be a *S. aureus* virulence molecule *in vitro*, its contribution to pneumonia pathogenesis in humans remains controversial. While the route of infection we studied does not mirror natural infection, our intention was not to evaluate the natural history of mild influenza infection. This can be best accomplished in human challenge experiments or natural history studies. Our intention was to model severe influenza pneumonia as observed in humans.

To expand the relevance of our findings and establish the utility of this model for assessing efficacy of vaccines and therapies for the prevention and treatment of severe influenza pneumonia, additional experiments are needed. Future studies should assess reproducibility of our findings with other relevant seasonal and high-path avian influenza strains with pandemic potential. *Streptococcus pneumoniae*, another clinically relevant bacterial co-

pathogen, should also be evaluated. Dose response studies are also needed. Quantitative assessment of lung histopathology correlated to CT findings at peak illness (day 6) will also strengthen the validity of this model. Interestingly aerosolized influenza alone induced only subclinical disease despite presence of interstitial pneumonia on lung histopathology. This was made only moderately worse with bacterial co-infection. Some variation in delivered inoculum was observed, primarily across routes of delivery. This is likely attributable to methodological differences required to deliver virus IB versus aerosol. Also, the design of the aerosol chamber, where not all inoculum is delivered into the airway, likely resulted in a dose reduction in the influenza aerosol groups. However, diffuse interstitial pneumonia observed on histopathology in these groups, and robust immune response in BAL suggest that aerosol exposure to influenza results in a distinct and more mild clinic-pathological phenotype.

Nonhuman primate models of influenza infection will not and should not replace mice and ferret studies for the preclinical assessment of influenza vaccines and therapies. Relevant small animal models will always be needed for initial higher throughput evaluation of interventions. However, nonhuman primate models provide an important adjunct for validating findings in small animal models and may more closely predict vaccine and therapeutic efficacy for severe disease in humans. Lung immune cell responses in nonhuman primates likely correlate better to those of humans than those of more genetically distant animals. Characterization of lung immune cell responses in nonhuman primates following influenza infection may facilitate discovery of improved correlates of influenza immunity in humans, needed for better vaccine design. Additionally, characterization of lung immune responses contributing to progression and resolution of lung injury may lead to discovery of novel therapeutic targets within the host to improve severe pneumonia outcomes.

In summary, we report a nonhuman primate model of IB influenza and MRSA co-infection that induced severe pneumonia similar to that observed in humans. With additional validation this model may serve as a pathway for regulatory approval of vaccines and therapeutics for the prevention and treatment of severe influenza pneumonia. This will be particularly useful for high-path avian influenza strains with pandemic potential that cause sporadic infections and are thus not easily amenable to large clinical trials of vaccine and therapeutic efficacy.

Table 1

Back-titration results for influenza and bacterial challenge inoculum.

Experimental group	Delivered inoculum (mean \pm standard deviation)	
	Sw31 (PFU/animal)	MRSA (CFU/animal)
1: Saline	X	X
2: MRSA	X	$1.20 \times 10^9 \pm 4.00 \times 10^8$
3: Sw31 IB	$2.06 \times 10^6 \pm 1.30 \times 10^6$	X
4: Sw31 IB + MRSA	$2.11 \times 10^6 \pm 3.15 \times 10^5$	$1.33 \times 10^9 \pm 3.8 \times 10^8$
5: Sw31 aero	$6.15 \times 10^6 \pm 4.86 \times 10^5$	X
6: Sw31 aero + MRSA	$6.21 \times 10^6 \pm 3.85 \times 10^6$	$8.88 \times 10^8 \pm 1.25 \times 10^8$

CORRESPONDENCE

Persistence and Evolution of SARS-CoV-2 in an Immunocompromised Host

TO THE EDITOR: A 45-year-old man with severe antiphospholipid syndrome complicated by diffuse alveolar hemorrhage,¹ who was receiving anticoagulation therapy, glucocorticoids, cyclophosphamide, and intermittent rituximab and eculizumab, was admitted to the hospital with fever (Fig. S1 in the Supplementary Appendix, available with the full text of this letter at NEJM.org). On day 0, Covid-19 was diagnosed by SARS-CoV-2 reverse-transcriptase–polymerase-chain-reaction (RT-PCR) assay of a nasopharyngeal swab specimen, and the patient received a 5-day course of remdesivir (Fig. S2). Glucocorticoid doses were increased because of suspected diffuse alveolar hemorrhage. He was discharged on day 5 without a need for supplemental oxygen.

From day 6 through day 68, the patient quarantined alone at home, but during the quarantine period, he was hospitalized three times for abdominal pain and once for fatigue and dyspnea. The admissions were complicated by hypoxemia that caused concern for recurrent diffuse alveolar hemorrhage and was treated with increased doses of glucocorticoids. SARS-CoV-2 RT-PCR cycle threshold (Ct) values increased to 37.8 on day 39, which suggested resolving infection (Table S1).^{2,3}

On day 72 (4 days into another hospital admission for hypoxemia), RT-PCR assay of a nasopharyngeal swab was positive, with a Ct value of 27.6, causing concern for a recurrence of Covid-19. The patient again received remdesivir (a 10-day course), and subsequent RT-PCR assays were negative.

On day 105, the patient was admitted for cellulitis. On day 111, hypoxemia developed, ultimately requiring treatment with high-flow oxygen. Given the concern for recurrent diffuse alveolar hemorrhage, the patient's immunosuppression was escalated (Figs. S1 through S3). On day 128, the RT-PCR Ct value was 32.7, which caused concern for a second Covid-19 recurrence,

and the patient was given another 5-day course of remdesivir. A subsequent RT-PCR assay was negative. Given continued respiratory decline and concern for ongoing diffuse alveolar hemorrhage, the patient was treated with intravenous immunoglobulin, intravenous cyclophosphamide, and daily ruxolitinib, in addition to glucocorticoids.

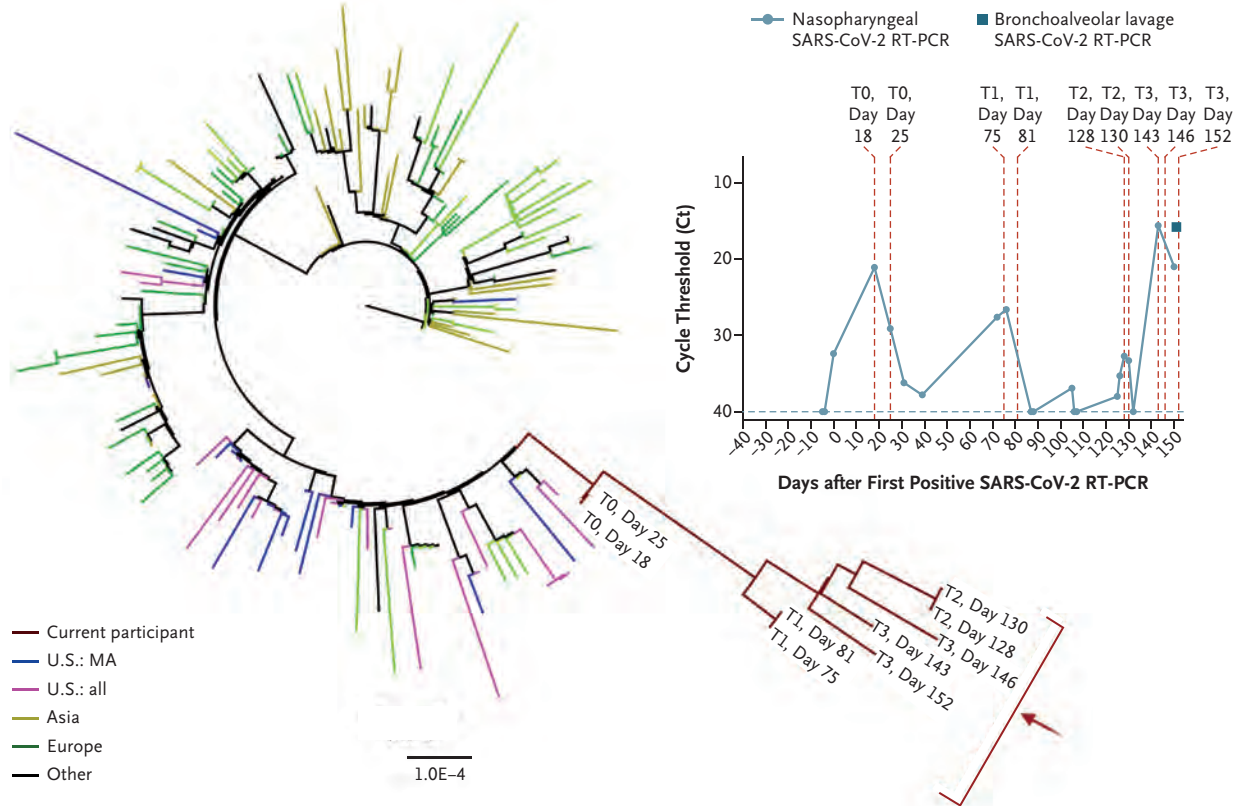

On day 143, the RT-PCR Ct value was 15.6, which caused concern for a third recurrence of Covid-19. The patient received a SARS-CoV-2 antibody cocktail against the SARS-CoV-2 spike protein (Regeneron).⁴ On day 150, he underwent endotracheal intubation because of hypoxemia. A bronchoalveolar-lavage specimen on day 151 revealed an RT-PCR Ct value of 15.8 and grew *Aspergillus fumigatus*. The patient received remdesivir and antifungal agents. On day 154, he died from shock and respiratory failure.

We performed quantitative SARS-CoV-2 viral load assays in respiratory samples (nasopharyngeal and sputum) and in plasma, and the results were concordant with RT-PCR Ct values, peaking at 8.9 log₁₀ copies per milliliter (Fig. S2 and Table S1). Tissue studies showed the highest SARS-CoV-2 RNA levels in the lungs and spleen (Figs. S4 and S5).

Phylogenetic analysis was consistent with persistent infection and accelerated viral evolution (Figs. 1A and S6). Amino acid changes were predominantly in the spike gene and the receptor-binding domain, which make up 13% and 2% of the viral genome, respectively, but harbored 57% and 38% of the observed changes (Fig. 1B). Viral infectivity studies confirmed infectious virus in nasopharyngeal samples from days 75 and 143 (Fig. S7). Immunophenotyping and SARS-CoV-2–specific B-cell and T-cell responses are shown in Table S2 and Figures S8 through S11.

Although most immunocompromised persons effectively clear SARS-CoV-2 infection, this case

A Global and Patient SARS-CoV-2 Sequences

B Locations of SARS-CoV-2 Sequence Polymorphisms over Time

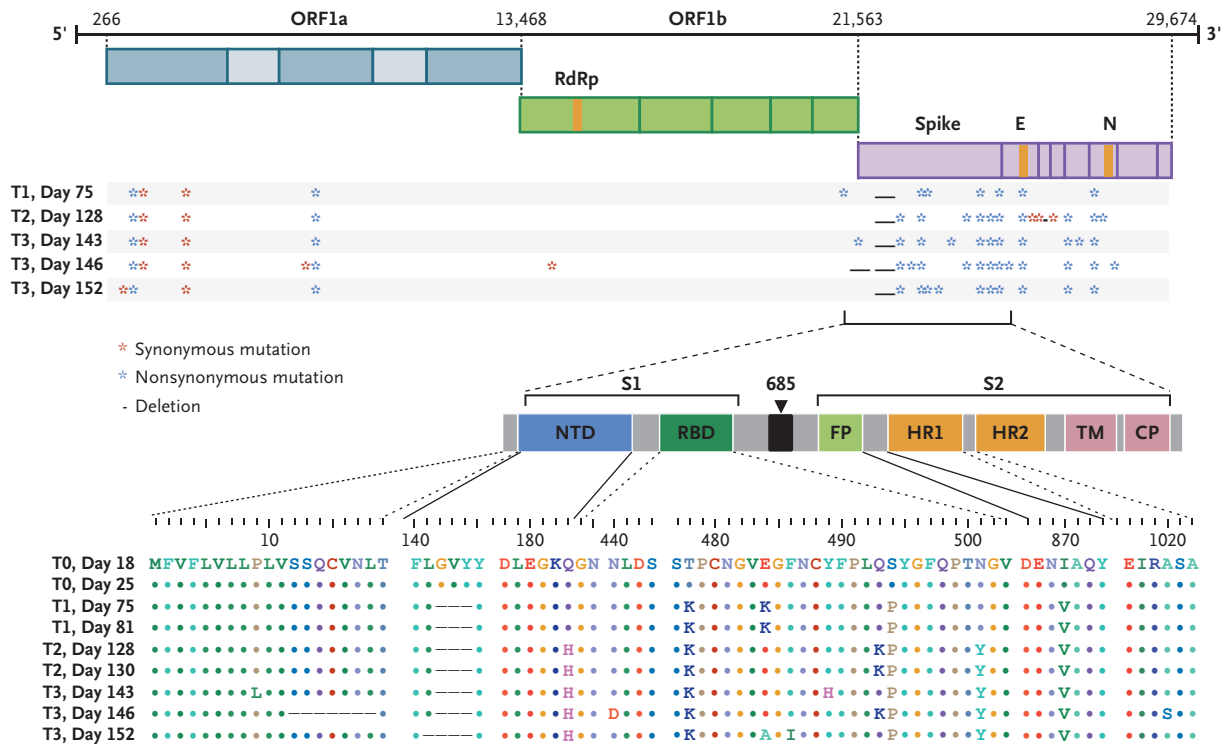

Figure 1 (facing page). SARS-CoV-2 Whole-Genome Viral Sequencing from Longitudinally Collected Nasopharyngeal Swabs.

Shown in Panel A is a maximum-likelihood phylogenetic tree with patient sequences (red arrow) at four time points with high levels of SARS-CoV-2 viral loads (T0 denotes days 18 and 25; T1 days 75 and 81; T2 days 128 and 130; and T3 days 143, 146, and 152), along with representative sequences from the state (U.S.: MA), country (U.S.: all), Asia, Europe, and Other (Africa, South America, and Canada). The scale represents 0.0001 nucleotide substitutions per site. The inset shows nasopharyngeal and bronchoalveolar-lavage SARS-CoV-2 RT-PCR cycle threshold (Ct) values; the horizontal dashed line represents the cutoff for positivity at 40, and vertical red dashed lines represent days of viral sequencing (days 18, 25, 75, 81, 128, 130, 143, 146, and 152). Shown in Panel B are the locations of deletions and synonymous and nonsynonymous mutations in the patient at T1, T2, and T3 as compared with T0. CP denotes cytoplasmic domain, E envelope, FP fusion peptide, HR1 heptad repeat 1, HR2 heptad repeat 2, N nucleocapsid, NTD N-terminal domain, ORF open reading frame, RBD receptor-binding domain, RdRp RNA-dependent RNA polymerase, S1 subunit 1, S2 subunit 2, and TM transmembrane domain.

highlights the potential for persistent infection⁵ and accelerated viral evolution associated with an immunocompromised state.

Englund, MD; Helen Y. Chu, MD, MPH

IMPORTANCE The association between COVID-19 symptoms and SARS-CoV-2 viral levels in children living in the community is not well understood.

OBJECTIVE To characterize symptoms of pediatric COVID-19 in the community and analyze the association between symptoms and SARS-CoV-2 RNA levels, as approximated by cycle threshold (Ct) values, in children and adults.

DESIGN, SETTING, AND PARTICIPANTS This cross-sectional study used a respiratory virus surveillance platform in persons of all ages to detect community COVID-19 cases from March 23 to November 9, 2020. A population-based convenience sample of children younger than 18 years and adults in King County, Washington, who enrolled online for home self-collection of upper respiratory samples for SARS-CoV-2 testing were included.

EXPOSURES Detection of SARS-CoV-2 RNA by reverse transcription-polymerase chain reaction (RT-PCR) from participant-collected samples.

MAIN OUTCOMES AND MEASURES RT-PCR-confirmed SARS-CoV-2 infection, with Ct values stratified by age and symptoms.

RESULTS Among 555 SARS-CoV-2-positive participants (mean [SD] age, 33.7 [20.1] years; 320 were female [57.7%]), 47 of 123 children (38.2%) were asymptomatic compared with 31 of 432 adults (7.2%). When symptomatic, fewer symptoms were reported in children compared with adults (mean [SD], 1.6 [2.0] vs 4.5 [3.1]). Symptomatic individuals had lower Ct values (which corresponded to higher viral RNA levels) than asymptomatic individuals (adjusted estimate for children, −3.0; 95% CI, −5.5 to −0.6; $P = .02$; adjusted estimate for adults, −2.9; 95% CI, −5.2 to −0.6; $P = .01$). The difference in mean Ct values was neither statistically significant between symptomatic children and symptomatic adults (adjusted estimate, −0.7; 95% CI, −2.2 to 0.9; $P = .41$) nor between asymptomatic children and asymptomatic adults (adjusted estimate, −0.6; 95% CI, −4.0 to 2.8; $P = .74$).

CONCLUSIONS AND RELEVANCE In this community-based cross-sectional study, SARS-CoV-2 RNA levels, as determined by Ct values, were significantly higher in symptomatic individuals than in asymptomatic individuals and no significant age-related differences were found. Further research is needed to understand the role of SARS-CoV-2 RNA levels and viral transmission.

The COVID-19 pandemic caused by SARS-CoV-2 has resulted in substantial morbidity and mortality worldwide. Early public health interventions, including the closure of schools, were implemented to prevent the spread of SARS-CoV-2. However, the role of children in community SARS-CoV-2 transmission remains poorly understood as most children with SARS-CoV-2 infection are asymptomatic¹ or experience mild disease.^{2,3} There have been few community-based studies of pediatric COVID-19 cases, and thus there are limited data on the role of children in the transmission of COVID-19.⁴

One potential driver of SARS-CoV-2 transmissibility is respiratory tract viral load, approximated by quantification of viral RNA levels via reverse transcription-polymerase chain reaction (RT-PCR) cycle threshold (Ct) values. Studies have shown a strong association between lower Ct values (higher RNA levels) and successful isolation of SARS-CoV-2 in culture.⁵⁻⁷ Early case reports showed that asymptomatic individuals had levels of detectable SARS-CoV-2 RNA comparable with symptomatic individuals,⁸⁻¹⁰ and this observation has been supported by a growing body of evidence from larger community-based studies in predominantly adult populations.¹¹⁻¹⁴ Studies examining SARS-CoV-2 RNA levels in children, which have generally involved small sample sizes and relied on sampling associated with presentation at medical care facilities or community-based contact tracing, have shown conflicting results¹⁵⁻¹⁸ and comparison of community-derived pediatric and adult data has been limited.¹⁹

In this study, using data from a novel countywide respiratory virus surveillance platform, we described the association between SARS-CoV-2 Ct values and symptoms in SARS-CoV-2-positive children in King County, Washington. We also compared these findings between children and adults with SARS-CoV-2 infection.

Methods

Study Platform and Setting

This is a cross-sectional population-based analysis of data collected as part of the Seattle Coronavirus Assessment Network (SCAN). SCAN launched on March 23, 2020, to evaluate the feasibility of testing individuals both with and without COVID-19-like illness via unsupervised home self-collected nasal swabs for detection of SARS-CoV-2 and other respiratory pathogens.²⁰ The network was originally established in November 2018 as the Seattle Flu Study (SFS),²¹ which focused on the community transmission of influenza and other respiratory viruses. SCAN was limited to residents of King County, Washington. We split the county into 16 groupings, defined roughly by the 16 public use microdata areas defined by the US Census Bureau. The proportion of individuals relative to the county population in each grouping dictated the proportion of daily test kits allotted to each public use microdata area. Individuals of all ages, whether they had any COVID-19 symptoms or not, were eligible to enroll on the study website.²⁰ The website and study materials were translated into 11 non-English languages and translation services were avail-

Key Points

Question How is the presence of symptoms associated with SARS-CoV-2 RNA levels in children vs adults in the community?

Findings In this cross-sectional study of 555 children and adults with SARS-CoV-2 confirmed by reverse transcription-polymerase chain reaction, symptomatic individuals had higher SARS-CoV-2 RNA levels (as indicated by lower mean cycle threshold values) compared with asymptomatic individuals. No significant differences in RNA levels were found between asymptomatic children and asymptomatic adults or between symptomatic children and symptomatic adults.

Meaning Regardless of age, in this community-based study, SARS-CoV-2 RNA levels were higher in symptomatic individuals.

able. This study was approved by the University of Washington Institutional Review Board. This study followed the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) reporting guideline.²⁹ All patients who enrolled online provided written informed consent.

Data and Sample Collection

After signing an electronic consent form, all participants, or parents or guardians for participants younger than 18 years, completed an electronic questionnaire to collect data on sociodemographic and clinical characteristics, exposures, and health-related behaviors. Race and ethnicity were self-classified by participants using provided standard race and ethnic categories.²² Race and ethnicity data were collected to examine disparities between racial/ethnic groups in study participation as well as in outcomes, such as SARS-CoV-2 positivity. Study data were collected and managed using REDCap Electronic Data Capture version 10.9.2 (Vanderbilt University) hosted at the University of Washington.^{23,24} Within 24 hours of enrollment, sample collection kits were delivered using a private courier for contactless receipt at the participants' homes. Samples were self-collected by participants 13 years and older via unsupervised middle turbinate (MTB) or anterior nares (AN) swabs.²⁵ Parents or guardians performed swab collection for children younger than 13 years. Swab collection instructions were included with the swab kit (eFigure 1 in the Supplement) and were available on the study website.^{26,27} Swab samples were returned to the laboratory within 48 hours via private courier.

This study included participants who enrolled in SCAN from March 23 to November 9, 2020, and who collected at home a nasal swab that tested positive for SARS-CoV-2 by RT-PCR. Repeated samples from individuals were excluded from analysis. Children were defined as participants younger than 18 years. For privacy, all adults older than 85 years were classified as aged 85 years. Symptomatic participants reported at least 1 symptom (ie, runny or stuffy nose, fever, headache, cough, fatigue, sore throat, muscle or body aches, chills, sweats, loss of smell or taste, diarrhea, eye pain, nausea or vomiting, trouble breathing, ear pain or discharge, or rash) within 7 days prior to study enrollment. Asymptomatic participants were

those who reported no symptoms in this time frame. Per guidelines from the US Centers for Disease Control and Prevention at the time of the study, close contact was defined as an encounter in the past 2 weeks in which the individual spent at least 10 minutes within 6 feet of a person who tested positive for SARS-CoV-2.

Laboratory Analyses

From March 23 to July 23, 2020, MTB swabs (Copan) were returned in 3-mL tubes of BD universal viral transport media (Becton, Dickinson and Company) or viral transport media (Brainbits) at room temperature, and aliquoted and stored at 4° C prior to testing. After July 23, 2020, AN swabs (US Cotton #3) were used by participants and returned in empty transport tubes. AN swabs were rehydrated and eluted in 1 mL of either phosphate-buffered saline or Tris-EDTA buffer. All samples were processed, including rehydration, within 48 hours of collection. Stability studies have shown consistent SARS-CoV-2 Ct values at 4° C and 40° C for both AN and MTB swabs up to 3 days²⁸ and 9 days,²¹ respectively. Laboratory testing was performed at the Brotman Baty Institute for Precision Medicine, Seattle, Washington, and the Northwest Genomics Center, Seattle, Washington. Total nucleic acids were extracted (before October 18, 2020, MagNA Pure 96, Roche; on or after October 18, 2020, KingFisher, Thermo Fisher) and tested for the presence of SARS-CoV-2 and the human marker ribonuclease P (RNase P) using a Clinical Laboratory Improvement Amendments-compliant laboratory developed test. RNase P Ct values were used as an extraction and sample collection control. The laboratory developed test consisted of 2 unique multiplexed assays run in duplicate for a total of 4 RT-PCR reactions; each multiplex reaction included a target for SARS-CoV-2 and RNase P. One assay targeted Orf1b with FAM fluor (Life Technologies 4332079 assay #APGZJKF) and was multiplexed with an RNase P probe set with VIC or HEX fluor (Life Technologies A30064 or Integrated DNA Technologies) on a QuantStudio 6 (Applied Biosystems), and the other targeted the S gene (Life Technologies 4332079 assay #APXGVC4) and was also multiplexed with RNase P-VIC or RNase P-HEX assay. Standard curves demonstrated a linear association with mean Ct values and logarithm of SARS-CoV-2 RNA copy numbers for each primer set and from each collection method (MTB vs AN) (eFigure 2 in the [Supplement](#)). At least 3 replicates for RNase P had to be detected for a valid test result. For a positive result, 3 or more SARS-CoV-2 targets must have had a Ct value of less than 40. Most samples were also tested for the presence of 24 respiratory pathogens by TaqMan RT-PCR on the OpenArray platform (Thermo Fisher).

Statistical Analyses

Mean SARS-CoV-2 Ct values were obtained using the 2 Ct values for the Orf1b gene primer. Results were not affected by the primer used (eFigure 3 in the [Supplement](#)) but we excluded analysis by S gene because of better Orf1b sensitivity and reproducibility. Analysis by RNase P Ct values did not show evidence of confounding by age or symptom status (eFigure 4 in the [Supplement](#)). We generated descriptive statistics for all variables. Proportions of missing data were reported. Data analy-

ses were performed using R version 4.0.5 (The R Foundation). Statistical comparisons between groups were determined using χ^2 tests, Welch *t* test, and multiple linear regression. Two-tailed tests were used for all comparisons and statistical significance was defined as $P < .05$. AN swabs were used in the later portion of the study when rates of positivity in children, many of whom were asymptomatic, increased. Therefore, because swab type is a confounder of the association between age and SARS-CoV-2 RNA levels, we used multiple linear regression to adjust individual Ct values to the average swab type in the study. This ensured that our figures would show an unconfounded comparison of ages and symptom status, while preserving the mean Ct value across the sample. Although 2 different nucleic acid extraction platforms were used, multiple linear regression analysis showed that the extraction platform used did not have statistically significant or clinically meaningful associations with our results.

Results

From March 23 to November 9, 2020, 37 067 samples were tested for SARS-CoV-2 via SCAN. Overall, 673 samples (1.8%) had positive results (493 of 31 664 [1.6%] of adult samples and 180 of 5356 [3.4%] of child samples; 47 positive samples did not have age data). Of these positive samples, 180 samples (26.7%) were from children younger than 18 years and 493 (73.3%) were from adults. We excluded 118 samples: 42 that represented repeated positive testing in SCAN and 76 that were missing clinical information.

Of the 555 participants with SARS-CoV-2-positive results, 123 (22.2%) were children and 432 (77.8%) were adults (**Table 1**), ranging in age from 73 days to 85 years. The mean (SD) age was 33.7 (20.1) years: 7.5 (5.3) years for children and 41.2 (16.0) years for adults. Among 123 SARS-CoV-2-positive children in this study, 50 (40.7%) were younger than 5 years, 45 (36.6%) were aged 5 to 11 years, and 28 (22.8%) were aged 12 to 17 years. Of the total positive sample, 320 (57.7%) were female. Of 123 SARS-CoV-2-positive children, 64 (52.0%) were female, 55 (44.7%) were White, and 30 (24.4%) were Hispanic or Latino. The most common underlying conditions among SARS-CoV-2-positive children included seasonal allergies (9 [7.3%]) and asthma (5 [4.1%]), but most children reported no previous underlying medical conditions (106 [86.2%]). Compared with the mean King County household size of 2.4 people,³⁰ people of all ages with SARS-CoV-2-positive results reported larger mean (SD) household sizes (3.8 [1.6]). Most children (91 [74.0%]) resided in households of 4 or more people. Most children (98 [79.7%]) had at least 1 known SARS-CoV-2-positive contact, and most contacts (84 [68.3%]) were in the same household. In contrast, only 179 of 432 SARS-CoV-2-positive adults (41.4%) reported any known positive contact.

Fewer children were symptomatic compared with adults (76 of 123 children [61.8%] vs 401 of 432 adults [92.8%]; $P < .001$) (**Table 2**). When symptomatic, fewer symptoms were reported in children compared with adults (mean [SD], 1.6 [2.0] vs 4.5 [3.1]) (**Figure 1**). Symptomatic children reported a mean

^a Signs and symptoms reported at enrollment.^b Number of days between participant-reported date of symptom onset and swab collection date. Symptom duration was limited to 10 or fewer days. Date of symptom onset was not reported by 392 participants (327 adults and 65 children).

Figure 1. Number of COVID-19 Signs and Symptoms Reported by Participants at Enrollment by Age

The total number of signs and symptoms at enrollment are shown by age group with individual locally estimated scatterplot smoothing regression lines plotted for each age group. Data points represent SARS-CoV-2-positive individuals. Shaded areas represent 95% CIs.

Figure 2. Adjusted Mean SARS-CoV-2 Orf1b Cycle Threshold (Ct) Values by Age Group, Grouped by Symptom Status

Boxes range from the first to third quartiles. Midlines represent median values. Error bars represent the minimum and maximum values. Individual points represent SARS-CoV-2-positive individuals. There were 47 asymptomatic children, 31 asymptomatic adults, 76 symptomatic children, and 401 symptomatic adults. Ct values are adjusted for swab type.

(SD) of 3.8 (3.8) days of symptoms compared with 4.9 (4.1) days in symptomatic adults. The most common signs or symptoms reported in children were runny or stuffy nose, fever, headache, and cough, while adults most frequently reported headache, cough, and fatigue (eFigure 5 in the [Supplement](#)).

Asymptomatic children were younger than symptomatic children (mean [SD] age, 6.2 [4.5] years compared with 8.3 [5.7] years; $P < .001$). Although there were differences in percentage symptomatic and symptoms reported between children younger than 5 years and children aged 5 to 17 years, these differences were not statistically significant. No comorbidities were reported for asymptomatic children. A higher proportion of asymptomatic children than symptomatic children reported any SARS-CoV-2-positive contact (41 of 47 [87.2%] vs 57 of 76 [75.0%]), most of whom were household contacts (36 of 47 [76.6%] vs 48 of 76 [63.2%]).

Of the 555 SARS-CoV-2-positive swabs, 487 were tested for 24 respiratory pathogens by RT-PCR. Only 3 of 108 children (2.8%) tested for other respiratory pathogens had another virus detected by RT-PCR. Rhinovirus was detected in 2 children and adenovirus in 1 child. Ten of 379 adults (2.6%) tested by respiratory pathogen RT-PCR had another virus identified, with rhinovirus predominantly detected (7 of 10); adenovirus (1 of 10), enterovirus (1 of 10), and influenza virus (1 of 10) were also detected.

MTB swabs were used by 176 participants (18 children and 158 adults) and AN swabs were used by 379 participants (105

children and 274 adults). Multiple linear regression of mean SARS-CoV-2 Ct value by age group and swab type showed that MTB swabs were associated with a 4.0-point higher mean Ct value compared with AN swabs ($P < .001$) (eFigure 6 in the [Supplement](#)).

Mean SARS-CoV-2 Ct values between children and adults were not significantly different (adjusted estimate for difference in mean Ct values, 0.3; 95% CI, -1.1 to 1.6; $P = .67$) after adjusting for swab type (**Figure 2**). Subgroup analyses showed that symptomatic individuals had consistently lower Ct values than asymptomatic individuals, regardless of age, after adjusting for swab type (adjusted estimate for children, -3.0; 95% CI, -5.5 to -0.6; $P = .02$; adjusted estimate for adults, -2.9; 95% CI, -5.2 to -0.6; $P = .01$) (eTable in the [Supplement](#)). The difference in mean Ct value between symptomatic children and adults was not significant (adjusted estimate, -0.7; 95% CI, -2.2 to 0.9; $P = .41$). Among 399 symptomatic individuals who reported a symptom onset date, the difference in mean Ct values between symptomatic children and symptomatic adults remained not significant after adjusting for swab type and for the number of days between symptom onset and swab collection (adjusted estimate, 0.5; 95% CI, -1.0 to 2.0; $P = .50$). The difference in mean Ct value between asymptomatic children and adults was also not significant (adjusted estimate, -0.6; 95% CI, -4.0 to 2.8; $P = .74$). No evidence of interaction by age and symptom status was found. Mean SARS-CoV-2 Ct values (as a continuous variable) did not vary significantly across age, even when adjusted for swab type (**Figure 3**).

There was a nonsignificant association of lower mean Ct values with an increase in the number of symptoms reported (eFigure 7 in the [Supplement](#)). Longer time since symptom onset to date of swab collection was associated with higher Ct values. There was not a significant difference between children and adults in this association (eFigure 8 in the [Supplement](#)).

Discussion

This countywide community-based study of SARS-CoV-2 infection in King County, Washington, showed that symptomatic individuals had lower Ct values than those who were asymptomatic. Ct values did not differ significantly between asymptomatic children vs asymptomatic adults or in symptomatic children vs symptomatic adults. This study was unique in that participant-driven community-wide surveillance was instituted in a large metropolitan area using methods without direct participant contact and directed at persons who were not actively seeking medical care or follow-up.

Overall, children with documented SARS-CoV-2 infection in our study were younger, with 40% younger than 5 years, than in other community-based studies.¹⁷⁻¹⁹ A variety of signs and symptoms were reported by SARS-CoV-2-positive children or their caregivers, with runny nose documented in nearly half of the children, followed by fever, headache, and cough. The predominance of rhinorrhea contrasts with other studies, which have shown fever and cough to be more common symptoms.^{17,31,32} The variation in symptoms and lack of predictive value of specific symptoms have been suggested as rea-

Figure 3. Mean SARS-CoV-2 Orf1b Cycle Threshold (Ct) Values by Age

The scatterplot depicts Ct values adjusted by swab type. The gray line represents the locally estimated scatterplot smoothing curve using unadjusted Ct values. Linear regression lines per age group (orange indicates adults; blue indicates children) are adjusted by swab type. Data points represent SARS-CoV-2-positive individuals. Shaded areas represent 95% CIs.

sons for failure of symptom-based testing when screening children for COVID-19.³³

This study was not designed to measure the prevalence of asymptomatic SARS-CoV-2 infection. The high proportion of asymptomatic infection we observed in children is within the upper limit of the asymptomatic ranges of 40% to 45% estimated in other studies.^{34,35} The high proportion of asymptomatic infection we observed in children might be attributed to household enrollment of children following interest in study participation from adults with symptoms. The true frequency of asymptomatic SARS-CoV-2 infection might be closer to 16% to 22%, as suggested by other pediatric studies.^{16,32,35,36}

Because we only assessed symptoms at one point before specimen collection, it is possible that we misclassified some participants who were presymptomatic (who would be expected to have low Ct values) as asymptomatic. Regardless, we were able to show a significant difference in Ct values between symptomatic and asymptomatic groups. Our findings of higher SARS-CoV-2 Ct values in asymptomatic children corroborate results from a small study of asymptomatic and mildly symptomatic SARS-CoV-2-positive children in South Korea¹⁶ and a large study of asymptomatic and symptomatic SARS-CoV-2-positive children from 9 US pediatric hospital testing programs.¹⁵ Two large community-based studies found similar SARS-CoV-2 Ct values in symptomatic and asymptomatic children.^{17,18} In these studies, children were tested as part of contact tracing, and both asymptomatic and sympto-

matic children might have had similarly low Ct values because of recent exposures to infected individuals. In contrast to early studies, which suggested that symptomatic children might have lower Ct values than symptomatic adults,^{37,38} we did not find a significant difference in SARS-CoV-2 Ct values between symptomatic children and symptomatic adults. As these prior studies included participants who sought medical attention, they likely involved more acutely ill children who might have had higher SARS-CoV-2 RNA levels corresponding to lower Ct values. For both symptomatic and asymptomatic individuals, SARS-CoV-2 Ct values did not vary by age when compared as a continuous or categorical variable (ie, children and adults), corroborating studies that examined viral loads and age.^{1,19,39,40} However, the comparison of SARS-CoV-2 Ct values between children and adults depends on the proportion of symptomatic vs asymptomatic individuals in each group and might differ in other settings.

The mechanisms of how SARS-CoV-2 RNA levels might influence transmission have yet to be fully delineated. One large retrospective cohort study suggested that children and adolescents were more likely to transmit SARS-CoV-2 in households.⁴¹ In contrast, multiple studies of household infections have suggested that children are not the key drivers of SARS-CoV-2 transmission.^{18,42-44} It could be that lack of symptoms is associated with decreased viral transmission; studies have found lower relative risks of SARS-CoV-2 transmission from asymptomatic infected household members^{35,41,45} and close contacts.⁴⁶

Another explanation is that asymptomatic infected individuals have lower levels of transmissible SARS-CoV-2 owing to their ability to rapidly clear the virus.^{47,48} In regards to disease acquisition, most transmission studies suggest that children might be less susceptible to SARS-CoV-2 infection.^{41,44,45,49} In contrast, a household seroprevalence study suggests that children are at equal risk as adults for SARS-CoV-2 infection.^{50,51} Current epidemiologic tracing methods might not be detecting asymptomatic infections or infections associated with brief windows of viral detection. Transmission studies have focused on household transmission and even those studies might have been confounded by school and daycare closures, which precluded evaluation of transmission within school or daycare settings. In the King County, Washington, region, public schools were closed for in-person learning during the study period. This may have decreased the number of SARS-CoV-2-positive children and our data may be reflective of secondary SARS-CoV-2 infections transmitted primarily from adult household members. As a result, studies completed thus far might not have fully identified the potential transmission risks by children. To confirm whether there are age-dependent factors associated with SARS-CoV-2 transmissibility, more epidemiological studies are needed.

Limitations

Our study had limitations. First, enrollment in the study relied on individuals to self-request home-collection kits. Individuals needed to be familiar with the study and to have had access to a device with internet capabilities. Therefore, while our study aimed to sample from across various demographic categories (eg, age, race/ethnicity, residence, and household income), our study findings might not be representative of the county population as a whole or completely generalize to other US counties. Second,

demographic and illness-related information were self-reported and therefore subject to response bias. Although the study accepted both asymptomatic and symptomatic individuals, individual self-reporting of symptoms might have been biased by participant-perceived eligibility criteria. Third, the exact duration of symptoms prior to obtaining a swab were self-reported and not independently verified. Fourth, the number of children enrolled increased in the later part of the study when we switched to using AN swabs because of supply chain disruptions. Because AN swabs had higher yield of viral RNA compared with MTB swabs, likely because of increased comfort and ease of swabbing, we adjusted for the different types of swabs in our analysis. Fifth, this study relied on Ct values from semiquantitative RT-PCRs as proxies for viral RNA levels; more studies using quantitative RT-PCRs to generate direct viral RNA levels are needed. Sixth, the cross-sectional design of this study in addition to brief delays between symptom reporting and swab collection might have led to misclassification of asymptomatic and presymptomatic individuals at the time of sample collection. Characteristics, including Ct values, might differ between these 2 groups.

Conclusions

In this community-based cross-sectional study, SARS-CoV-2 RNA levels, as determined by RT-PCR Cts, were significantly higher in symptomatic individuals than in asymptomatic individuals. There were no significant differences in RNA levels in asymptomatic children vs asymptomatic adults or in symptomatic children vs symptomatic adults. Further research is needed to understand the role of SARS-CoV-2 RNA levels in transmission among children and adults.

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Impact assessment of non-pharmaceutical interventions against coronavirus disease 2019 and influenza in Hong Kong: an observational study

Summary

Background A range of public health measures have been implemented to suppress local transmission of coronavirus disease 2019 (COVID-19) in Hong Kong. We examined the effect of these interventions and behavioural changes of the public on the incidence of COVID-19, as well as on influenza virus infections, which might share some aspects of transmission dynamics with COVID-19.

Methods We analysed data on laboratory-confirmed COVID-19 cases, influenza surveillance data in outpatients of all ages, and influenza hospitalisations in children. We estimated the daily effective reproduction number (R_t) for COVID-19 and influenza A H1N1 to estimate changes in transmissibility over time. Attitudes towards COVID-19 and changes in population behaviours were reviewed through three telephone surveys done on Jan 20–23, Feb 11–14, and March 10–13, 2020.

Findings COVID-19 transmissibility measured by R_t has remained at approximately 1 for 8 weeks in Hong Kong. Influenza transmission declined substantially after the implementation of social distancing measures and changes in population behaviours in late January, with a 44% (95% CI 34–53%) reduction in transmissibility in the community, from an estimated R_t of 1.28 (95% CI 1.26–1.30) before the start of the school closures to 0.72 (0.70–0.74) during the closure weeks. Similarly, a 33% (24–43%) reduction in transmissibility was seen based on paediatric hospitalisation rates, from an R_t of 1.10 (1.06–1.12) before the start of the school closures to 0.73 (0.68–0.77) after school closures. Among respondents to the surveys, 74.5%, 97.5%, and 98.8% reported wearing masks when going out, and 61.3%, 90.2%, and 85.1% reported avoiding crowded places in surveys 1 ($n=1008$), 2 ($n=1000$), and 3 ($n=1005$), respectively.

Interpretation Our study shows that non-pharmaceutical interventions (including border restrictions, quarantine and isolation, distancing, and changes in population behaviour) were associated with reduced transmission of COVID-19 in Hong Kong, and are also likely to have substantially reduced influenza transmission in early February, 2020.

Introduction

The first wave of coronavirus disease 2019 (COVID-19) in China, outside of Hubei province, was addressed with the implementation of aggressive public health measures.¹ These measures relied heavily on massive mobility restrictions, universal fever screening in all settings, and neighbourhood-based, household-focused social distancing that was enforced by large teams of community workers, as well as pervasive deployment of artificial intelligence-based social media applications and the use of big data.² Whether some or all of these measures would be acceptable and feasible in settings outside of mainland China has been questioned.³

Hong Kong is a Special Administrative Region of China that operates with a large degree of autonomy. It is located outside the mainland on the southern coast of China, neighbouring Guangdong province—which has recorded the largest number of confirmed cases of COVID-19 (1490 cases as of March 31, 2020) outside of Hubei. Having

been one of the most heavily affected epicentres during the severe acute respiratory syndrome (SARS) epidemic in 2003, the community in Hong Kong has been prepared to respond to emerging infectious diseases. A range of public health measures have been implemented to delay and reduce local transmission of COVID-19, and there have been major changes in population behaviour.

The initial containment or current suppression measures used to control COVID-19 in Hong Kong include intense surveillance for infections, not only in incoming travellers but also in the local community, with around 400 outpatients and 600 inpatients tested each day in early March, 2020. Once individuals are identified to be positive for COVID-19, they are isolated in hospital until they recover and cease virus shedding. Their close contacts are traced (from 2 days before illness onset) and quarantined in special facilities, including holiday camps and newly constructed housing estates. Because not every infected person will be identified, containment measures only work if social distancing

Research in context

Evidence before this study

Coronavirus disease 2019 (COVID-19) was first identified in late December 2019, in a cluster of cases of atypical pneumonia in Wuhan. Infections increased through January until the implementation of a lockdown of Wuhan and other affected cities. Since January, 2020, COVID-19 cases have been reported outside China in increasing numbers, with many countries not taking strong control measures, such as lockdowns, until relatively larger numbers of cases had been reported. In Hong Kong, Singapore, and Taiwan public health measures to prevent community epidemics were quickly implemented and were able to avoid the need for complete lockdowns. We searched PubMed on March 31, 2020, for studies reporting the impact of alternative public health measures against COVID-19 using keywords including "COVID-19", "2019-nCoV", "novel coronavirus-infected pneumonia", "SARS-CoV-2", "lockdown", "social distancing", "isolation", "contact tracing", and "quarantine". We scanned 227 published studies and found six that estimated the impact of public health measures in Wuhan or elsewhere in mainland China, one study that described the early application of testing and contact tracing in Singapore,

and one study reporting the impact of quarantine on transmission on the Diamond Princess cruise ship.

Added value of this study

We estimated the effective reproduction number of COVID-19 in Hong Kong as a measure of transmissibility over time and found that it has remained at approximately 1 for the past 8 weeks. We described the public health measures that have been introduced to contain COVID-19 transmission and the behavioural changes reported by the population, and found that distancing measures and changes in behaviour were associated with rapid declines in influenza activity. The speed of decline in influenza activity in 2020 was quicker than in previous years in which school closures were implemented but there were no other social distancing measures or voluntary changes in behaviour.

Implications of all the available evidence

The experience in Hong Kong indicates that COVID-19 transmission can be contained with a combination of testing and isolating cases, plus tracing and quarantining their close contacts, along with some degree of social distancing to reduce community transmission from unidentified cases.

measures or behavioural changes also reduce so-called silent transmission in the community as a whole.

Hong Kong offers an opportunity to study the impact of public health interventions and population behavioural changes that could be rolled out in resource-sufficient settings in other countries. We aimed to quantify the effect of containment measures on COVID-19. In addition, to identify whether social distancing and behavioural changes have been associated with reducing silent transmission of COVID-19, we analysed data on influenza activity as a proxy for potential changes in transmission of infection in line with the interventions implemented, assuming a similar mode and efficiency of spread of influenza and COVID-19. The specific objective of this study was to quantify population behavioural changes in Hong Kong during the COVID-19 outbreak, and to describe the likely impact of the behavioural changes and public health measures on COVID-19 transmission and influenza transmission in the community.

Methods

Data collection

Data on laboratory-confirmed COVID-19 cases were obtained from the Hong Kong Centre for Health Protection, which provides daily updates with individual case data on a dedicated webpage.

We obtained sentinel surveillance data on influenza-like illnesses in a network of around 60 general outpatient clinics from the Centre for Health Protection. These include weekly reports on the proportion of outpatient consultations that were in patients with influenza-like

illness, defined as fever plus cough or sore throat. We obtained laboratory surveillance data from the Public Health Laboratory Services on influenza testing results on specimens from public hospitals and sentinel surveillance sites, including the weekly number of specimens tested and the number testing positive for influenza by type and subtype. Data on the current population of Hong Kong by age and sex were obtained from the Census and Statistics Department of the Hong Kong Government. We obtained the daily hospitalisation rates for influenza-positive cases among children in Hong Kong using the daily hospital admissions for influenza to the paediatric departments of two large hospitals in Hong Kong and the relevant catchment populations.⁴

We did three cross-sectional telephone surveys among the general adult population in Hong Kong, on Jan 20–23, Feb 11–14, and March 10–13, 2020. The methods and survey instruments used were similar to those used for surveys during the SARS epidemic in 2003,^{5,6} the influenza A H1N1 pandemic in 2009,⁷ and the influenza A H7N9 outbreak in China in 2013.⁸ Participants were recruited using random-digit dialling of both landline and mobile telephone numbers. Telephone numbers were randomly generated by a computer system. Calls were made during both working and non-working hours by trained interviewers to avoid over-representation of non-working groups. Respondents were required to be at least 18 years old and able to speak Cantonese Chinese or English. New respondents were recruited for each survey round. Within each household, an eligible household member with the nearest birthday was invited to participate in the survey,

which was not necessarily the person that initially answered the telephone. Survey items included measures of risk perception, attitudes towards COVID-19, and behaviours taken against contracting COVID-19, including hygiene, face masks, and reduction of social contact. In the second and third surveys, respondents who were parents of school-age children were asked to answer additional questions about social contact patterns of their children because schools were closed at the time of the interviews. Ethical approval for this study was obtained from the Institutional Review Board of the University of Hong Kong. All participants gave verbal informed consent.

Statistical analysis

Means and proportions of survey responses were directly weighted by sex and age to the general population. Categorical variables with ordinal Likert-type response scales, including risk perception and attitudes towards COVID-19, were first dichotomised as either above or below a threshold. Responses to perceived susceptibility were dichotomised as 1 (likely, very likely, or certain) versus 0 (never, very unlikely, unlikely, or even chance); responses to perceived severity were dichotomised as 1 (serious or very serious) versus 0 (very mild, mild, or moderate); responses about worry were dichotomised as 1 (moderately worried or very worried) versus 0 (not at all worried or slightly worried); responses about attitudes towards COVID-19 were dichotomised as 1 (agree or strongly agree) versus 0 (strongly disagree, disagree, or neutral).

We estimated changes in COVID-19 transmissibility over time via the effective reproduction number (R_t), which represents the mean number of secondary infections that result from a primary case of infection at time t . Values of R_t exceeding 1 indicate that the epidemic will tend to grow, whereas values below 1 indicate that the epidemic will tend to decline. We estimated the time-varying reproduction numbers from serial intervals and incidence of COVID-19 cases over time,^{9,10} assuming a serial interval of 7.5 days.¹¹ We extended the approach used by Thompson and colleagues¹⁰ to allow for undetected cases due to censoring and imperfect detection of local cases. We assumed that 99% of imported cases and 80% of local cases would be detected. We developed a data-augmented Markov chain Monte Carlo algorithm to jointly estimate the time-varying reproduction number, the delay distribution from onset to reporting which can be used to inform censoring and undetected cases. Time-varying estimates of reproduction numbers were made with a 7-day sliding window.

To measure changes in influenza transmissibility over time, we first calculated the influenza proxy^{12,13} for influenza A H1N1 during the 2019–20 winter by multiplying the weekly influenza-like illness consultation rates by the weekly proportions of specimens positive for influenza A H1N1, which was the predominant strain. This influenza proxy is a better correlate of the incidence

of influenza virus infections in the community than either influenza-like illness rates or laboratory detection rates alone.¹³ We interpolated daily influenza proxy values from the weekly influenza proxy values with use of flexible cubic splines.¹⁴

Using the daily influenza proxy, we estimated daily transmissibility via the daily effective reproduction number, R_t . We used a simple branching process model for epidemic spread to estimate the time-varying intensity of transmission.¹⁵ We assumed the serial interval distribution for influenza followed a gamma distribution with a mean of 2.85 days and SD of 0.93 days.¹⁶ We repeated these analyses for the daily influenza A H1N1 hospitalisation rates among children in two large local hospitals (Queen Mary Hospital and Princess Margaret Hospital). We evaluated the changes in transmissibility by comparing the R_t values during the 2 weeks before and after the start of the school closures (including the Chinese New Year holidays) for the 2019–20 winter influenza season. The 95% CIs for the change in R_t were calculated using Fieller's theorem.¹⁷ We compared the reductions in 2019–20 with reductions in previous years when the Chinese New Year holidays occurred during influenza epidemics. All analyses were done with R version 3.6.2.

Role of the funding source

The funder of the study had no role in study design, data collection, data analysis, data interpretation, or writing of the report. The corresponding author had full access to all the data in the study and had final responsibility for the decision to submit for publication.

Results

As of March 31, 2020, Hong Kong had confirmed 715 cases of SARS coronavirus 2 (SARS-CoV-2) infection, including 386 individuals that were presumed to have acquired infection outside of Hong Kong (imported cases), 142 cases that could not be linked to any other case (unlinked local cases), and 187 cases that were linked to the other known cases (secondary cases; appendix p 1). Among these 715 cases of SARS-CoV-2 infection, 94 were asymptomatic infections and 621 were symptomatic infections. Figure 1 shows the timeline of interventions that were implemented by the government in Hong Kong, including travel restrictions and bans, flexible working arrangements, and school closures from kindergartens up to tertiary and post-tertiary institutions, including tutorial centres. Some religious organisations cancelled services from Feb 13 onwards, and many conferences and other local mass gatherings have been cancelled. Quarantine orders have been issued to the close contacts of individuals with confirmed infection, as well as travellers arriving from affected countries (figure 1).

Although unlinked COVID-19 cases have been detected in increasing numbers since early March, transmissibility (R_t) remains around the critical threshold of 1 (figure 2). Increases in local cases could be attributed to the

Figure 1: COVID-19 cases in Hong Kong by date of reporting (A) and date of symptom onset (B)

The Chinese New Year, a major winter festival in Hong Kong, was on Jan 25, and there were public holidays on Jan 25–28. Most schools started holidays on Jan 22 and were scheduled to resume on Feb 3. The Hong Kong Government has deferred class resumption several times and closures are now until further notice without an expected resumption date. 94 asymptomatic cases are not shown in panel B. All dates are in 2020. COVID-19=coronavirus disease 2019.

transmission of infections into the community, resulting from an increasing number of imported infections since early March. With a local effective reproduction number of 1, a gradual increase in the incidence of local infections would be expected.

Data on influenza activity based on the community influenza proxy were consistent with the rate of hospitalisation of children with influenza A H1N1 in Hong Kong (figure 3A, B). Influenza incidence peaked in the third week of January, with influenza A H1N1 predominating, and declined to low levels by the second week of February. The R_t for influenza A H1N1 gradually declined from the second week of January but was

greater than 1 before the start of the school closures and Chinese New Year. The R_t then declined to less than 1 shortly after the school closures and continued to decrease until early February (figure 3C, D). The estimated R_t was 1.28 (95% CI 1.26–1.30) during the 2-week period before the start of the school closures and 0.72 (0.70–0.74) during the first 2 weeks of school closures, corresponding to a 44% (34–53%) reduction in transmissibility (figure 3C). Similarly, the R_t calculated from hospitalisation data was 1.10 (1.06–1.12) before the start of the school closures and reduced to 0.73 (0.68–0.77) after school closures, corresponding to a 33% (24–43%) reduction in transmissibility (figure 3D).

Figure 2: Incidence and transmissibility of COVID-19 in Hong Kong

(A) Incidence of local COVID-19 cases in Hong Kong (dark blue bars) and cases infected overseas but detected locally (light blue bars). Augmented incidence includes estimated additional cases that have occurred but have not yet been identified due to reporting delays. (B) Estimates of the daily R_t of COVID-19 over time. The pink shaded area indicates 95% CIs. The dashed line indicates the critical threshold of $R_t=1$. All dates are in 2020. COVID-19=coronavirus disease 2019. R_t =effective reproduction number.

In comparison, during the 2010–11 winter, we estimated the reduction in transmissibility of influenza associated with the Chinese New Year holidays to be 15% (95% CI 11–19%), declining from an R_t of 1.10 (1.08–1.13) in the 11-day period before the start of the school holidays to 0.95 (0.92–0.96) during the 11-day school holiday (figure 4). In the 2014–15 winter, the reduction in transmissibility associated with the Chinese New Year holidays was 14% (7–22%), declining from an R_t of 0.94 (0.93–0.96) in the 11-day period before the start of the school holidays to 0.81 (0.75–0.86) during the 11-day school holiday.

We interviewed 1008 participants on Jan 20–23 (22% response rate), 1000 participants on Feb 11–14 (23% response rate), and 1005 participants on March 10–13 (response rate 15%; appendix p 3). Respondents included a broad cross-section of the adult population of Hong Kong (appendix p 2). Respondents perceived that they had similar susceptibility to COVID-19 as they did to seasonal influenza, but that COVID-19 was a much more serious infection, and around half of the respondents reported worrying about being infected with COVID-19 compared with around a third of respondents for seasonal influenza (table). In survey 2, 76.4% of respondents agreed with the statement that complete border closure would be effective in preventing the spread of COVID-19 to Hong Kong,

84.1% were worried about the availability of medical supplies, including face masks, but only 27.7% were worried about the availability of living supplies, including food and household goods, in Hong Kong (table).

We identified considerable increases in the use of preventive measures in response to the threat of COVID-19. In recent years, face masks have mainly been used by individuals in the general community who are ill and by those who feel particularly susceptible to infection and want to protect themselves. We found that 74.5%, 97.5%, and 98.8% of respondents wore masks when going out; 61.3%, 90.2%, and 85.1% avoided going to crowded places; and 71.1%, 92.5%, and 93.0% reported washing or sanitising their hands more often, in surveys 1, 2, and 3, respectively (table). In surveys 2 and 3, 88.0% and 83.8% reported staying at home as much as possible.

In surveys 2 and 3, we asked the subset of respondents who were parents of school-age children about their support for school closures and the activities of their children during the school closures. Among respondents who were parents, 249 (95.4%) of 261 and 192 (93.7%) of 205 agreed or strongly agreed that school closure was needed as a control measure for COVID-19 in Hong Kong, and 209 (80.1%) of 261 and 141 (68.8%) of 205 responded that their children had no contact with people other than their household members on the preceding day.

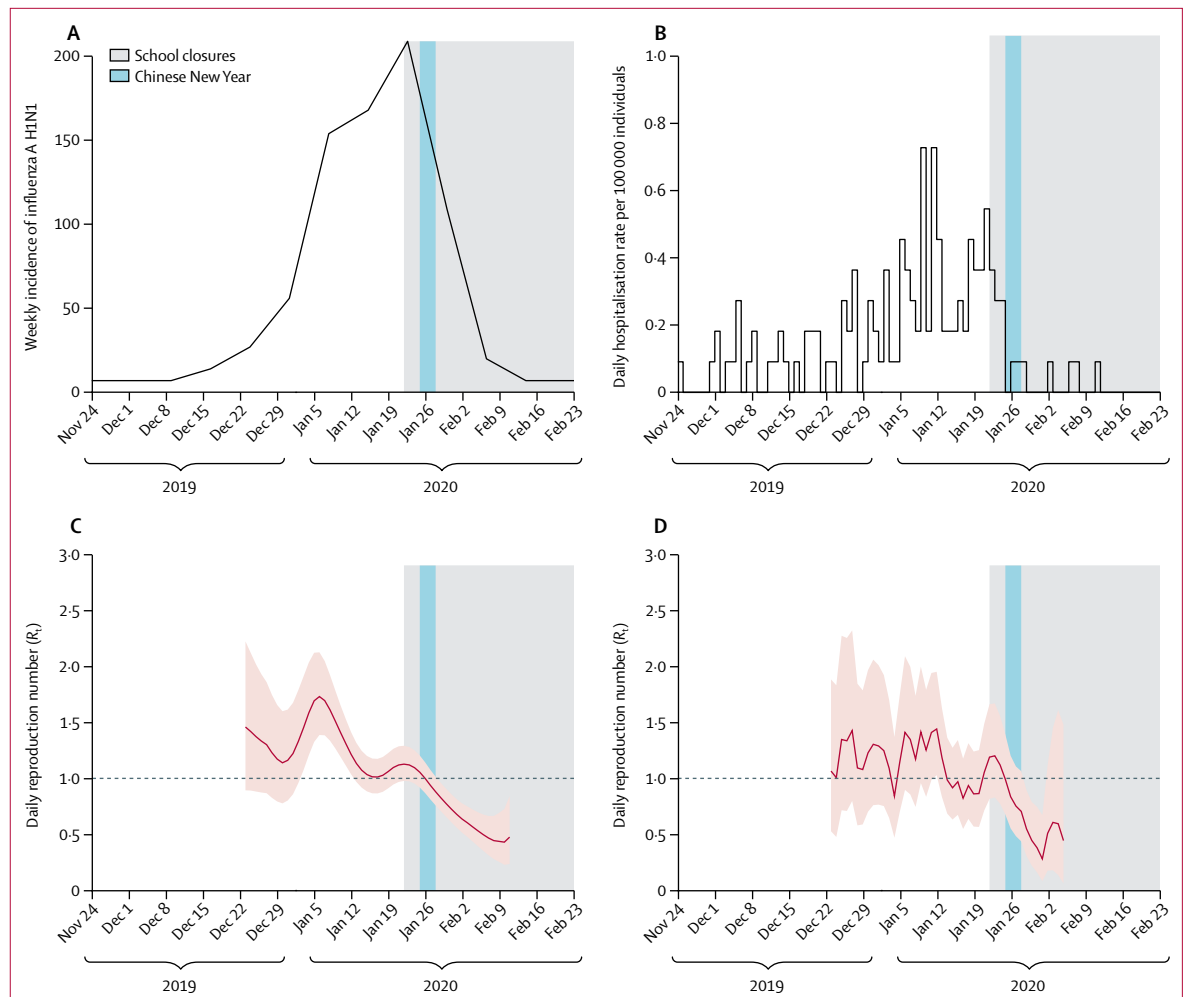

Figure 3: Incidence, hospitalisation rate, and R_t of influenza A (H1N1) in 2019–20

(A) Weekly incidence, calculated as the weekly consultation rate multiplied by the proportion of laboratory specimens testing positive for influenza A (H1N1). (B) Daily hospitalisation rate with influenza A (H1N1) in children in two large hospitals in Hong Kong. (C) Estimated R_t in Hong Kong based on the influenza proxy data, with 95% CIs indicated by the pink shaded region. (D) Estimated R_t in Hong Kong based on the hospitalisation data, with 95% CIs indicated by the pink shaded region. We stopped estimating R_t when the local epidemic ended, indicated by a reduction in influenza proxy to very low levels and no further influenza hospitalisations in children. Dashed lines indicate the critical threshold of $R_t=1$. Shaded bars show the dates of Chinese New Year (light blue) and school closures (grey). R_t =effective reproduction number.

Discussion

Our findings suggest that the package of public health interventions (including border entry restrictions, quarantine and isolation of cases and contacts, and population behaviour changes, such as social distancing and personal protective measures) that Hong Kong has implemented since late January, 2020, is associated with reduced spread of COVID-19. In the 10 weeks (corresponding to about ten generation times) since the first known individual with COVID-19 in Hong Kong began to show symptoms, there has been little sustained, local transmission of the disease. Our findings strongly suggest that social distancing and population behavioural changes—that have a social and economic impact that is less disruptive than total lockdown—can meaningfully control COVID-19.

The increasing number of imported infections in March poses a challenge to suppression efforts. This increase has occurred at the same time as relaxation of some voluntary avoidance behaviours in the general community. Without a strengthening of social distancing measures, local infections are likely to continue to occur, given that the effective reproduction number is approximately 1 or slightly higher than 1. Travel measures and testing, tracing, and treating efforts are particularly important in maintaining suppression, although these measures will be increasingly difficult to implement as case numbers increase.

In addition to the identification of cases with isolation, contact tracing, and quarantine, social distancing has also likely played an important role in suppressing transmission. We found that control measures and changes in population behaviour coincided with a substantial reduction in

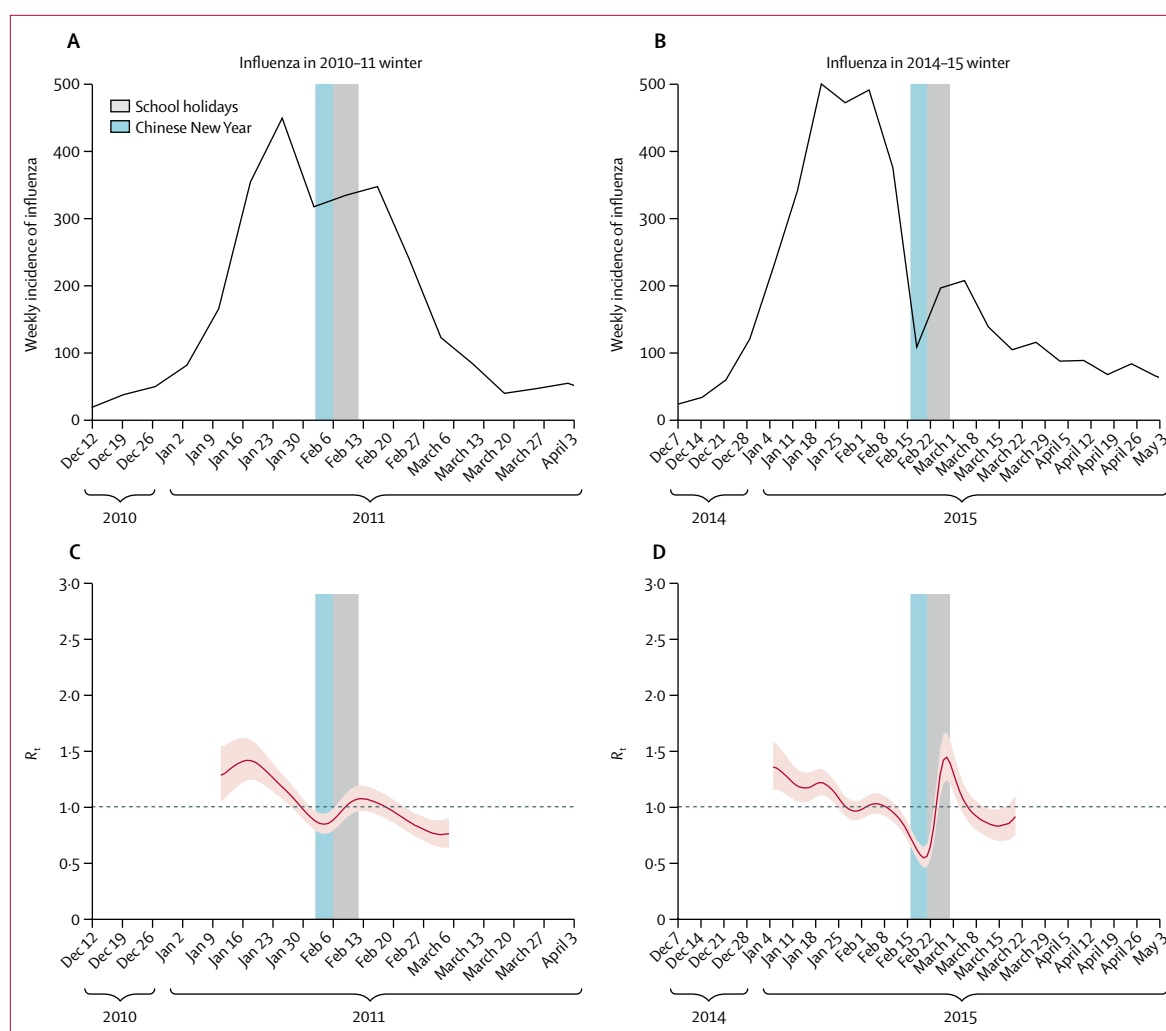

Figure 4: Incidence and R_t of influenza in 2010–11 and 2014–15

Weekly incidence of influenza (all type and subtypes) was calculated as the weekly consultation rate multiplied by the proportion of laboratory specimens testing positive for influenza in the winter influenza season of 2010–11 (A) and 2014–15 (B). R_t in Hong Kong was estimated based on the influenza proxy data, with 95% CIs indicated by the pink shaded region, for the winter influenza season of 2010–11 (C) and 2014–15 (D). Dashed lines indicate the critical threshold of $R_t=1$. Shaded bars show the dates of Chinese New Year (light blue) and school holidays (grey). R_t =effective reproduction number.

influenza transmission in early February, 2020. This observation suggests that the same measures would also have affected COVID-19 transmission in the community, because there will be some similarities—as well as some differences—in the modes of transmission of influenza and COVID-19. The potentially higher basic reproduction number for COVID-19 indicates that it might be more difficult to control than influenza.¹¹ Because a variety of measures were used simultaneously, we were not able to disentangle the specific effects of each one, although this may become possible in the future if some measures are strengthened or relaxed locally, or with use of cross-national or subnational comparisons of the differential application of these measures.

The estimated 44% reduction in influenza transmission in the general community in February, 2020, was

much greater than the estimated 10–15% reduction in transmission associated with school closures alone during the 2009 pandemic,¹⁸ and the 16% reduction in transmission of influenza B associated with school closures during the 2017–18 winter in Hong Kong.¹⁹ We therefore estimate that the other social distancing measures and avoidance behaviours have had a substantial effect on influenza transmission in addition to the effect of school closures. However, if the basic reproduction number of COVID-19 in Hong Kong exceeds 2, (it was 2.2 in Wuhan),¹¹ we would need more than a 44% reduction in COVID-19 transmission to completely avert a local epidemic. A reduction of this magnitude could, however, substantially flatten the peak of and area under the epidemic curve, thus reducing the risk of exceeding the capacity of the health-care system,

Risk perception of seasonal influenza			
Perceived susceptibility to seasonal influenza*	260 (25.1%; 22.0–28.3)	231 (22.5%; 19.4–25.6)	NA
Perceived severity of seasonal influenza†	406 (42.3%; 38.4–46.3)	311 (32.7%; 28.9–36.6)	NA
Worried about being infected with seasonal influenza‡	370 (36.5%; 32.9–40.0)	283 (30.3%; 26.6–33.9)	NA
Attitudes towards COVID-19§			
I'm confident that I can take measures to protect myself against COVID-19	518 (50.5%; 46.6–54.4)	594 (59.2%; 54.9–63.5)	679 (68.0%; 64.3–71.7)
I believe that the Hong Kong Government can take effective measures to control the spread of COVID-19 in Hong Kong	338 (33.5%; 29.9–37.1)	271 (31.8%; 27.8–35.8)	336 (35.8%; 32.2–39.3)
I believe that the Central Chinese Government can take effective measures to control COVID-19	308 (31.7%; 28.1–35.3)	352 (39.0%; 34.8–43.2)	NA
I believe that complete border closure is an effective measure to prevent COVID-19 spreading from mainland China to Hong Kong	NA	784 (76.4%; 72.3–80.5)	NA
Complete border closure will seriously affect the life of citizens	NA	298 (33.2%; 29.2–37.1)	NA
I worry about medical supplies, such as face masks, in Hong Kong	NA	860 (84.1%; 80.0–88.2)	NA
I worry about the living supplies in Hong Kong due to border closure	NA	244 (27.7%; 24.0–31.4)	NA
Preventive measures taken against COVID-19¶			
Avoided going to crowded places	627 (61.3%; 57.2–65.4)	920 (90.2%; 86.2–94.2)	860 (85.1%; 81.7–88.4)
Avoided visiting mainland China	800 (78.1%; 73.9–82.2)	NA	NA
Avoided contact with people with respiratory symptoms	687 (66.8%; 62.7–70.9)	834 (80.0%; 76.0–84.0)	806 (78.7%; 75.3–82.1)
Used face masks	778 (74.5%; 70.4–78.6)	976 (97.5%; 93.5–100.0)	992 (98.8%; 96.0–100.0)
Washed hands more often (including using hand sanitiser)	726 (71.1%; 67.0–75.2)	938 (92.5%; 88.6–96.5)	941 (93.0%; 90.0–96.0)
Avoided touching public objects or used protective measures when touching public objects (eg, use tissue)	387 (36.4%; 32.3–40.5)	767 (73.8%; 69.8–77.9)	746 (73.1%; 69.6–76.7)
House disinfection	NA	897 (89.3%; 85.2–93.4)	899 (89.6%; 86.4–92.8)
Used serving utensils when eating	NA	686 (66.0%; 61.9–70.1)	692 (67.7%; 64.1–71.3)
Stayed at home as much as possible	NA	894 (88.0%; 83.9–92.1)	868 (83.8%; 80.5–87.1)
Avoided going to health-care facilities	NA	832 (81.0%; 77.0–85.1)	759 (74.7%; 71.1–78.3)
Data are n (%; 95% CI). Proportions were weighted by age and sex to the adult population in Hong Kong. All dates are in 2020. NA=not applicable (question was not asked in the survey). COVID-19=coronavirus disease 2019. *Numbers and proportions represent respondents that answered likely, very likely, or certain, rather than never, very unlikely, unlikely, or even chance. †Numbers and proportions represent respondents that answered serious or very serious, rather than very mild, mild, or moderate. ‡Numbers and proportions represent respondents that answered moderately worried or very worried, rather than not at all worried or slightly worried. §Numbers and proportions represent respondents that answered agree or strongly agree to these statements, rather than strongly disagree, disagree, or neutral. ¶Numbers and proportions represent respondents who had taken the measure in the previous 7 days to prevent contracting COVID-19.			

Table: Public attitudes, risk perceptions, and behavioural responses towards COVID-19 and seasonal influenza in three telephone surveys in Hong Kong

and potentially saving many lives, especially among older adults.

The postponement of class resumption in local schools in Hong Kong after the Chinese New Year holiday is technically a class dismissal or suspension rather than a school closure, because most teachers are still required to go to school premises to plan e-learning activities and set homework. Full school closures have been implemented locally in previous years, including during the SARS epidemic in 2003,⁶ during the influenza pandemic in 2009,¹⁸ and to control seasonal influenza epidemics in 2008 and 2018.^{19,20} Although school closures can have considerable effects on influenza transmission, their role in reducing COVID-19 transmission would depend on the susceptibility of children to infection and their infectiousness if infected. Both of these factors are

major unanswered questions at present.^{21,22} Despite this acknowledged uncertainty, our surveys revealed considerable local support for school closures.

Individual behaviours in the Hong Kong population have changed in response to the threat of COVID-19. People have been choosing to stay at home, and in our most recent survey, 85% of respondents reported avoiding crowded places and 99% reported wearing face masks when leaving home. Using similar surveys, face mask use during the SARS outbreak in 2003 was 79%,⁵ and it reached a maximum of 10% during the influenza A (H1N1) pandemic in 2009.⁷ These changes in behaviour indicate the level of concern among the population about this particular infection, and the extent of voluntary social distancing in addition to the distancing created by school closures. However, we did identify evidence of

reductions in voluntary social distancing behaviours in our third survey in March, perhaps indicating some fatigue with these measures.

Our study has some limitations. First, we could not identify which measure was potentially the most effective and whether border restrictions, quarantine and isolation, social distancing, or behavioural changes are most important in suppressing COVID-19 transmission. It is likely that each plays a part. Unlinked cases have been identified in the community and will continue to be identified, indicating that not every chain of transmission has been identified by contact tracing from known cases. Although we have noted major effects of control measures and behavioural changes on influenza transmission, the effects could be of a different magnitude for COVID-19 because of differences in transmission dynamics. Second, our surveys of population behaviours could have been affected by response bias, because we relied on self-reported data. They also could have been affected by selection bias away from working adults, although this should have been reduced by conducting surveys in non-working as well as working hours—we were unable to assess potential selection bias. Without a baseline survey before Jan 23, 2020, we could not compare changes in behaviours, although the results of similar surveys from previous epidemics can be used for comparison.^{6–8,11} Finally, although we identified reductions in the incidence of influenza virus infections in outpatients and paediatric inpatients, it is possible that these time series were affected by reduced health-care-seeking behaviours and limited health-care access that probably resulted from private clinic closure, which occurred around the period of the Chinese New Year holiday.

In conclusion, our study suggests that measures taken to control the spread of COVID-19 have been effective and have also had a substantial impact on influenza transmission in Hong Kong. Although the transmission dynamics and modes of transmission of COVID-19 have not been precisely elucidated, they are likely to share at least some characteristics with influenza virus transmission, because both viruses are directly transmissible respiratory pathogens with similar viral shedding dynamics.²³ The measures implemented in Hong Kong are less drastic than those used to contain transmission in mainland China, and are probably more feasible in many other locations worldwide. If these measures and population responses can be sustained, avoiding fatigue among the general population, they could meaningfully mitigate the impact of a local epidemic of COVID-19.

Contributors

BJC and GML designed the study. STA, TWYN, MWF, QL, MYWK, SLL, and SSC collected the data. STA, TWYN, TKT, JCML, and MWF analysed the data. BJC, STA, TWYN, PW, and GML interpreted the data. BJC wrote the first draft. All authors contributed to the final draft.

Declaration of interests

BJC reports honoraria from Sanofi Pasteur and Roche. All other authors declare no competing interests.

Data sharing

Data on the incidence of coronavirus disease 2019 and influenza activity are freely available from the Centre for Health Protection website (<https://www.chp.gov.hk/en/index.html>). Survey data are available from the corresponding author on request.

Acknowledgments

This project was supported by a commissioned grant from the Health and Medical Research Fund, Food and Health Bureau, Government of the Hong Kong Special Administrative Region.

Abstract

Purpose:

To evaluate the follow-up chest radiographic findings in patients with Middle East respiratory syndrome coronavirus (MERS-CoV) who were discharged from the hospital following improved clinical symptoms.

Materials and Methods:

Thirty-six consecutive patients (9 men, 27 women; age range 21–73 years, mean \pm SD 42.5 \pm 14.5 years) with confirmed MERS-CoV underwent follow-up chest radiographs after recovery from MERS-CoV. The 36 chest radiographs were obtained at 32 to 230 days with a median follow-up of 43 days. The reviewers systemically evaluated the follow-up chest radiographs from 36 patients for lung parenchymal, airway, pleural, hilar and mediastinal abnormalities. Lung parenchyma and airways were assessed for consolidation, ground-glass opacity (GGO), nodular opacity and reticular opacity (i.e., fibrosis). Follow-up chest radiographs were also evaluated for pleural thickening, pleural effusion, pneumothorax and lymphadenopathy. Patients were categorized into two groups: group 1 (no evidence of lung fibrosis) and group 2 (chest radiographic evidence of lung fibrosis) for comparative analysis. Patient demographics, length of ventilations days, number of intensive care unit (ICU) admission days, chest radiographic score, chest radiographic deterioration pattern (Types 1-4) and peak lactate dehydrogenase level were compared between the two groups using the student *t*-test, Mann-Whitney *U* test and Fisher's exact test.

Results:

Follow-up chest radiographs were normal in 23 out of 36 (64%) patients. Among the patients with abnormal chest radiographs (13/36, 36%), the following were found: lung fibrosis in 12 (33%) patients GGO in 2 (5.5%) patients, and pleural thickening in 2 (5.5%) patients. Patients with lung fibrosis had significantly greater number of ICU admission days (19 ± 8.7 days; P value = 0.001), older age (50.6 ± 12.6 years; P value = 0.02), higher chest radiographic scores [10 (0-15.3); P value = 0.04] and higher peak lactate dehydrogenase levels (315-370 U/L; P value = 0.001) when compared to patients without lung fibrosis.

Conclusion:

Lung fibrosis may develop in a substantial number of patients who have recovered from Middle East respiratory syndrome coronavirus (MERS-CoV). Significantly greater number of ICU admission days, older age, higher chest radiographic scores, chest radiographic deterioration patterns and peak lactate dehydrogenase levels were noted in the patients with lung fibrosis on follow-up chest radiographs after recovery from MERS-CoV.

Keywords: Lung fibrosis, MERS-CoV, Chest radiograph

Introduction

Outbreaks of infection of the Middle East respiratory syndrome coronavirus (MERS-CoV) are an emerging global health crisis.[1] Until recently, most cases (1,223 with 520 deaths) have occurred in Saudi Arabia and exhibit a case fatality of approximately 43%.[2] The morbidity and mortality caused by MERS-CoV are particularly alarming. The majority of affected patients typically present with a severe respiratory illness that requires hospitalization; the mortality rate approaches 60%.[3]

Chest radiography is found to be useful in the diagnosis of MERS-CoV by demonstrating lung abnormalities and in the evaluation of the progress of disease and its response to treatment.[4] Two recently published studies reported MERS-CoV chest radiographic findings and showed that sequential chest radiographs were valuable in the evaluation of the early diagnosis and monitoring of the radiographic progression of the disease.[5,6,7] Approximately 55% of MERS-CoV patients require ICU admission for respiratory failure and adult respiratory distress syndrome (ARDS).[5,6,7] Survivors of ARDS have a clinically significant reduction in health-related quality of life and varied radiological changes.[8,9,10] In the present study, we focused on investigating the lung parenchymal, airway, pleural, hilar and mediastinal abnormalities which can be present on short- and medium-term follow-up chest radiographs during the recovery period; this may have important clinical implications for understanding the sequelae of the disease and contribute to the future management of affected patients.

Therefore, the purpose of this study is to evaluate the follow-up chest radiographic findings in MERS-CoV patients who were discharged from the hospital following improved clinical symptoms.

Materials and Methods

Participants

This retrospective study was approved by the institutional review board with a waiver of informed consent. Our study ran from August 10, 2014 to September 02, 2015 and included 36 patients who were discharged from the hospital following recovery from the MERS-CoV infection. The final study population consisted of nine male and 27 female patients. Patient age ranged from 21 years to 73 years (mean \pm SD, 42.5 ± 14.5 years).

In our study population, MERS-CoV diagnosis was based on the World Health Organization (WHO) criteria.[11] At our institution, the treatment protocol for non-ICU patients suspected of having MERS-CoV was empiric treatment with oseltamivir (Tamiflu) until screening for respiratory viruses excluded

influenza A and H1N1. In addition, antibiotics (ceftriaxone and azithromycin) were started to manage the potential of bacterial pneumonia. For ICU patients, the same patient management policy was followed, but the choice of antibiotics was broader, such as piperacillin-tazobactam (Zosyn) with or without vancomycin (Vancocin). All 36 patients were discharged from the hospital after the following: 1) complete recovery from their current illness, 2) complete resolution of respiratory symptoms and oxygen dependency, 3) improved radiological parameters based upon serial radiographs and 4) improved laboratory parameters. All these patients fulfilled above mentioned criterion before discharge from the hospital.

The chest radiographic findings and computed tomographic findings of 36 out of 55 patients obtained during the active phase of the infection that are included in this report have previously been published. [5,6,7] The current study focused on the retrospective analysis of follow-up chest radiographic findings of the 36 patients after they had recovered from MERS-CoV as this had not been previously investigated.

Imaging technique

Digital radiography equipment (Mobilett Plus; Siemens, Erlangen, Germany) was used to obtain anteroposterior (AP) projection radiographs with standardized parameters [65 kV, 4–8 mAs according to body mass index (BMI) and focus-film distance of 100 cm. Non-portable radiography equipment (Philips Medical Systems, Hamburg, Germany) was used to obtain anteroposterior (PA) and lateral projection radiographs with standard techniques at a 180-cm focus-film distance.

Among the 36 follow-up chest radiographs from the 36 patients, 31 (86%) were obtained with a portable one-view technique (AP projection radiographs), while the remaining five (14%) radiographs were obtained with standard chest two-view techniques (PA and lateral projection radiographs).

Chest radiograph review

Two thoracic radiologists with 20 (K.M.D) and 8 (K.D.) years of experience of interpreting chest radiographs independently reviewed all chest radiographs which had been randomized prior to the evaluation process. The reviewers reached a decision on the final interpretation by consensus. Although the two reviewers were aware of the MERS-CoV infection diagnosis in our study population, other information, such as clinical information, laboratory results, prior imaging or non-imaging studies, original radiologic interpretation of chest radiographs and the group into which each of the patients were categorized, was blinded to decrease potential reviewer bias. For the studies with interpretation discrepancies from the two initial reviewers, a third reviewer (S.G.L., with 40 years of experience) served as the arbitrator and made the final decision after independently reviewing the chest radiographs.

A dedicated radiology picture archiving and communication system (PACS) workstation (Centricity 2.1.2.1; GE Healthcare, Milwaukee, WI, USA) that is available in our department was used for the evaluation of the chest radiographs from our study population. During the evaluation, reviewers could manually alter the degree of radiodensity settings and zoom into areas of interest to achieve a complete and detailed assessment.

Chest radiograph evaluation

Initially, all chest radiographs were categorized into two groups, normal or abnormal, based on lung parenchymal, airway, pleural, hilar and mediastinal findings on follow-up chest radiographs. Abnormal follow-up chest radiographs were subsequently assessed by established criteria as detailed in the following sections.

Lung parenchyma and airways were evaluated for the following: 1) consolidation, 2) ground-glass opacity (GGO), 3) nodular opacity, and 4) reticular opacity (i.e., fibrosis). [12,13,14,15,16,17,18] A diagnosis of consolidation was made when there was an area of increased opacity present that obscured the vessel margin and airway walls, with or without an air bronchogram. [14] GGO was defined as an area of

increased lung opacity within which margins of pulmonary vessels may be indistinct.[14] A diagnosis of nodular opacity was considered when an opacity was focal and round in shape. Reticular opacity which signals fibrosis, was defined as linear opacities forming a mesh-like pattern.[12,13,14,15,16,17,18] Follow-up chest radiographs were also evaluated for the presence of pleural thickening, effusion, or pneumothorax. Additionally, the hilar and mediastinum were assessed for lymphadenopathy. A hilar lymphadenopathy was considered to be present when there was an increase in the size and opacity of the hilum with a lobulated hilar contour and obscuration of the interlobular artery.[18,19] Mediastinal lymphadenopathy was defined as the presence of the widening of one or more mediastinal contours at known anatomic lymph node sites.[19]

Furthermore, if any other thoracic abnormalities not included in the aforementioned categories during the evaluation process were detected on follow-up chest radiographs, the reviewers were instructed to record them.

Comparison of chest radiograph findings and clinical parameters

Patient demographics, length of ventilations days, number of ICU admission days, chest radiographic score, chest radiographic deterioration pattern (Types 1–4)[5,6,7] and peak lactate dehydrogenase level[20,21] were compared between the cohort's two study groups[5,6,7] in order to evaluate the association with the presence of lung fibrosis seen on follow-up chest radiographs.

The chest radiographic score of MERS-CoV infection can be obtained by first dividing each lung into three zones and evaluating the levels of involvement in each zone.[22] The development of MERS-CoV lesions within each lung zone is then scored as follows: 0 = normal; 4 = complete involvement of one zone; or, 24 = complete involvement of all six zones.[5] The scores for all six zones per chest radiograph are added together to yield a cumulative chest radiographic score ranging from 0 to 24, depending upon the involvement of the lung parenchyma.

Chest radiographic deterioration during disease progression can be classified into four types.[1,2,3,4] Type 1 disease progression represents initial radiographic deterioration followed by improvement.[12,13] Type 2 disease progression is defined as static radiographic changes with no discernible radiographic peak or a change in overall mean lung involvement of less than 25%. Type 3 disease progression is represented by fluctuating radiographic changes with at least two radiographic peaks separated by a period of mild remission (remission is defined as a level of mean lung parenchyma involvement that differs from the peak level by >25%). Type 4 progression is defined as progressive radiographic deterioration.

Statistical analysis

Descriptive statistics in the form of mean, standard deviation, median and range as appropriate for age, length of ventilations days, number of ICU admission days, chest radiographic score, chest radiographic deterioration pattern, peak lactate dehydrogenase (LDH) level and frequency, with percentages for categorical variables, were calculated separately for the group of patients with lung fibrosis and without. The student *t*-test for normally distributed data and the Mann-Whitney *U*-test for non-normal distributed data were applied to assess statistically significant differences between with and without evidence of lung fibrosis groups. Fisher's exact tests were used to evaluate associations for categorical variables. A *P* value 0.05 (two-tailed) was considered for the statistically significant level. The IBM SPSS version 21.0 (IBM, Armonk, NY, USA) statistical package was used for the analysis of the study.

Results

Study cohort

There were no significant gender differences between the two groups ($p = 0.41$). However, group 2 patients with evidence of lung fibrosis were significantly older ($p = 0.02$) than group 1 patients and had a significantly greater number of ICU admission days ($p = 0.001$). The mean \pm SD, median, and range of follow-up of the 36 chest radiographs were 64.8 ± 85 days, 43 days, and 32–230 days, respectively. The mean \pm SD, median and range of lung fibrosis development of 12 patients were 82.4 ± 66 days, 44 days, and 32–230 days, respectively.

Chest radiograph findings

Two reviewers (K.M.D., K.D.) were able to reach a consensus on all abnormal findings detected on follow-up chest radiographs. The follow-up chest radiographs were normal in 23 of 36 (64%) patients. Abnormal chest radiographic findings were detected in 13 of 36 (36%) patients and are shown in Tables [1](#), [2](#) and [3](#).

The most frequent abnormality found on follow-up chest radiographs in MERS-CoV patients who recovered was lung fibrosis which was seen in 12 of 36 (33%) patients. Lung fibrosis was confined to one lobe in the 10 patients, including the right upper lobe in three (8%) patients, left lower lobe in three (8%) patients, right middle lobe in two (5.5%) patients and lingula in two (5.5%) patients [[Figure 1](#)]. The remaining lung fibrosis involved multiple zones in two (5.5%) patients [[Figures 2](#) and [3](#)]. GGO was the next most frequently detected abnormality on follow-up chest radiographs as seen in two (5.5%) patients and it was located in the lingula [[Figure 4](#)] in one patient and in the left lower lobe in one patient, respectively. No consolidation or nodular opacity was detected on follow-up chest radiographs.

In regard to pleural abnormality detected on follow-up chest radiographs in our study population, pleural thickening was seen in two patients and it was located in the right lower and left lower lobes, respectively [[Figure 5](#)]. No pleural effusion or pneumothorax was identified.

None of the patients had hilar and/or mediastinal lymphadenopathy. No other additional thoracic abnormalities were observed on follow-up chest radiographs in our study population.

Comparison of chest radiograph findings and clinical parameters

With regard to the extent of lung parenchymal involvement (chest radiographic score) during the course of the disease, the patients with evidence of lung fibrosis were associated with a significantly higher number of chest radiographic score ($P = 0.04$) [[Table 2](#)].

The association of lung fibrosis was highest (67%) in the Type 2 radiographic deterioration pattern, followed by the Type 3 (25%, $P = 0.01$) radiographic deterioration pattern [[Table 3](#)]. The association with the Type 4 radiographic deterioration pattern could not be ascertained due to lack of follow-up following the highest number of deaths in this group [[Table 3](#)].

The peak lactate dehydrogenase level was also higher in group 2 than in group 1 [315 (0–370 U/L) vs. 0 (0–310 U/L)] [[Table 2](#)]. The normal range of lactate dehydrogenase level at our institution is 121–214 U/L.

Discussion

The results of our study show that a substantial portion (33%) of the follow-up chest radiographs obtained from the MERS-CoV patients who recovered is abnormal. In our study population, the chest radiographic abnormalities are characterized by the presence of lung fibrosis, GGOs, and pleural thickening.

We believe that our finding of potentially permanent damage, such as lung fibrosis and pleural thickening, seen in a substantial portion of our MERS-CoV patients who recovered is important because typical viral pneumonia usually results in a complete recovery without any significant radiological consequences.[\[23\]](#) The results of our study suggest that MERS-CoV may be a novel, more aggressive type of lung infection than other viral lung infections and that it may be associated with more significant morbidity in affected

patients. In fact, our study also shows that lung fibrosis developed rather rapidly in the study population with a mean \pm SD, median and range of lung fibrosis development of 82.4 ± 66 days 44 days, and 32–230 days, respectively, after discharge from the hospital.

Lung fibrosis has been detected on follow-up imaging studies in patients who recovered from relatively new pulmonary infections such as swine influenza (i.e. H1N1) pneumonia[24] and severe acute respiratory syndrome (SARS).[25] We found that the incidence (33%) of lung fibrosis seen in our study population is higher than the rate (10%) of lung fibrosis seen in patients who recovered from swine influenza pneumonia.[24] However, the incidence (33%) of lung fibrosis seen in patients who recovered from MERS-CoV is similar to the incidence (38%) of lung fibrosis detected in patients who recovered from SARS.[25] Given that the presence of pulmonary fibrosis was evaluated based on follow-up chest radiographs in our study population, in comparison to the chest computed tomography (CT) used in another study that focused on detecting lung fibrosis in patients who recovered from SARS, we believe that the presence of lung fibrosis would be much higher if lung fibrosis was evaluated on chest CT rather than on chest radiographs as in our study population. Unfortunately, most of our patients underwent chest radiographs rather than chest CT for a follow-up evaluation after MERS-CoV recovery, which prevented us from investigating pulmonary fibrosis with chest CT. A future study using chest CT for the detection of lung abnormalities in our study population would be helpful to gain a more precise evaluation as CT is more sensitive than chest radiographs for accurately detecting such abnormalities.

In our study, direct comparison of the follow-up chest radiographic findings with clinical data revealed several significant differences between patients with follow-up chest radiographic evidence of lung fibrosis and those without evidence of lung fibrosis. We found that patients with lung fibrosis detected on follow-up chest radiographs were associated with a greater number of ICU admission days, older age, higher chest radiographic score and higher peak lactate dehydrogenase level. In other words, we believe that these are the underlying risk factors and/or predictors for developing lung fibrosis in MERS-CoV patients who recovered. It is understandable that lung fibrosis develops in patients who have been more severely infected with MERS-CoV (i.e. higher chest radiographic score) and who experience a longer infection period (i.e., greater number of ICU admission days). In addition, older patients with already aged lungs and decreased immune systems may not be able to completely recover from MERS-CoV and may be prone to develop viral-induced lung fibrosis.[26]

The exact triggers which initiate the lung fibrotic process remain unknown. Infectious agents, including both viruses and bacteria, have the capacity to cause alveolar epithelial cell injury and apoptosis.[24,27,28] Presumably, because of the similar reaction, a considerable number of the patients in our cohort with MERS-CoV have developed pulmonary fibrosis. If infection plays a causal role in the process of pulmonary fibrosis, then it is possible that therapeutic strategies, utilizing currently available antiviral or antibiotic drugs, may be effective in modifying the course of this dreadful condition.[27,28]

In regard to our finding of the association between the presence of lung fibrosis on follow-up chest radiographs and higher peak lactate dehydrogenase level, we believe that this can be explained because the higher peak of lactate dehydrogenase level may indicate underlying lung tissue destruction (i.e. lung fibrosis). This finding of the higher peak of lactate dehydrogenase level has been seen in patients affected with SARS and shown to be a good independent predictor of a worse clinical outcome.[20,21] Future studies focusing on understanding the underlying pathophysiology of developing lung fibrosis in this patient population would be valuable to better elucidate the direct underlying risk factors and their consequences.

This study has some limitations. First, some of the patients in our study had only frontal radiographs. Although we believe that this did not have a significant effect on our findings, we acknowledge that there may have been a limitation regarding the complete assessment of subtle retrocardiac abnormalities and small pleural effusions that can be better seen on lateral radiographs. However, we would like to

emphasize that the reason for obtaining a single view (i.e. frontal radiograph only) was primarily due to our concerted effort to reduce the radiation exposure of our patient population. Second, as we have briefly mentioned in the discussion section, CT has better sensitivity than chest radiography in the diagnosis of lung fibrosis. Thus, the frequency of imaging findings such as lung fibrosis may have been underestimated in our study. A future study focusing on follow-up CT findings in patients who have recovered from MERS-CoV would be valuable in this regard. Lastly, our study focused on short- and intermediate-term follow-up imaging findings in our study population. A future study focusing on a long-term follow-up would be helpful for understanding the full spectrum of the sequelae of this new lung infection.

In conclusion, it is alarming that a substantial portion of the follow-up chest radiographs from the MERS-CoV patients who recovered are abnormal and characterized by potentially permanent lung damage such as lung fibrosis. Based on the observations made in our study, we believe that the greater number of higher ICU admission days, older age, higher chest radiographic score and higher peak lactate dehydrogenase level may have value in the prediction of lung fibrosis development in patients who have recovered from MERS-CoV. However, we wish to stress that our findings are based on short- and intermediate-term follow-up evaluation. Future studies consisting of a larger patient population with a longer follow-up period would be necessary in order to confirm our findings and better determine the long-term outcomes of patients who recovered from MERS-CoV.

Abstract

The 1918 influenza pandemic caused ~50 million deaths. Many questions remain regarding the origin, pathogenicity, and mechanisms of human adaptation of this virus. Avian-adapted influenza A viruses preferentially bind α 2,3-linked sialic acids (Sia) while human-adapted viruses preferentially bind α 2,6-linked Sia. A change in Sia preference from α 2,3 to α 2,6 is thought to be a requirement for human adaptation of avian influenza viruses. Autopsy data from 1918 cases, however, suggest that factors other than Sia preference played a role in viral binding and entry to human airway cells. Here, we evaluated binding and entry of five 1918 influenza receptor binding domain variants in a primary human airway cell model along with control avian and human influenza viruses. We observed that all five variants bound and entered cells efficiently and that Sia preference did not predict entry of influenza A virus to primary human airway cells evaluated in this model.

INTRODUCTION

Influenza A viruses cause acute respiratory viral disease in humans in both annual epidemics and in infrequent pandemics (1). The 1918 “Spanish” influenza pandemic resulted in approximately 50 million deaths globally and is the most severe influenza pandemic on record (2, 3). Many questions remain regarding the origin, pathogenicity, and mechanisms of human host adaptation of this deadly virus (4). Influenza A viruses bind to terminal sialic acids (Sia) on target cell glycans and it is hypothesized that changes in the influenza A virus hemagglutinin (HA) protein receptor-binding domain (RBD) are important in the process of host adaptation, specifically allowing avian-origin influenza A viruses to adapt to humans.

The 1918 HA gene has been sequenced from multiple postmortem human lung samples, and several naturally occurring 1918 HA RBD sequence variants have been reported (5–7). These include A/South Carolina/1/1918 (SC), which has an aspartic acid at both positions 187 and 222 in HA1 (H1 subtype numbering) (5) conferring an $\alpha 2,6$ Sia receptor-binding specificity and A/NY/1/1918 (NY), which differs from SC by a single amino acid, encoding a glycine at position 222 that confers a mixed $\alpha 2,3/\alpha 2,6$ binding specificity (8–10). Sheng et al., 2011 reported two 1918 HA sequences with new RBD variants with yet to be confirmed binding specificities (Table 1). The HA RBD of A/Virginia/1/1918 (VA), which, in addition to aspartic acids at positions 187 and 222 has a change from glutamine to arginine at position 189 in the HA1 domain, may have an enhanced $\alpha 2,6$ binding specificity based on computational modeling (7, 9). No binding specificity data is available for the A/New York/3/1918 (NY3), although deep sequencing revealed a predominance of asparagine rather than glycine at position 222 (11). Finally, the ‘avianized’ laboratory-produced variant of the 1918 virus HA (AV), in which the aspartic acid at position 187 in NY was mutagenized back to the avian influenza virus consensus glycine, is reported to be exclusively $\alpha 2,3$ Sia binding (8–10).

It is not yet fully clear how influenza A virus Sia preferences, as predicted by *in vitro* glycan array analysis with limited numbers of synthetic oligosaccharides, relate to binding and entry of influenza viruses into the human respiratory tract, including the epithelium of the distal trachea and bronchi. Review of 1918 autopsy material, including correlative analyses of histopathology, distribution of influenza viral antigen by immunohistochemistry, and 1918 HA RBD variant gene sequencing, demonstrated no difference in cell tropism between the four naturally occurring 1918 RBD variants outlined above (7). Autopsy sections demonstrated that the 1918 virus, regardless of HA RBD sequence, infected the entirety of the respiratory tract, including ciliated cells and goblet cells of the tracheobronchial tree and of the bronchiolar epithelium, and alveolar lining type I and type II cells. Based on lectin histochemistry, however, the upper airway and distal trachea in humans is reported to display predominantly $\alpha 2,6$ Sia on apical epithelial cell surfaces (12–14). Mouse models of 1918 influenza viral infection also suggested that factors other than Sia preference play a role in influenza binding and entry to airway cells (15). Histopathological changes, cell tropism, and viral antigen distribution in lungs of mice infected with the 1918 RBD variants SC, NY, and AV were similar across viral variants and correlated with human autopsy findings.

Normal human bronchial epithelial (NHBE) cells, are primary human airway cells, and are variably reported to display exclusively $\alpha 2,6$ Sia or a mixture of $\alpha 2,3/\alpha 2,6$ Sia on their cell surfaces (14, 16–20). This laboratory has previously characterized the Sia distribution on a single lot of NHBE cells harvested from a healthy female donor and showed that this lot displays near exclusively $\alpha 2,6$ Sia on goblet and ciliated cell surfaces and rarely displays $\alpha 2,3$ Sia on goblet cell surfaces (14). Additionally it was shown that this lot of cells readily supports both human- and avian-adapted influenza virus growth to peak titers of 10^4 -to- 10^6 viral plaque forming units (pfu)/mL (14, 21). , Experiments described here were conducted to evaluate the binding, entry, and peak replication of 1918 HA RBD variants, utilizing this lot of well-characterized NHBE cells, and to compare their binding and entry to human-adapted and avian H1 subtype influenza virus controls. Prevailing hypotheses suggest that variants with $\alpha 2,6$ Sia preferences would bind and enter human airway epithelial cells more efficiently than those the $\alpha 2,3$ Sia or mixed $\alpha 2,3/\alpha 2,6$ Sia preferences. Here NHBE cells were infected at a constant multiplicity of infection (MOI). In multiple experiments binding and entry was examined by immunofluorescence at 5- and 20-minutes post-addition of virus and quantification of cell-associated virus was performed by quantitative reverse transcriptase polymerase chain reaction (qRT-PCR). Viral replication was assessed at 12, 24, and 36-hours post-infection in a subset of viruses representing the a range of Sia binding preference (AV $\alpha 2,3$; NY mixed $\alpha 2,3$ and 2,6; and SC $\alpha 2,6$).

MATERIALS AND METHODS

Growth and differentiation of cells

Primary Normal Human Bronchial/Tracheal Epithelial (NHBE) cells (CC-2541, Lonza; Walkersville, MD) from a single donor were grown as per manufacturer's instructions as described in detail previously (14). Briefly, NHBE cells were grown submerged in vendor-supplied medium on transwell-clear membrane supports coated with rat-tail collagen until fully confluent, at which point the apical medium was removed, creating an air-liquid interface and the media type was changed. Cells were then grown until they formed a mature pseudostratified epithelium, ~28 days total time.

Construction and rescue of chimeric viruses

Five variants of 1918 influenza A HA RBD virus were generated including four previously reported and a fully avianized version (5, 7, 8). Table 1 shows the amino acid sequences of each HA RBD variant's critical amino acid mutations, its hemagglutinin Sia binding preference (if known), and the abbreviated name as used in this study. In summary, all viruses but AV encode an aspartic acid (D) at position 187 [H1 numbering used throughout]; AV was engineered to encode the avian H1 influenza virus consensus glutamic acid (E) at this position. At position 222, SC and VA have D, NY and AV have glycine (G), and the HA of NY3 encodes an asparagine (N) (7). VA encodes a D at positions 187 and 222 as does SC but additionally encodes an arginine (R) at position 189 instead of the consensus glutamine (Q).

The fully reconstructed 1918 H1N1 influenza viruses were isogenic except for the above HA RBD polymorphisms, and were prepared by reverse genetics as previously described (15).

RBD mutations in the 1918 HA gene for each of the other viruses were generated with a site-directed mutagenesis kit following the manufacturer's instructions (Stratagene; La Jolla, CA). All rescued viruses were propagated in Madin-Darby canine kidney (MDCK) cells (ATCC; Manassas, VA). The genomic sequence of each rescued virus was then confirmed by sequence analysis of the inoculum prior to performing the experiments. All viruses and infectious samples were handled under BSL3+ conditions in accordance with the Select Agent guidelines of the National Institutes of Health (NIH) and the Centers for Disease Control and Prevention under the supervision of the NIH Select Agent and Biosurety Programs and the NIH Department of Health and Safety.

Hemagglutination Assay

Viral stocks were titrated by plaque assay as previously described (15) and NHBE infections were normalized by multiplicity of infection (MOI). Given a primary experimental focus on viral binding and entry, viral stocks were also quantitated by hemagglutinin units using a standard hemagglutination assay for influenza A virus with turkey red blood cells (22).

Viral infections

Uninfected histologic control inserts were immersed in 10% neutral buffered formalin (NBF) prior to transporting the rest of the cells into the select agent suite where infections were conducted. In order to examine variation in binding and entry patterns of the five 1918 viruses, infections were initially conducted as a single experiment with MOIs of 1.0 and 3.0 in triplicate for all five viruses (three inserts per MOI/virus combination). Following aspiration of mucus from each well, adherent mucus was solubilized by incubation in 200 μ L of PBS for 1 hr, removed by aspiration, and then infected with 100 μ L virus at the appropriate MOI (diluted in sterile PBS). Cells were incubated with virus for 20 min at 37 °C in an atmosphere of 5% CO₂, followed by aspiration of the virus supernatant from the apical aspect of the upper chamber. Cells were then washed once with sterile PBS, and inserts were placed in NBF. After 48 hr, fixed noninfectious inserts were removed from the Select Agent suite. Subsequent experiments were conducted as above but with variations to the MOI and incubation times. These experimental conditions included infections with MOIs of 0.1 and 0.01 for a 20 min incubation period, and infections with MOIs of 1.0, 0.1, and 0.01 for a 5 min period.

Quantitative reverse transcriptase PCR on cell lysates

We determined viral load (intracytoplasmic and plasma membrane bound) by qRT-PCR for the influenza A virus matrix protein 1 (M1) gene using RNA isolated from cell lysates from parallel experiments with all 5 1918 RBD variants at MOI of 0.1 and 0.01 for both 5- and 20- minute incubation time periods, conducted in triplicate. Further, we compared 1918 RBD variants AV, NY, and SC to a set of control influenza viruses, including human seasonal influenza A/New York/312/2001 (H1N1) [NY312] (14), 2009 H1N1 pandemic influenza A/Mexico/4108/09 (H1N1) [Mex09] (23), and low-pathogenic avian influenza A/mallard/Ohio/265/1987 (H1N9) (24) [LPAI]. These infections were performed at an MOI of 0.01 at 5 and 20 minutes incubations in sextuplicate. Briefly, total RNA was isolated from individual infected NHBE samples and their viral loads estimated as previously described (23). Results were graphed as a threshold cycle threshold (C_T) ratio of the human

housekeeping gene glyceraldehyde-3-phosphate-dehydrogenase (GAPDH) over influenza A viral gene Matrix. Two-way ANOVAs with Tukey's Multiple Comparison Tests were used for statistical analysis of both cell lysate real-time PCR data and replication kinetics and with alpha set to 0.05. Graphs and analyses were performed in Prism 6.0c (GraphPad; La Jolla, CA) and graphs further annotated in Adobe Illustrator CC 2014 (Adobe; San Jose, CA).

Viral replication kinetics

Replication kinetics including the 12, 24, and 36-hour time-points were determined for the AV, SC, and NY 1918 viruses. These viruses were selected to represent the range of known Sia binding preferences (AV α 2,3; NY mixed α 2,3 and 2,6; and SC α 2,6). Timepoints were selected to cover peak viral infection as seen in prior experiments with human and avian influenza A viruses in this lot of NHBE cells (14, 21). These experiments had also indicated that live-virus could not be detected in cell supernatants prior to 8 hours post-infection and that cell viability drops off between 24 and 48 hours post-viral infection (14, 21). Cells were infected with 100 μ L of virus at an MOI of 0.1 and wells were cultured at 37°C in an atmosphere of 5% CO₂ until each time-point was reached. This experiment was conducted in triplicate for each time-point/virus combination. Apical media was collected at the appropriate time for each infected insert by addition of 400 μ L PBS (200 μ L X 2) to each biological replicate and then collecting all fluid at the apical aspect. The remaining insert was placed into NBF. All supernatants were stored individually in cryovials at -80 °C for subsequent evaluation of viral titers by standard influenza A virus plaque assays (15).

Immunofluorescence (IF)

Fixed, differentiated infected and uninfected cells on their transwell membranes were individually embedded on edge in paraffin. Approximately 5 μ m thick cross sections of differentiated cells were cut and placed on positively charged slides, two sections per slide (NC State University College of Veterinary Medicine Histopathology Lab; Raleigh, NC). Each slide included two serial sections from a given well. In order to determine which epithelial cell types facilitated binding and entry of the influenza A viruses, sections for each MOI/virus combination were labeled using immunofluorescence for influenza A antigen as well as NHBE ciliated, goblet, and basal epithelial cell types as previously described (14) with the following changes. The donkey serum block was reduced to 5% strength as the lot of the anti-influenza antibody lacked the background issues documented in Davis et al., 2015 (14). Goblet cells were detected with 2 μ g/mL biotinylated Jacalin (B-1155, Vector Labs; Burlingame, CA) and visualized with 10 μ g/ml of Streptavidin Alexa Fluor-488 conjugate (S-11223, Molecular Probes; Eugene, OR), instead of fluorochrome conjugated Jacalin. Ciliated and basal cells were detected as before but visualized with Dylight-549 AffiniPure Donkey Anti-Mouse (discontinued, Jackson ImmunoResearch (JI); West Grove, PA) and Dylight-649 AffiniPure Donkey Anti-Rabbit (discontinued, JI) respectively. Sia distribution by lectin histochemistry was not repeated in this experiment given prior detailed characterization of this in the same NHBE donor and cell lot (14).

Immunofluorescence for endocytic pathway markers was used to determine the cellular compartment in which the influenza antigen signal was located. Slides were prepared for

antibody application as described previously (14). Dual labels were prepared with influenza A virus antibody, and an early endosome marker, rabbit polyclonal Anti-Rab5 antibody (ab13253, Abcam; Cambridge, MA), or the lysosome marker mouse monoclonal antibody Anti-LAMP1 [H4A3] (ab25630, Abcam). Additionally, a triple label was prepared with both endosome markers and influenza A virus antibody. Rab5 was applied at a 1:50 dilution and Lamp1 at 2 ug/mL, with both dilutions made in TBS. Appropriate secondary antibody pairings were selected for each of the markers in accordance with the previously described immunofluorescence work (14). All slides were mounted in Prolong Gold (P36930, Life Technologies; Grand Island, NY) as per vendor instructions. Slides were visualized and images captured on a Leica TCS SP5 X White Light Laser confocal system (Leica Microsystems; Buffalo Grove, IL) configured with Argon laser, 405 nm diode and photomultiplier tube detectors.

Image capture and analysis

Individual confocal sessions focused on an entire batch, defined as a single MOI/incubation time. In this manner, intra-batch image capture conditions were as constant as possible. Also, settings were reused between sessions, re-checking the thresholding of the influenza antigen signal against batch-specific uninfected control slides at each session start. Slides from the first experiment, MOI 3.0 and 1.0 with 20 min incubation, were reviewed manually with representative images taken for each virus/MOI combination.

For the second experiment, each well for each virus/MOI combination was reviewed manually for all virus/MOI combinations, visually scanning both strips of cells on the slide. Minimally, three representative 63x oil objective at zoom 1, 1024 x 1024 pixels full-thickness z-stacks were taken. Additionally, a 63x oil objective at zoom 2.5, 1024 x 1024 pixels representative full-thickness z-stack was captured for each virus/MOI combination was taken. As there was little difference between MOI 0.1 and 0.01, subsequent analyses focused on infections at an MOI of 0.01 at the 5 minute time point.

Image post-processing and analysis were done with the Leica Application Suite (Leica Microsystems) and Imaris 7.6.3 (Bitplane; Zurich, Switzerland). Maximum projected fluorescent images for influenza antigen with and without cell type markers were created. Within an experimental batch, intensity levels were adjusted consistently across all samples. Additionally, the differential interference contrast (DIC) slice, wherein ciliated and goblet cells were near equivalently in focus for the largest number of cells, was selected from each z-stack and merged with a max projected image of multi-label fluorescence. These images were reviewed for presence of influenza A virus antigen by cell type. Final figure compilation was done in Adobe Photoshop CS6 Extended (Adobe).

RESULTS

1918 RBD variants bound and entered NHBE cells efficiently

Infections at all MOI and incubation time combinations resulted in binding and entry of influenza virus in all samples. Immunofluorescence (IF) analysis of virus infections at MOI 3.0 or 1.0 incubated for 20 minutes demonstrated intracytoplasmic influenza antigen from

nearly every apical epithelial cell (data not shown). To look for more subtle differences between the 1918 virus RBD variants (Table 1), experiments with lower MOI and shorter incubation periods were performed. Variance in the virus entry patterns at MOI 0.1, especially for the 5 min incubation time, was noted. The results from the MOI 0.01, 5 min incubation time combination reinforced these findings. Therefore the main focus of the subsequent detailed analyses were infections at MOI 0.01 for 5 min along with cross checks with the 20 min incubations from the same MOI and the MOI 0.1 triplicates. Representative images for each 1918 virus at MOI 0.01 at the 5 min timepoint are shown in Figure 1.

1918 Influenza viral antigen was intracytoplasmic as well as bound to the apical epithelial surface of both goblet and ciliated cells. The relative intensity of influenza antigen labeling across the entire epithelium of the NHBE cells was highest for AV (Figure 1A), lowest for SC (Figure 1B), and intermediary for the other three viruses (Figure 1C–E; no virus control shown in Figure 1F). For each of the 1918 variants examined, intracytoplasmic influenza viral antigen signal was more prominent in goblet cells than in ciliated cells. Overall, patterns of 1918 viral antigen in NHBE cells at MOI 0.01 after incubation for 5 minutes were very similar for the naturally occurring 1918 RBD variants (Figure 1B–E), with more prominent labeling with the AV variant (Figure 1A). When the intracytoplasmic location of the influenza antigen was explored using endosomal markers (Fig. 2), there was occasional co-localization with early, Rab5 (Fig. 2D, yellow color), and more co-localization with late, Lamp1 (Fig. 2D, white), endosomal markers as well as a noticeable portion of intracytoplasmic influenza antigen signal that failed to co-localize with either marker (Fig. 2D, green color), suggesting that the majority of intracytoplasmic influenza virus was not present in endosomes at 20 minutes.

Evaluation of hemagglutination by three 1918 RBD variant viruses

We selected the 1918 viral variants AV, NY, and SC, representing the diversity of Sia preferences and conducted hemagglutination assays in order to determine if HA binding capacity varied across viral stocks. AV viral stock titer by plaque assay and HA units were approximately 4 times lower than those of NY and SC. After adjusting for differences in viral stock titer, however, HA units were equivalent across the three viruses (Table 2).

Quantitative reverse transcriptase PCR for viral RNA in NHBE cells

1918 RBD variant viral RNA was detected in lysates from cells infected at MOIs of 0.1 and 0.01 following 5 and 20 min incubations. The relative amounts of viral RNA were not statistically different across all viruses when infections were performed at an MOI of 0.1 for either incubation time (data not shown). When performed at an MOI of 0.01 at 5 minutes, AV viral RNA was present in statistically significantly higher amounts than the other four viral variants at 5 minutes ($p < 0.05$) (Figure 3). At 20 min after MOI 0.01 infection, AV viral RNA was still present in statistically significantly higher amounts than NY ($p < 0.05$) and SC ($p < 0.05$), but not as compared to NY3 or VA (Figure 3).

To determine the significance of these observations an additional experiment was performed comparing 1918 AV, NY, and SC RBD variant binding and entry to a set of control influenza viruses, including human seasonal influenza A/New York/312/2001 (H1N1) [NY312] (14),

2009 H1N1 pandemic influenza A/Mexico/4108/09 (H1N1) [Mex09] (23), and low-pathogenic avian influenza A/mallard/Ohio/265/1987 (H1N9) (24) [LPAI] as described above. At 5 and 20 minutes after addition of virus, the relative amounts of cell-associated viral RNA were generally comparable between human seasonal, pandemic, and avian H1 subtype influenza viruses with the seasonal H1N1 strain NY312 showing the highest amount of cell-associated viral RNA at both time points ($p < 0.05$). Otherwise, viral RNA levels were comparable between the different 1918 RBD strains, Mex09, and LPAI H1 viruses (Figure 4).

Viral replication of selected 1918 viral variants

Viral replication was measured in NHBE cells at 12, 24, and 36 hours following infection with the 1918 SC, NY, and AV viruses (Fig. 5). There was no statistical difference between viral titers among these groups at 12 hours, but at 24 and 36 hours, the AV variant replicated to slightly higher titers as compared to NY and SC ($p < 0.05$), with AV replicating $\sim 1 \log_{10}$ pfu/mL higher than SC and NY.

DISCUSSION

In this study we evaluated whether 1918 influenza viral variants with polymorphisms in their HA RBD differed in binding and entry to primary human airway cells from a single donor source. During preliminary studies performed at high MOIs (3.0 and 1.0), it was observed that the majority of luminal NHBE cells were positive for intracytoplasmic influenza antigen by IF labeling. Consequently we decreased MOIs to 0.1 and 0.01 in an effort to detect subtle differences in viral binding and entry under more discerning conditions. Following a 20-minute incubation at these lower MOIs, no difference in viral binding and entry could be detected by IF. At an MOI of 0.01 and 5-minute incubation, the “avianized” 1918 virus AV, with an $\alpha 2,3$ Sia receptor-binding specificity, was found to bind and enter NHBE cells more efficiently than the other four variants as assessed by IF (Figure 1).

The extent of antigen signal by IF was greater than predicted for MOIs of 0.1 (i.e., 1 viral particle per 10 cells) and 0.01 (i.e., 1 viral particle per 100 cells) for all viruses. Replication competent virus is believed to compose only a small fraction of viral stocks, which are otherwise largely composed of replication incompetent viral-like particles (25). Given this we sought to confirm that the proportion of HA binding particles did not vary significantly across viral stocks. We performed HA assays on AV, SC and NY, representing the range of binding configurations, and after adjusting for baseline viral stock titers, we confirmed that these infections were performed with equivalent HA units (Table 2). Additionally, we sequence-confirmed all rescued viral variants to rule out the possibility that observed differences in viral binding and entry might be attributable to human error during viral rescue or viral mutations during cell passage.

The observation that AV infections at MOI 0.01 following a 5-minute incubation resulted in slightly enhanced binding and entry to NHBE cells as compared with the four other 1918 RBD variants was further assessed by qRT-PCR for cell-associated viral RNA. In independent parallel experiments performed at MOI 0.01, we observed that cell-associated AV viral RNA was detected in slightly greater proportions than the 4 other RBD variants

following both a 5- and a 20-minute incubation (Figure 3). To further validate these results an additional experiment was performed comparing a seasonal H1N1 virus [NY312], a 2009 pandemic H1N1 virus [Mex09], and a low-pathogenic avian influenza H1N9 virus [LPAI] to three 1918 RBD variants - AV, NY, and SC (Figure 4). As shown, all viruses tested bound and entered NHBE cells, including an avian H1 virus with an $\alpha 2,3$ Sia preference. These data support the primary observation that avian viruses with an $\alpha 2,3$ Sia preference bound and entered NHBE cells in our system efficiently.

All five 1918 RBD variants were detected on the apical surface and within the cytoplasm of both ciliated and goblet cells with no discernable qualitative or quantitative difference in cell-type tropism between viruses. The potential for subtle quantitative differences in cell-type tropism between variants exists and could be evaluated in future work. While we did not repeat lectin histochemical analysis of cell surface Sia distribution in this study, prior detailed studies of the same NHBE cell donor and lot grown in the same conditions indicate that $\alpha 2,6$ Sia are predominantly displayed on ciliated and goblet cell surfaces and rarely $\alpha 2,3$ Sia are displayed on goblet cell surfaces (14). Similarly, we did not repeat glycan-binding arrays on the 1918 RBD variants AV, NY, and SC given that these have been previously well characterized and that we sequence-confirmed the 1918 RBD variants used in these experiments. Consequently in the present study cell surface Sia distribution did not predict binding and entry or cell-type preference of the five 1918 RBD variants in the primary human airway epithelial cells examined here.

Previously published data support that influenza viruses with $\alpha 2,3$ Sia preferences successfully infect NHBE cells. Oshansky et al., 2011 showed that low pathogenic avian influenza viruses with $\alpha 2,3$ binding preference infected differentiated NHBE cells displaying only $\alpha 2,6$ Sia receptors (26). Similar findings have been observed in *ex vivo* human respiratory tissue using an H5N1 avian virus (26–28). Our data fit with these prior observations. Sia-independent pathways for influenza viral entry into airway cells likely exist (29, 30). For example, when NHBE cells are treated with neuraminidase to remove the Sia, it has been observed that both avian and human influenza viruses readily infect them (26, 28). Mice lacking the enzyme ST6Gal I sialyltransferase, and thus unable to attach $\alpha 2,6$ Sia to cell surface N-linked glycoproteins, had similar viral titers in lung tissue as wild-type mice following influenza infection (31).

In an effort to discern intracellular location of influenza virus in our study, immunohistochemistry multi-labeling analysis for both viral antigen with early (Rab5) and late (Lamp1) endosomal markers was employed. Influenza viral antigen co-localized with early and late endosomal markers but was predominantly observed independent of endosomes within the cytoplasm (Fig 2). Influenza viruses are thought capable of entering cells through a variety of mechanisms including macropinocytosis, calveolar entry, clathrin-mediated endocytosis, as well as a non-calveolar, non-clathrin dependent pathways (32, 33). In this study, while co-localization of virus with early and late endosomal markers supports viral entry via endocytosis, the preponderance of virus independent of endosomes also suggests a non-endocytic entry (Figure 2). Future studies in primary human airway cell lines may further characterize mechanisms of influenza A viral binding and entry.

Finally at 24 and 36 hours post-infection, 1918 AV with $\alpha 2,3$ Sia-preference, replicated to higher titers than NY with mixed $\alpha 2,3/\alpha 2,6$ preference and SC with $\alpha 2,6$ preference. It was previously shown that seasonal and pandemic H1N1 influenza viruses replicated to peak viral titers of $\sim 10^4$ pfu/mL following MOI 0.1 infection in this NHBE cell lot (14) and multiple avian influenza viruses following MOI 1.0 infection replicate to peak titers between 10^4 and 10^5 pfu/mL at similar time-points post-infection (21). Similar to these prior observations, in this study two naturally occurring human 1918 influenza A RBD variants NY and SC replicated to peak titers of 10^4 pfu/mL while the avianized variant AV replicated to peak titers of $\sim 10^5$ pfu/mL.

Understanding viral and host factors contributing to influenza virus infection of human airway cells is necessary to elucidate the process of host-switch events and thus pandemic viral emergence. While cell surface Sia specificity may be important, it is conceivable that influenza viruses with $\alpha 2,6$ Sia receptor-binding specificity are better adapted to humans not due to an advantage in viral binding and entry at the cell surface but due to an advantage in evading decoy receptors present in mucus lining the human airway. Mucus is known to be rich in O-linked $\alpha 2,3$ sialic acids that efficiently bind influenza viruses with an $\alpha 2,3$ Sia binding preference (34). In our NHBE model, mucus was systematically solubilized and removed from the NHBE cell surfaces prior to infection so as not to interfere with viral infection. This process may have eliminated any selective advantage of influenza variants with $\alpha 2,6$ Sia receptor-binding specificity exposing subtle binding and entry advantages of the AV virus.

It is worth noting that *in vitro* glycan array hybridization has been relied upon to predict *in vivo* influenza virus Sia preference. However, *in vitro* glycan arrays likely do not reproduce the spectrum of Sia receptors present on human airway epithelia. A spectrum of Sia receptors on the human airway was recently characterized by mass spectrometry, confirming a wide variety of both N- and O-linked glycans, both $\alpha 2,3$ and $\alpha 2,6$, that correlated poorly with those found on the glycan arrays currently employed to determine viral binding preferences (35). Consequently Sia preference as predicted by glycan array hybridization may not accurately predict Sia preference *in vivo*. Additionally, the variability of airway Sia receptors with co-factors such as age, co-morbid medical conditions, etc. remains unknown. Host factors that result in differential expression of Sia receptors on cell surfaces may in part account for observed variability in host susceptibility to respiratory viral infections. Finally, plant lectins, which have been used to characterize the distribution of $\alpha 2,3$ Sia versus $\alpha 2,6$ Sia receptors on cell surfaces, have variable sensitivity and specificity. It is possible that in our model AV preferentially bound $\alpha 2,3$ Sia receptors distributed on NHBE cell surfaces not detected by standard lectins previously employed (14).

The primary limitation of this work is that all experiments were performed using a single NHBE cell donor and lot and a limited subset of viruses. Generalizability of our observations to other primary human airway cell lines and viruses would need to be evaluated in future work. Additionally *in vitro* models, even with primary human airway cell lines, cannot replicate the full spectrum of pathogen-host interactions that influence viral binding and entry *in vivo*. The strength of utilizing a single lot of NHBE cells in this study, however, relates to our prior detailed characterization of $\alpha 2,3$ versus $\alpha 2,6$ Sia distribution

over multiple experiments from this donor and cell lot (14). Despite a clear predominance of $\alpha 2,6$ Sia on cell surfaces we have shown that 1918 influenza viral variants with $\alpha 2,3$ and mixed $\alpha 2,3/\alpha 2,6$ Sia preferences readily bind, enter, and replicate within primary human airway cells. These findings suggest that predicted Sia preferences alone do not dictate influenza A viral binding and entry to human airway cells.

In summary, five 1918 RBD influenza viral variants efficiently bound and infected primary human airway cells comparably to control human and avian influenza A viruses. The experimental findings in this study correlated with the post-mortem observations of lung specimens from fatal 1918 influenza infections, which show no differences in viral distribution along the airway for the four naturally occurring 1918 RBD viral variants studied here (7). Taken together, these observations support that viral and host factors unrelated to Sia binding preference likely contribute to influenza binding and entry into human tracheobronchial airway epithelial cells, or perhaps Sia preferences restrict $\alpha 2,3$ Sia binding and entry in the nasopharyngeal epithelium. Further probing of these factors is needed to unravel the complexities of host switch events, the essential first step in the initiation of a pandemic.

Acknowledgments

The authors would like to acknowledge the staff at the NIAID RTB Bioimaging Section for their assistance with confocal microscopy and image post-processing. We thank Sandra Horton and her staff at the North Carolina State University College of Veterinary Medicine Histopathology Laboratory for their preparation of tissue and embedded NHBE cell sections for immunofluorescence and histological analysis. This work was supported by the Intramural Research Program of the National Institute of Allergy and Infectious Diseases, National Institute of Health. ASD and JKT are further thankful for the support of the NIH Comparative Molecular Pathology Research Training Program. This work was done in partial fulfillment of A. Sally Davis' dissertation work towards a Ph.D. in Comparative Biomedical Sciences at the North Carolina State University College of Veterinary Medicine.

Highlights

- 1918 influenza viral receptor-binding variants all bound and entered primary human airway cells.
- All 1918 variants were detected on the apical surface and cytoplasm of ciliated and goblet cells.
- Viral RNA levels in cells were comparable between human, pandemic, and avian influenza viruses.
- Sialic acid preference predicted by glycan array may not accurately predict preference *in vivo*.

Figure 1.

Comparison of influenza viral antigen distribution by cell type for 1918 receptor binding domain variants. Leica SP5 white light laser confocal maximum projection images of full thickness zstacks of immunofluorescence labeled formalin-fixed paraffin embedded NHBE cells. All imaging was done with a 63x oil objective at zoom 1, 1024 x 1024 pixels. (A) 1918 AV, (B) 1918 SC, (C) 1918 NY, (D) 1918 NY3, (E) 1918 VA and (F) media control (no virus); all were 5 min incubations with virus at MOI 0.01. The pseudo-colors are influenza viral antigen (green), goblet cells (magenta), ciliated cells (red), basal cells (blue), and nuclei (gray). Presented images are representative of the relative influenza viral antigen intensity across three individually infected wells for each virus and where there was inter- or intra-well variance in influenza antigen intensity, a field representative of the median relative intensity was selected. The influenza antigen signal in SC (B) is less than the other viruses and AV (A) has the strongest signal. Scale, 20 μ m.

Figure 2.

Endosomal markers with influenza antigen. Leica SP5 white light laser confocal maximum projection images of full thickness zstacks of immunofluorescence labeled formalin-fixed paraffin embedded NHBE cells infected with AV at MOI 1.0 for 20 min. All imaging was done with a 63x oil objective at zoom 3.5, 1024 x 1024 pixels. All images have nuclei (gray): (A) influenza viral antigen (green), (B) early endosomal marker Rab5 (red), (C) late endosomal marker Lamp1 (magenta), and (D) the fluorescence merge. Yellow or orange indicates colocalization of influenza viral antigen with the early endosomal marker Rab5. White indicates co-localization of influenza antigen with late endosomal marker LAMP1. Bar = 5 μ m.

Figure 3.

Real-time PCR results for all five viruses at a multiplicity of infection of 0.01. Real-time PCR data for MOI 0.01 both 5 min (left side) and 20 min (right side) post-viral infection. The data are presented as GAPDH cycle time (C_T)/Influenza viral Matrix C_T as previously described (23). At 5 min (*) denotes AV cell associated viral RNA level is significantly higher as compared to all other viruses and at 20 min is significantly higher than SC and NY by ANOVA with an alpha of 0.05.

Figure 4.

Real-time PCR results for Mex09, NY312, LPAI virus and three 1918 RBD variants AV, NY, SC. Real-time PCR data for MOI 0.01 both 5 minutes (left panel) and 20 minutes (right panel) post-viral infection. The data are presented as GAPDH cycle time (C_T)/Influenza viral Matrix C_T as previously described (23). At 5 min (*) denotes NY312 cell-associated viral RNA level is significantly higher as compared to all other viruses, except the LPAI virus. At 20 min (*) denotes NY312 cell-associated viral RNA level is significantly higher as compared to all other viruses by ANOVA with an alpha of 0.05.

Figure 5.

Replications kinetics for viruses AV, NY and SC. Plaque forming units at 12-, 24- and 36-hours post-infection with MOI 0.1 of NY, SC and AV. (*) denotes that AV is significantly different than both NY and SC at both 24 and 36 hours post-viral infection by ANOVA with an alpha of 0.05.

1918 Pandemic Influenza HA Receptor Binding Domain Variants Amino Acid Sequences

Table 1

Virus (Reference)	Abbreviation	Residue at HA1 domain			Binding
		187	189	222

ABSTRACT

Background Coronavirus disease-2019 (COVID-19) has caused a great global threat to public health. The World Health Organization (WHO) has declared COVID-19 disease as a pandemic, affecting the human respiratory and other body systems, which urgently demands for better understanding of COVID-19 histopathogenesis.

Objective Data on pathological changes in different organs are still scarce, thus we aim to review and summarise the latest histopathological changes in different organs observed after autopsy of COVID-19 cases.

Materials and methods Over the period of 3 months, authors performed vast review of the articles. The search engines included were PubMed, Medline (EBSCO & Ovid), Google Scholar, Science Direct, Scopus and Bio-Medical. Search terms used were 'Histopathology in COVID-19', 'COVID-19', 'Pathological changes in different organs in COVID-19' or 'SARS-CoV-2'. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2009 guidelines were used for review writing.

Result We identified various articles related to the histopathology of various organs in COVID-19 positive patients. Overall, 45 articles were identified as full articles to be included in our study. Histopathological findings observed are summarised according to the systems involved.

Conclusion Although COVID-19 mainly affects respiratory and immune systems, but other systems like cardiovascular, urinary, gastrointestinal tract, reproductive system, nervous system and integumentary system are not spared, especially in elderly cases and those with comorbidity. This review would help clinicians and researchers to understand the tissue pathology, which can help in better planning of the management and avoiding future risks.

INTRODUCTION

Coronavirus disease 2019 (COVID-19), which is zoonotic in origin and most commonly spread through respiratory droplets or aerosol transmission, has caused a big threat to mankind.¹ The disease was originated in the seafood market of Wuhan, Hubei, China, in early December 2019 with clinical presentations greatly resembling viral pneumonia.² This disease has affected most of the countries in the period of 2 months itself. The outbreak of COVID-19 has been declared a pandemic by World Health Organization (WHO)

and presents a great challenge for the healthcare communities across the globe.

The presently identified causative agent for COVID-19, severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), has shared 82% genome sequence similarity to previously identified SARS-CoV-1, which also originated in China in 2002.^{3,4} The structure of the enveloped single-stranded RNA virus consists of spike protein, which is mainly responsible for the pathogenesis in the human species. The spike protein of the virus, through its receptor binding domain (RBD) gets attached to a human cell surface receptor protein Angiotensin Converting Enzyme -2 (ACE-2), encoded by the ACE2 gene, followed by its priming through auxiliary protein TMPRSS2 (transmembrane protease, serine 2), a cell-surface protein that is expressed by epithelial cells of specific tissues including those in the aerodigestive tract. ACE-2, which acts as a viral host cell entry receptor, has ubiquitous distribution on the organs, therefore SARS-CoV-2 in severe cases causes a systemic disease, with possible involvement of the kidneys, the heart and blood vessels, the liver, the pancreas and also regulates alterations in circulating lymphocytes and the immune system.^{5–7} The maximum expression of the ACE-2 receptors according to the consensus dataset from the human protein atlas is found in small intestine, duodenum and colon followed by kidney, testis, gall bladder, heart, thyroid gland, adipose tissue, rectum and lungs.⁸

The lungs are affected the most, with patients presenting symptoms related to the respiratory system such as sore throat, fever, malaise, and respiratory distress, and in worst cases may proceed to respiratory failure. Mice-related studies show that there is no gender difference in ACE-2 activity in lungs and heart but an expression of ACE-2 is more in male kidneys as compared with female kidneys, making the males more prone to kidney-related disorders, due to SARS infection.⁹

The entry of virus in the host cells induces immune response with wide secretion of inflammatory cytokines and chemokines. Because SARS-CoV-1 and SARS-CoV-2 have the same mechanism of action, both can cause rapid production of multiple cytokines in body fluids following infection, leading to acute respiratory distress and multiple organ failure. This also explains why most patients with COVID-19 have mild symptoms at the onset of the disease, while conditions of a few affected patients are suddenly worsened

Table 1 Important histopathological findings of systems/organs observed by authors in different studies

S.N.	Histopathological findings	Authors
Respiratory system: Lung		
1.	<ul style="list-style-type: none"> ▶ Alveoli: Damaged or atypical enlarged pneumocytes with large nuclei, type II pneumocyte hyperplasia, diffuse alveolar damage (DAD), focal sloughing, hyaline membrane formation, intra-alveolar haemorrhage, intra-alveolar neutrophil infiltration, amphophilic granular cytoplasm and prominent nucleoli characteristic of viral cytopathic-like changes. ▶ Vessels: Oedematous and congested vessels, plug formation, fibrinoid necrosis of the small vasculature, hyaline thrombi in microvessels. Significant deposits of complements—C5b-9 (membrane attack complex), C4d, and mannose binding lectin (MBL)-associated serine protease (MASP)-2, in the microvasculature. ▶ Cellular components: Presence of syncytial giant cells, focal infiltration of immune and inflammatory (lymphocytes and monocytes) and increased stromal cells. ▶ Ultrastructural changes: Viral particles in bronchial mucosal epithelia and type II alveolar epithelia. 	Tian <i>et al</i> , Barton <i>et al</i> , Xu <i>et al</i> , Luo <i>et al</i> , Yao, Magroet <i>et al</i> , Bradley <i>et al</i>
Urinary system: Kidney		
2.	<ul style="list-style-type: none"> ▶ Glomerulus: Ischaemic changes, podocyte vacuolation, focal segmental glomerulosclerosis, accumulation of plasma in Bowman's space. ▶ Renal tubules: Loss of brush border in proximal tubule, non-isometric vacuolar degeneration, and necrosis, oedematous epithelial cells. ▶ Vessels: Erythrocyte aggregates obstructing the lumen of capillaries without platelet or fibrinoid material with occasional hemosiderin granules and pigmented casts, hyalinosis of arteriole, arteriosclerosis of medium sized arteries, fibrin thrombus, shrinkage of capillary loops in glomeruli. ▶ Ultrastructural changes: Clusters of viral particles with distinctive spikes in the tubular epithelium and podocytes. 	Yao <i>et al</i> , Su <i>et al</i> , Tietäväinen <i>et al</i> , Grimes <i>et al</i> , Bradley <i>et al</i>
Gastrointestinal system		
3.	<ul style="list-style-type: none"> ▶ Liver: Focal macrovesicular steatosis, nuclear glycogen accumulation in hepatocytes, dense atypical small lymphocytes in portal tracts. Regenerative nodules and thick fibrous bands, mild zone 3 sinusoidal dilatation, mild lobular lymphocytic infiltration. Patchy hepatic necrosis in the periportal and centrilobular areas. Hepatic cell degeneration and focal necrosis, biliary plugs in the small bile duct. ▶ Oesophagus: Occasional lymphocytic infiltration in the oesophageal squamous epithelium. ▶ Stomach: Partial epithelial degeneration, necrosis and shedding of the gastric mucosa. Dilatation and congestion of small blood vessels and oedema of lamina propria and submucosa with infiltration of immune cells (as lymphocytes, monocytes and plasma cells). ▶ Intestine: Stenosis of the small intestine and segmental dilatation. Numerous infiltrating plasma cells and lymphocytes with interstitial oedema in the lamina propria. ▶ Pancreas: Degeneration of the cells of islets. 	Tian <i>et al</i> , Yao <i>et al</i> , Liu <i>et al</i> , Xiao <i>et al</i>
Cardiovascular system		
4.	<ul style="list-style-type: none"> ▶ Foci of lymphocytic inflammation. ▶ Acute myocyte necrosis. ▶ Presence of inflammatory cells and apoptotic bodies. ▶ Ultrastructural observation: Viral inclusion bodies in vascular endothelial cells. ▶ Immunohistochemistry: Presence of CD61+ megakaryocytes in purpuric papulovesicular. 	Tian <i>et al</i> , Bradley <i>et al</i> , Wichmann <i>et al</i> , Tavazzi <i>et al</i> , Yao <i>et al</i> , Varga <i>et al</i> , Fox <i>et al</i> , Gianotti <i>et al</i> , Kolivras <i>et al</i> , Varga <i>et al</i>
Reproductive system		
5.	<ul style="list-style-type: none"> ▶ Thickened basement membrane with peritubular fibrosis and vascular congestion. ▶ Leucocyte infiltration. ▶ Extensive germ cell destruction. ▶ TUNEL assay: Increased apoptotic spermatogenic cells. 	Jian Xu <i>et al</i> , Chen <i>et al</i>
Nervous system		
6.	<ul style="list-style-type: none"> ▶ Acute hypoxic ischaemic injury, hyperaemia, oedema and neuronal degeneration. ▶ CT, MRI: Ischaemia and/or haemorrhage, and enhanced cortical/subcortical grey matter and fibre tracts. ▶ SARS-CoV-2 RNA was detected in the brain tissue and cerebrospinal fluid in some patients. 	Solomon <i>et al</i> , Mahammedi <i>et al</i> , Moriguchi <i>et al</i>
Histopathological findings (skin)		
7.	<ul style="list-style-type: none"> ▶ Vessels: Perivascular inflammatory cells, intraluminal thrombi. ▶ Epidermis: Parakeratosis, acanthosis, dyskeratotic keratinocytes, necrotic keratinocytes, acantholytic clefts, lymphocyte satellitosis and pseudoherpetic. ▶ Immunohistochemistry: ACE-2 positivity in basal layer of cells in hair follicle, sebaceous glands, smooth muscle cells. 	Hamming <i>et al</i> , Gianotti <i>et al</i> , Kolivras <i>et al</i>

after being diagnosed in hospital, which may be related to the body producing excessive cytokines after the disease, leading to 'cytokine storm' in the body.¹⁰ The association of viral infection with any comorbid conditions such as hypertension, diabetes and renal failure has shown more severe form of clinical presentations such as respiratory failure to multiple organ failure.^{8,9} To understand the effects, presenting symptoms and the pathophysiology of SARS-CoV-2 on various organs, it is of utmost need to understand the pathological findings related to the coronavirus disease, depending on the localisation of the ACE-2 receptors in various organs.

MATERIALS AND METHODS

Objective

Data on histopathological changes in different organs are still scarce, thus we aim to review and summarise the latest histopathological findings observed in different organs related to the infection following autopsy of patient's corpse who died following SARS-CoV-2 infection.

Information sources and search strategy

Over the period of 3 months, the authors performed vast review of the articles. The search engines used included PubMed,

Figure 1 Histopathological changes in lungs of COVID-19 patients. (A) Infiltration of lung tissue by mononuclear inflammatory cells, along with desquamation of alveolar epithelium and formation of hyaline membrane (arrow). (B) Hyaline membrane formation with no signs of inflammatory cell infiltrate. (C) Interstitial thickening with hyperplasia of type II alveolar epithelium. (D) Red blood cells present in alveolar lumen (asterisk) along with formation of fibrin plugs. (E) Diffuse hyperplasia of type II alveolar epithelium and presence of fibrinoid vascular necrosis (inset). (F) Infiltration of inflammatory cells, predominantly neutrophils into the alveolar lumen, indicative of broncho-pneumonia. (Courtesy: Tian S, Xiong Y, Liu H, Niu L, Guo J, Liao M, et al. *Pathological study of the 2019 novel coronavirus disease (COVID) through postmortem core biopsies. Mod Pathol.* 2020 Apr 14;1–8.)

Medline (EBSCO & Ovid), Google Scholar, Science Direct, Scopus and Bio Medical. Search terms used were 'Histopathology in COVID-19', 'COVID-19', 'Coronavirus', 'Pathological changes in different organs in COVID-19' or 'SARS-CoV-2', 'Lung pathology in COVID-19', 'Liver pathology in COVID-19', 'Cardiac involvement in COVID-19', 'Kidney pathology in COVID-19', 'Neuropathology in COVID-19', 'Endothelium and COVID-19' and so on. All the authors were asked to take one system and to extract all the data related to that particular system. Titles and abstracts were screened independently and reviewed with inclusion/exclusion criteria. After data extraction, findings were summarised and reported in [table 1](#) according to the objective of the study.

Protocol followed

Systematic review writing was performed using the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2009 guidelines (online supplementary table).

Inclusion and exclusion criteria

Articles (original, review, case series, case reports, published and preprints) that reported histopathological findings of organs in patients with COVID-19 after autopsy or endoscopic biopsy, from 31 December 2019 to 15 June 2020, were included in the study. Exclusive articles of SARS and MERS related to histopathological findings and a very few studies on animal models related to the topic were also included. Articles that did not

Figure 2 Histopathological changes in lungs of COVID-19 patients. (A) Ultrastructure of an epithelial cell of a bronchiole. Left panel shows organelle within epithelial cell while right panel shows viral particles. (B) Ultrastructure of a type II pneumocyte shows presence of organelle (yellow arrow) and viral particles (red arrows). (C) Positive (dark brown signals) SARS-CoV-2 nucleocapsid (N) in pulmonary tissue, confirmed by immunohistochemistry (IHC) and nuclei counter stained with hematoxylin. Inset shows magnified selected area. (D) Enlarged epithelial cells with areas of desquamation, stained with H & E. (E) Alveoli shows signs of exudation and infiltration by macrophages along with monocytes. (F) Formation of hyaline membrane within the lung tissue. (G) Infiltration of lung tissue with immune cells, which, immunohistochemically detected as CD68+ macrophages, CD20+ B cells, and CD8+ T cells. Scale bar: 50 μ m. (Courtesy: Yao X-H, He Z-C, Li T-Y, Zhang H-R, Wang Y, Mou H, et al. *Pathological evidence for residual SARS-CoV-2 in pulmonary tissues of a ready-for-discharge patient. Cell Res.* 2020;30(6):541–3.)

mention about histopathology of organs, unavailable full text, no target observations and other article types (letters, comments, news and so on) as well as studies reporting cases with incomplete information were excluded. As the study was a systematic review of the literature, institutional ethical committee approval and informed consent were not obtained as we limited our study to published information and human subjects were not involved directly.

RESULTS AND DISCUSSION

In this review, authors identified various articles related to the histopathology of different organs in COVID-19 positive patients. Overall, 45 articles were identified using different databases as full articles to be included in our study. Histopathological findings observed are summarised according to the systems involved.

Pathological features

The early pathological findings identified in the COVID-19 suggested that SARS-CoV-2 can widely spread in the epithelial lining of the respiratory tract, digestive tract, distal convoluted tubules of the kidney, the sweat glands of the skin and testicular epithelium including spermatogonia and sertoli cells. Now, it has been found that, in addition to respiratory transmission, the virus might also be transmitted through faeces, urine and skin. The new findings have also necessitated new ways to prevent the transmission of disease. Many studies on epidemiology and clinical characteristics of COVID-19 have been published but data on pathological changes in different organs are still scanty.¹¹ Hence, the histopathological findings in details have been described below according to the body systems involved.

Figure 3 Histopathological changes in kidneys of COVID-19 patients (A) Epithelium of proximal convoluted tubules shows decreased/loss of the brush border. (B) Tubular epithelial cells show vacuolar degeneration (arrows), leading to collection of necrotic debris in the lumen (asterisks). Blocked peritubular capillaries due to erythrocytic aggregates (arrowheads). (C,D) Inflammatory cells (arrowhead) infiltrate the tubules and arcuate artery (arrows). Bacterial foci (asterisks) is also observed. (E,F) Tubular deposition of hemosiderin granules, calcium deposits (arrowhead) and pigmented cast (arrow). (G,H) Glomeruli show ischaemic contraction (arrows) and fibrin thrombi (arrowhead). Bowman's space show presence of leaked accumulated plasma; hematoxylin and eosin. Bars = (F) 50 μ m, (A–C, E, G, H) 100 μ m, and (D) 250 μ m. (Courtesy: Su H, Yang M, Wan C, Yi L-X, Tang F, Zhu H-Y, et al. *Renal histopathological analysis of 26 postmortem findings of patients with COVID-19 in China*. *Kidney Int*. 2020 Jul;98(1):219–2.)

Histopathological findings in respiratory system

Patients with affected upper respiratory tract usually present with mild to moderate symptoms but patients with lower respiratory tract infection show features of pneumonia and land up with organ failure. The severity increases with presence of comorbidities like hypertension, chronic kidney disease, obstructive sleep apnoea and metabolic diseases like diabetes and obesity,^{11,12} and the pathological changes may even vary between right and left lung.¹¹ Macroscopically, lungs appear congestive, with patches of haemorrhagic necrosis.¹¹ Alveolitis with atrophy, vacuolar degeneration, proliferation, desquamation and squamous metaplasia of alveolar epithelial cells (figure 1A), with presence of exudative monocytes and macrophages (figure 2E) are prominent features microscopically. There may be presence of massive fibrinous exudate, multinucleate giant cells and intracytoplasmic viral inclusion bodies and presence of epithelial

Figure 4 (A) Hepatocytes showing glycogenated nuclei and atypical small lymphocytes densely infiltrating the area of portal triad and showing CD20 positivity (inset). Dense portal infiltration by atypical small lymphocytes (inset: CD20 immunostaining) and focal glycogenated nuclei in hepatocytes have also been observed. (B) Hepatic nodules showing fibrosis, indicative of cirrhosis. Cirrhotic nodules with thick fibrosis. (C) Hepatic sinusoids are dilated and filled with lymphocytes. Mild sinusoidal dilatation with increased lymphocytic infiltration. (D) High power view showing sinusoidal lymphocytes. (E,F) Periportal and centrilobular areas show necrosis, indicative of injury. (Courtesy: Tian S, Xiong Y, Liu H, Niu L, Guo J, Liao M, et al. *Pathological study of the 2019 novel coronavirus disease (COVID) through postmortem core biopsies*. *Mod Pathol*. 2020 Apr 14;1–8.)

cells in the lumen suggesting necrotic changes (necrotising bronchiolitis).¹¹ There may be presence of diffuse alveolar damage (DAD), hyaline membrane formation and vascular congestion with occasional inflammatory cells, damaged pneumocytes with focal sloughing and formation of syncytial giant cells, along with focal infiltration of immune cells in the form of lymphocytes, monocytes and increased stromal cells (figure 1A).¹² Additional findings included intra-alveolar haemorrhages, cluster or plug formation due to the accumulated fibrin (figure 1D) and degraded hyaline membrane remnants in some of the alveoli, type II pneumocyte hyperplasia, fibrinoid necrosis of the small vasculature and abundant intra-alveolar neutrophil infiltration (suggestive of superimposed bacterial infection) leading to bronchopneumonia (figure 1F).⁵ There may be presence of patchy and sparse chronic inflammation, composed mainly of lymphocytes, along with thrombi in branches of pulmonary artery and focal areas of congestion in alveolar septal capillaries along with septal capillary injury with mural and luminal fibrin deposition.^{10,13} Inflammatory oedema in the respiratory mucosa⁶ along with CD3+, CD4+ T cells, CD20+ B-lymphocytes and presence of CD68+ macrophages highlight the presence of inflammatory changes.¹³ There is also evidence of significant deposits of terminal complement components C5b-9 (membrane attack complex), C4d, and mannose binding lectin (MBL)-associated serine protease (MASP)-2, in the microvasculature, consistent with sustained, systemic activation of the alternative and lectin-based complement pathways.¹⁴ Pneumocytes may contain the

Figure 5 Pathological changes observed in testes from patients with COVID-19. (A,B) Defoliated and oedematous sertoli cells with vacuoles along with reduced spermatogenesis and scattered Leydig cells (arrow). (C) Tubular cells shows sloughing into the lumen (asterisks) indicative of injury. There is marked interstitial oedema. (D) Non-Covid testis with protracted disease showing interstitial edema with infiltration of inflammatory cells. (E) Immunohistochemical findings showing CD3-positive+T lymphocytes and (F) CD68-positive+ histiocytes. (Courtesy: Yang M, Chen S, Huang B, Zhong J-M, Su H, Chen Y-J, et al. *Pathological Findings in the Testes of COVID-19 Patients: Clinical Implications. Eur Urol Focus.*2020 May 31; pp 1–6.)

virus within the cytoplasm and may show nucleomegaly and prominent nucleoli with small basophilic and larger eosinophilic cytoplasmic inclusions. Ultrastructural examination can reveal more details regarding the viral particles. Type II pneumocytes harbour numerous autophagosomes, characterised by double membranes and presence of organelles, in the cytoplasm (figure 2). These autophagosomes which contain viral aggregates, may also be present in tracheal epithelial cells and within the extracellular mucus in the tracheal lumen.⁵ Presence of virus particles has been shown by immunohistochemical staining using monoclonal antibody against SARS-CoV-2 nucleocapsid protein (figure 2C).¹⁵

Most of the histopathological findings are similar to those described in severe acute respiratory syndrome corona virus-1 (SARS-CoV-1) and Middle East respiratory syndrome coronavirus (MERS-CoV).¹⁶ These data suggest similarities in the pathogenesis and the mechanisms of tissue damage in lung tissue and inflammatory response to coronavirus infections, highlighting that the successful methodology in managing SARS and MERS could be referred to patients with COVID-19. Microscopic study of the COVID-19 lung tissue raises a possibility that nasopharyngeal swab showing negative result might not reflect the actual viral load in lung tissue.¹³ This study is important for the clinicians and virologists dealing with patients with COVID-19

Figure 6 Histopathological changes in skin of COVID-19 patients. (A) Arrow showing telangiectatic blood vessels in early exanthematous rash. (B) Epidermis (arrow) showing groups of Langerhans cells in the laterphase of exanthematous rash. Superficial dermis also shows perivascularinfiltration of lymphocytes. (C) An intraepidermal group of Langerhans cell seen in apapulovescicular rash. (D) Micrographic feature in a Maculo-papular eruption. (E) Capillary thrombosis (arrow) along with diffusehaemorrhage in an exanthemous (Courtesy: Raffaele Gianotti, *Clinical and histopathological study of skin dermatoses in patients affected by COVID-19 infection in the Northern part of Italy. Letter to the Editor. Journal of Dermatological Science.* G Model DESC 3594 No. of Pages 3.)

as this study provides the pathological evidence for residual virus in the lungs for a patient with three consecutive negative PCR test results for the virus. Hence, PCR detection of SARS-CoV-2 nucleic acid on bronchoalveolar lavage fluid, extension of quarantine time and timely follow-up medical examination on discharged patients, especially older or immunocompromised patients, should be preferred.

Figure 7 Histopathological changes in skin of COVID-19 patients(A) Acanthosis with presence of cleft (arrow) observed in skin of COVID-19 patients. Parakeratosis is also observed along with abnormal keratinization. (B) Localized necrotic keratinocytes (arrow) with abnormal keratinization InsetInset, with lymphocytic infiltration (arrow). (C) Acantholytic cleft with an adjacent apoptotic keratinocyte (arrow). (D) Pseudoherpetic features (arrow) along with apoptotic keratinocytes (double arrow). (Courtesy: Raffaele Gianotti, *Clinical and histopathological study of skin dermatoses in patients affected by COVID-19 infection in the Northern part of Italy. Letter to the Editor. Journal of Dermatological Science.* G Model DESC 3594 No. of Pages 3.)

Histopathological findings in urinary system (kidney)

ACE-2 is found to be upregulated in patients with COVID-19, and immunostaining with SARS-CoV-2 nucleoprotein antibody is positive in tubules. In addition to the direct virulence of SARS-CoV-2, factors contributing to acute kidney injury (AKI) includes systemic hypoxia, abnormal coagulation and possible drug or hyperventilation-relevant rhabdomyolysis.¹⁷ In some patients, pigmented casts is observed to be associated with high creatine phosphokinase levels possibly representing rhabdomyolysis.¹⁸

Clinically, the incidence of AKI in COVID-19 varies from 0.9% to 29%¹² with new onset proteinuria. Microscopic changes in adult may range from diffuse proximal tubule injury with loss of brush border, non-isometric vacuolar degeneration to even frank necrosis.¹⁷ Other changes seen are swollen glomerular endothelial cells with small amount of protein exudate in the balloon cavity, and presence of thrombus in the capillaries, tubular epithelial cell oedema, vacuolar degeneration (figure 3A,B),¹⁸ with occasional cellular swelling and oedematous expansion of the interstitial spaces in distal collecting tubules and collecting ducts.¹⁵ Non-specific fibrosis along with lymphocytic infiltrates may be found beneath the renal capsule.¹⁵ Absence of interstitial haemorrhage or vasculitis differentiates this type of tissue injury from other causative factors like Hanta virus or injury by anti-neutrophil cytoplasmic antibodies.^{15 16} There can be presence of prominent erythrocyte aggregates, obstructing the lumen of capillaries, without platelet or fibrinoid material, with occasional hemosiderin granules and pigmented casts (figure 3E,F). Electron microscopic (EM) examination shows clusters of viral particles with distinctive spikes, in the tubular epithelium and podocytes.¹⁴

Microscopic changes associated with the comorbid conditions such as diabetes and hypertension show characteristic findings in glomeruli, which include nodular mesangial expansion and hyalinosis of arterioles (associated with diabetic nephropathy) and arteriosclerosis of medium-sized arteries with ischaemic glomeruli.¹⁷ Occasional findings include segmental fibrin thrombus, podocyte vacuolation, focal segmental glomerulosclerosis and shrinkage of capillary loops with accumulation of plasma in Bowman's space (ischaemic changes)(figure 3G,H).¹⁸

Histopathological findings in digestive system (liver)

Although microscopic changes of hepatic tissue in COVID-19 have not been reported much, hepatic injuries cannot be ignored as the ACE-2 receptors have also been detected in the hepatobiliary system where cholangiocytes (59.7%) showed higher expression of ACE-2 cell surface receptor compared to hepatocytes (2.6%).¹⁹ Considering the fact that cholangiocytes expressed ACE-2 in the same manner as the type-2 alveolar cells, there is every possibility for the liver to be a potential target for SARS-CoV-2.¹⁹ Besides, concomitant use of medications also has effect on the hepatobiliary system. Hepatic injury mostly occurs in those with moderate to severe illness.²⁰

Hepatic cell degeneration and focal necrosis in addition to presence of some biliary plugs in the small bile duct²¹ has been observed in light microscopic study. Although endothelial cells show positive ACE-2 expression, the endothelial lining of the liver sinusoids may be negative for ACE-2 along with Kupffer cells and hepatocytes.²² However, it cannot be denied that apart from the SARS-CoV-2 infection, parallel use of hepatotoxic drugs, pre-existing chronic liver disease and COVID-19 related hyperinflammatory conditions can lead to hepatic injury, particularly when the patient is in hypoxic state.

Microscopically, a liver, injured due to SARS-CoV-2 infection, may show signs of cirrhosis and regeneration with macrovesicular steatosis and glycogen accumulation in the liver cells along with atypical lymphocytic infiltration in the portal tract (figure 4A,B). Sinusoidal dilatation in zone 3, mild lymphocytic infiltration and patchy hepatic necrosis have also been observed in the area of portal triad and centrilobular areas²⁰ (figure 4E,F).

Histopathological findings in other parts of digestive system (gastrointestinal tract)

Common gastrointestinal symptoms with which COVID-19 positive patients presented were diarrhoea, decreased appetite, nausea, vomiting, abdominal pain and gastrointestinal bleeding during the onset and subsequent hospitalisation.¹²

There are pieces of evidence of stenosis of the small intestine and segmental dilatation along with varying degrees of degeneration, necrosis and shedding in the gastrointestinal mucosa.²³ Gastric tissue may show epithelial degeneration, necrosis and shedding of the mucosa with the presence of dilated and congested small blood vessels in lamina propria and submucosa along with infiltration of lymphocytes, monocytes and plasma cells. Endocrine pancreas may show evidence of tissue degradation.²¹ However, mucosal epithelial cells of the gastrointestinal tract may be apparently normal with occasional inflammatory infiltrates.²⁴

Histopathological findings in cardiovascular system

Cardiac pathology

Viral infections being one of the most common causes of infectious myocarditis, cardiac involvement by SARS-CoV-2 cannot be ruled out.²⁵ Endomyocardial biopsy from a 69-year-old COVID-19 positive patient, who died of septic shock, depicted low-grade myocardial inflammation and viral particles in the myocardial interstitial cells but not in cardiomyocytes or endothelial cells.²⁶ However, involvement of cardiomyocytes cannot be ruled out as there are reports of hypertrophied cardiomyocytes along with inflammatory infiltrates, focal oedema, interstitial hyperplasia, fibrosis, degeneration, necrosis and signs of lymphocytic myocarditis.¹⁸ Besides ultrastructural changes like swelling of myocardial fibres, myocardium also shows presence of CD4 Tcells along with other inflammatory infiltrates. However, pre-existing morbidity cannot be ruled out like hypertension-associated myocardial hypertrophy and past ischaemic injury.^{5 9 21}

Endomyocardial biopsy from non-ischaemic heart showed endocarditis and inflammation of interstitial tissue and viral particles have been observed in interstitial cells with damaged cell membrane, but myocytes were apparently normal with no viral particles.²⁶ Viral particles may be absent while other signs of inflammation may be present within the cardiac tissue like leucocyte infiltration and presence of CD4+ Tcells^{22 23} indicating indirect injury to the cells by the virus.

Blood vessels

Due to the presence of ACE-2 receptor in the vascular endothelial cells, these are easy target for the SARS-CoV-2 virus.²² Studies show presence of viral inclusions along with inflammatory cells and apoptotic bodies in the endothelial cells.²⁴ There are pieces of evidence of oedematous changes in alveolar capillaries and small vessels with the presence of fibrin thrombi, neutrophils and CD61+ megakaryocytes.²⁷ Histological findings in purpuric papulovesicular rash of skin showed dense perivascular lymphocytic infiltration around the swollen blood vessels

with extravasation of red blood cells.²⁸ While punch biopsy from a case showed plump endothelial cells in lymphoplasmacytic infiltrate surrounded venules without intraluminal thrombi.²⁹

Histopathological findings in nervous system

Neurological symptoms in COVID-19 have been frequently reported; however, the histopathological studies that investigated central nervous system (CNS) lesions are currently very limited.¹⁰ Dizziness and headache were most common CNS manifestations, while taste and smell impairment were the most common peripheral nervous system symptoms.³⁰ Stroke, acute encephalopathy, convulsions, ataxia or nerve demyelination symptoms were occasional neurological presentations in some patients.³¹ Based on the analysis of spectrum of neurological symptoms, possible routes of CNS entry for SARS-CoV-2 virus have been proposed through the hematogenous route by breaching blood-brain barrier or retrograde neuronal spread involving olfactory nerves.³¹ Olfactory route of viral entry into CNS were shown in mice models of SARS-CoV-1 and MERS-CoV which also showed widespread brain lesions following olfactory inoculation of the virus; however, no such evidence is specifically available at present for SARS-CoV-2.^{32,33} A recent postmortem examination study in patients with COVID-19 who displayed neurological symptoms showed widespread brain lesions.³⁴ Autopsied brain tissue showed signs of acute hypoxic ischaemic injury like hyperaemia, oedema and neuronal degeneration.^{31,33} Neuroimaging scans (CT and MRI) for patients with COVID-19 presenting with acute neurological symptoms showed signs of ischaemia and/or haemorrhage, and enhanced cortical/subcortical grey matter and fibre tracts.³⁵ SARS-CoV-2 RNA was detected in the brain tissue and cerebrospinal fluid of some autopsied patients with COVID-19 who had presented with neurological symptoms.^{36,37}

Histopathological findings in genital system (testis)

Evidence has been found between the association of coronavirus family and orchitis in humans.³⁸ ACE2 is present in seminiferous tubules, leydig cells, sertoli cells and spermatogonia.³⁹ Binding of the virus with the testicular cells expressing ACE2 receptors not only damages the testicular tissue but also forms a potential safehouse for the virus. These hidden hotbeds for the virus may form an important cause for infertility worldwide.

Studies show that sertoli cells are more susceptible than germ cells as more than 90% of the sertoli cells expressed ACE-2 receptors. Also, spermatogonia stem cells show higher expression of TMPRSS2 but lower expression of ACE-2, while the sertoli cells show higher expression of ACE-2 but lower expression of TMPRSS2, suggesting the mutual role of spermatogonia and somatic cells or sertoli cells for the invasion of the virus.⁴⁰

All SARS-infected testes demonstrate histological findings with extensive germ cell destruction and decreased spermatogenesis in the seminiferous tubules. The basement membrane gets thickened with peritubular fibrosis along with leucocyte infiltration and vascular congestion in the interstitial tissue. Sertoli cells show swelling, vacuolation and cytoplasmic rarefaction (figure 5A,B). TUNEL assay shows increased apoptosis in the spermatogenic cells and leydig cells of the SARS patients' testes.⁴⁰ One of the evident phenomena in the COVID-19 testis is leucocyte infiltration (figure 5D). These cells could affect the function of leydig cells and thus responsible for decreased production of testosterone (figure 5C). These infiltrated cells especially the lymphocytes and histiocytes, also damage the blood-testis barrier and destroy the seminiferous tubules directly (figure 5E,F).⁴¹

Similar to other viruses like HIV, mumps and hepatitis B virus, SARS-CoV-2 also may lead to activation of inflammatory cytokines, which may potentiate the autoimmune response. They may cause orchitis by several mechanisms, which may result in the testicular damage leading to infertility and sterility, which may further increase the chances of testicular tumours.³⁸ Hence, it is a point of concern for patients suffering from testicular cancers with superadded SARS-CoV-2 infection. According to Song *et al*, no positive RT-PCR result was found in the semen or testicular biopsy specimen, hence suggesting that possibly it will not be transmitted through the sexual route.⁴²

Histopathological findings in skin

The virus reaches the cutaneous tissue through the blood vessels. Since the endothelium abundantly expresses ACE-2, it can easily bind to the viral spike protein and facilitate viral invasion into the skin tissue thus initiating the pathogenesis. Inflammatory response caused by the viral invasion leads to inflammatory cell infiltrates, giving the pathological feature of vasculitis. Immune response leads to activation of Langerhans cells causing a cascade of reactions.⁴³ With the usual common manifestations in COVID-19 positive cases, the dermatological manifestations may go unnoticed and a person may be a source of infection without his or her knowledge. As any other viral infection, the skin manifestations of a COVID-19 positive person may also show signs of erythematous rash, dermatitis, urticaria, chicken pox-like vesicles purpuric papulovesicular rash which may even be painful, pseudo-chilblains on fingertips and toes, macular/maculopapular exanthems, livedo reticularis lesions, petechiae and so on (figure 6). Since there is no correlation with disease severity or duration,⁴⁴ an apparently normal person with positive test may come with only dermatological complaints, with the dermatological lesions mostly in trunk, hands and feet, as they are the most exposed regions of the body.⁴⁵ Most of the skin lesions heal without any residual signs.⁴⁵ Knowledge of skin manifestation may aid in early diagnosis of an asymptomatic COVID-19 patient.

In the epidermis of the skin, the ACE-2 expression is observed in the stratum basale. ACE-2 expression has also been identified in smooth muscle cells of the skin along with the cells around the hair follicle.²² Although not very strong, the cytoplasm of the cells of sebaceous glands also expresses ACE-2 along with its strong expression in the cells of eccrine glands.²² Dense perivascular lymphocytic and plasmacytic infiltration has also been observed around the swollen blood vessels with extravasation of red blood cells and intraluminal thrombi.^{28,29} Parakeratosis, acanthosis, dyskeratotic keratinocytes, necrotic keratinocytes, acantholytic clefts along with lymphocytes satellitisms have also been observed in biopsy samples of COVID-19 positive patients (figure 7).²⁸ Presence of COVID-19 cutaneous manifestations may not be specific to SARS-CoV-2, but may be secondary to the various chains of events taking place due to the viral invasion. But keeping the features in mind will be a good approach towards determining the clinical value of the medical examinations required.

CONCLUSIONS

Information regarding the pathological findings in COVID-19 is limited, although the virus mainly affects respiratory and immune systems, but other systems like cardiovascular, urinary (kidneys), gastrointestinal tract, reproductive (testes), and nervous system are not spared, especially in elderly patients, more often if comorbidities are also present. This review would definitely help

clinicians and researchers to understand the tissue pathology, which can further help in better planning of the disease management and avoiding future health risks.

Take home messages

- COVID-19 mainly affects respiratory and immune systems.
- Other systems like cardiovascular, urinary, gastrointestinal tract, reproductive, nervous and integumentary systems are also not spared, indicating that it is a multi-system disease.
- The elderly and those with comorbidities are affected more severely.

Epidemiology of COVID-19 Among Children in China

Yuanyuan Dong, MD,^{a,b,*} Xi Mo, PhD,^{a,*} Yabin Hu, MD,^a Xin Qi, PhD,^c Fan Jiang, MD, PhD,^a Zhongyi Jiang, MD,^{a,b} Shilu Tong, MD, PhD^{a,d,e}

OBJECTIVE: To identify the epidemiological characteristics and transmission patterns of pediatric patients with the 2019 novel coronavirus disease (COVID-19) in China. abstract

METHODS: Nationwide case series of 2135 pediatric patients with COVID-19 reported to the Chinese Center for Disease Control and Prevention from January 16, 2020, to February 8, 2020, were included. The epidemic curves were constructed by key dates of disease onset and case diagnosis. Onset-to-diagnosis curves were constructed by fitting a log-normal distribution to data on both onset and diagnosis dates.

RESULTS: There were 728 (34.1%) laboratory-confirmed cases and 1407 (65.9%) suspected cases. The median age of all patients was 7 years (interquartile range: 2–13 years), and 1208 case patients (56.6%) were boys. More than 90% of all patients had asymptomatic, mild, or moderate cases. The median time from illness onset to diagnoses was 2 days (range: 0–42 days). There was a rapid increase of disease at the early stage of the epidemic, and then there was a gradual and steady decrease. The disease rapidly spread from Hubei province to surrounding provinces over time. More children were infected in Hubei province than any other province.

CONCLUSIONS: Children of all ages appeared susceptible to COVID-19, and there was no significant sex difference. Although clinical manifestations of children's COVID-19 cases were generally less severe than those of adult patients, young children, particularly infants, were vulnerable to infection. The distribution of children's COVID-19 cases varied with time and space, and most of the cases were concentrated in Hubei province and surrounding areas. Furthermore, this study provides strong evidence of human-to-human transmission.

WHAT'S KNOWN ON THIS SUBJECT: A growing number of studies have focused on the 2019 novel coronavirus disease (COVID-19) since its outbreak, but few data are available on epidemiological features and transmission patterns in children with COVID-19.

WHAT THIS STUDY ADDS: Children of all ages were susceptible to COVID-19, but no significant sex difference was found. Clinical manifestations of pediatric patients were generally less severe than those of adult patients. However, young children, particularly infants, were vulnerable to 2019 novel coronavirus infection.

In early December 2019, a number of pneumonia cases of unknown origin emerged in Wuhan, Hubei province, China.^{1,2} Most of these patients reported exposure to the Huanan Seafood Wholesale Market selling many species of live animals. The disease rapidly spread, domestically, to other parts of China, and globally to many countries across 6 continents. On January 3, 2020, a novel member of enveloped RNA coronavirus was identified in samples of bronchoalveolar lavage fluid from a patient in Wuhan and subsequently confirmed as the cause of this disease by the Chinese Center for Disease Control and Prevention (CDC).^{3–5} On January 7, 2020, the World Health Organization (WHO) named it the 2019 novel coronavirus (2019-nCoV). On February 11, 2020, the WHO named the illness associated with 2019-nCoV the 2019 novel coronavirus disease (COVID-19).

Emergence of 2019-nCoV has attracted global attention, and the WHO has declared the COVID-19 a public health emergency of international concern (PHEIC).⁶ Since the outbreak of severe acute respiratory syndrome in Guangdong, China, in 2003, the WHO has declared 5 PHEICs: H1N1 (2009), polio (2014), Ebola in West Africa (2014), Zika (2016), and Ebola in the Democratic Republic of the Congo (2019). Declaring a PHEIC is an urgent call, at the highest level, for the international community to launch a global coordinated effort to stop the outbreak, which requires a strong public health response, high-level political commitment, and sufficient funding. As of March 2, 2020, a total of 80 174 COVID-19 cases in China and 8774 cases in 64 countries (and regions) have been confirmed.⁷ Despite the worldwide spread, the epidemiological and clinical patterns of COVID-19 remain largely unclear, particularly among children. In this study, we explored the

epidemiological characteristics and transmission patterns of 2135 pediatric patients with COVID-19 in mainland China.

METHODS

Data Sources

We conducted a retrospective study on the epidemiological characteristics of 2135 pediatric patients with COVID-19. Children were defined as being <18 years old.

The cases were initially diagnosed on the basis of clinical manifestations and exposure history.^{8,9} Within the last 2 weeks, if a child was exposed to a COVID-19 case patient or lived in an epidemic area (ie, Hubei province), a community where a COVID-19 case (or cases) was reported, or a nonepidemic area where no COVID-19 case(s) was reported, she or he was defined as having high, medium, or low risk, respectively, on the basis

of the possibility of contracting the disease. Suspected cases were identified if a child at high risk had 2 of the following conditions: (1) fever, respiratory, digestive symptoms (eg, vomiting, nausea, and diarrhea), or fatigue; (2) laboratory test white blood cell count was normal, decreased, or had a lymphocyte count or increased level of C-reactive protein; or (3) abnormal chest radiograph imaging result. For a child at medium or low risk, similar diagnostic criteria were applied after excluding influenza and other common respiratory infections. Suspected cases that met any one of the following criteria were defined as confirmed cases:

1. Nasal and pharyngeal swab specimens or blood samples tested positive for 2019-nCoV nucleic acid by using real-time reverse-transcriptase polymerase chain reaction assay.

TABLE 1 Characteristics of Children's COVID-19 Cases in China

Characteristics	All Cases	Category		P
		Confirmed	Suspected	
Age, median (interquartile range)	7 (2–13)	10 (4–15)	6 (2–12)	<.001

TABLE 2 Different Severity of Illness by Age Group

Age Group, y ^a	Asymptomatic, n (%)	Mild, n (%)	Moderate, n (%)	Severe, n (%)	Critical, n (%)	Total, n
<1	7 (1.9)	204 (54.2)	125 (33.2)	33 (8.8)	7 (1.9)	376
1–5	15 (3.1)	245 (49.9)	195 (39.7)	34 (6.9)	2 (0.4)	491
6–10	30 (5.8)	277 (53.3)	191 (36.7)	22 (4.2)	0 (0.0)	520
11–15	27 (6.5)	198 (48.1)	170 (41.3)	14 (3.4)	3 (0.7)	412
>15	15 (4.5)	164 (49.1)	145 (43.4)	9 (2.7)	1 (0.3)	334
Total	94 (4.4)	1088 (51.0)	826 (38.7)	112 (5.3)	13 (0.6)	2133

See also Supplemental Table 3.

^a Two cases had missing values.

2. Genetic sequencing of respiratory tract or blood samples is highly homologous with 2019-nCoV.

The severity of COVID-19 was defined on the basis of the clinical features, laboratory testing, and chest radiograph imaging, including asymptomatic infection, as mild, moderate, severe, or critical. The diagnostic criteria were as follows.⁸

1. Asymptomatic infection: without any clinical symptoms and signs, and the chest imaging results

normal, whereas the 2019-nCoV nucleic acid test result is positive.

2. Mild: symptoms of acute upper respiratory tract infection, including fever, fatigue, myalgia, cough, sore throat, runny nose, and sneezing. Physical examination shows congestion of the pharynx and no auscultatory abnormalities. Some cases may have no fever or have only digestive symptoms, such as nausea, vomiting, abdominal pain, and diarrhea.

3. Moderate: with pneumonia, frequent fever, and cough (mostly dry cough, followed by productive cough); some may have wheezing, but no obvious hypoxemia such as shortness of breath, and lungs can hear sputum or dry and/or wet snoring. Some cases may have no clinical signs and symptoms, but chest computed tomography shows lung lesions, which are subclinical.

4. Severe: early respiratory symptoms, such as fever and

**FIGURE 1**

Onset and diagnosis dates of 2135 children's COVID-19 cases in China. A, Onset date. B, Diagnosis date.

FIGURE 2
Onset and diagnosis dates of 418 confirmed male children's COVID-19 cases in China. A, Onset date. B, Diagnosis date.

cough, may be accompanied by gastrointestinal symptoms, such as diarrhea. The disease usually progresses at ~1 week, and dyspnea occurs with central cyanosis. Oxygen saturation is <92% with other hypoxia manifestations.

5. Critical: children can quickly progress to acute respiratory distress syndrome or respiratory failure and may also have shock, encephalopathy, myocardial injury or heart failure, coagulation dysfunction, and acute kidney injury. Organ dysfunction can be life-threatening.

Both the laboratory-confirmed and suspected cases were included in the analysis. The data sets were extracted from the National Notifiable Infectious Disease Surveillance System at the Chinese CDC. Data were entered into a computer and secured with a password at Shanghai Children's Medical Center.

Cross-check and data cleaning were performed before the data analysis.

Statistical Analysis

We first described case characteristics, including age, sex, dates of disease onset and diagnosis, and location where the case was notified. χ^2 tests and Fisher's exact tests were used for categorical variables as appropriate, and the Mann-Whitney *U* test was used for comparing median values of nonnormally distributed variables. The epidemic curves were constructed by key dates of disease onset and case diagnosis. Because of the data unavailability (ie, no detailed exposure data), we were unable to estimate the incubation period. Onset-to-diagnosis curves were constructed by fitting a log-normal distribution to data on both the onset and diagnosis dates. All analyses were conducted with the use of SPSS 22.0 software (IBM SPSS Statistics, IBM Corporation), and distribution maps

were plotted by using ArcGIS version 10.2.

Ethics

Because of the nature of aggregated data and the ongoing public health response to control the outbreak, as well as the importance of sharing the research findings and bridging the knowledge gaps, an ethical approval was waived by institutional review board.

RESULTS

By February 8, 2020, 2135 pediatric patients with COVID-19 were reported to the Chinese CDC (Table 1). Of the patients, 728 (34.1%) were identified as laboratory-confirmed cases, and 1407 (65.9%) were suspected cases. The median age of all patients was 7 years (interquartile range: 2–13 years). Among those patients, 1208 cases (56.6%) were boys, and there was no statistically significant difference in the number of pediatric patients

FIGURE 3 Onset and diagnosis dates of 310 confirmed female children's COVID-19 cases in China. A, Onset date. B, Diagnosis date.

between boys and girls. Regarding the severity (including both confirmed and suspected cases), 94 (4.4%), 1088 (51.0%), and 826 (38.7%) cases were diagnosed as asymptomatic, mild, or moderate, respectively; and totally accounted for 94.1% of all cases. Approximately half of the patients were from Hubei province (981; 46.0%), whereas 396 (18.5%) case patients were from Anhui, Henan, Hunan, Jiangxi, Shanxi and

Chongqing, which border Hubei province.

Table 2 shows the severity of illness by age and reveals that young children, particularly infants, were vulnerable to 2019-nCoV infection. The proportions of severe and critical cases were 10.6%, 7.3%, 4.2%, 4.1%, and 3.0% for the age groups <1, 1 to 5, 6 to 10, 11 to 15, and ≥ 16 years, respectively. A 14-year-old boy from

Hubei province died on February 7, 2020.

In the temporal distribution, among the 2135 pediatric patients, there was a trend of rapid increase of disease onset in the early stage of the epidemic and then a gradual and steady decrease (Fig 1). The total number of pediatric patients increased remarkably between mid-January and early February, peaked around February 1, and then has declined since early February 2020. The number of diagnoses had been rising every day from January 20, when the first case was diagnosed. Similar trends of onset and diagnoses were found in confirmed cases (Figs 2 and 3) and suspected cases (Supplemental Figs 6 and 7). The earliest date of illness onset was December 26, 2019, whereas the earliest date of diagnosis was January 20, 2020. The median number of days from illness onset to diagnosis was 2 days (range: 0–42 days). Figure 4 shows that most cases were

FIGURE 4 Relative frequency of days from symptom onset to diagnosis.

diagnosed in the first week after illness onset occurred.

In the spatial distribution, there was a clear trend that disease spread rapidly from Hubei province to surrounding provinces and cities over time. There were more children infected in the areas around Hubei province than in areas farther away except for Heilongjiang province (Fig 5).

DISCUSSION

To the best of our knowledge, this is the first retrospective study on the epidemiological characteristics and transmission dynamics of children's COVID-19 in China. Because most of these children were likely to expose themselves to family members and/or other children with COVID-19, it clearly indicates person-to-person transmission. Supportive evidence of such a transmission pathway has also been reported from studies on adult

patients.^{10–12} As of February 8, 2020, of the 2135 pediatric patients included in this study, only 1 child died and most cases were mild, with much fewer being severe and critical cases (5.8%) than in adult patients (18.5%).¹³ The evidence suggests that, compared with adult patients, clinical manifestations of children's COVID-19 may be less severe.

Coronaviruses are large, enveloped, positive-strand RNA viruses that can be divided into 4 genera, α , β , δ , and γ , of which α and β coronaviruses are known to infect humans, which are called human coronaviruses (HCoVs).¹⁴ Four HCoVs (HCoV 229E, NL63, OC43, and HKU1) are endemic globally and account for 10% to 30% of upper respiratory tract infections in adults.¹⁵ Although HCoVs have long been regarded as inconsequential pathogens because of their mild phenotypes in humans, in the early 21st century, 2 large-scale epidemics with alarming morbidity and

mortality (ie, severe acute respiratory syndrome coronavirus [SARS-CoV] and Middle East respiratory syndrome coronavirus), have changed that view. From December 2019 to March 25, 2020, 2019-nCoV, another highly pathogenic HCoV, caused 81285 confirmed cases of illnesses and 3287 deaths.¹⁶ The epidemic is ongoing and rapidly evolving, and the ultimate scope and impact of this event is still unclear.

Genomic analyses suggest that the 2019-nCoV may originally come from bats because of the similarity of its genetic sequence to those of other known coronaviruses, but the pathogen was probably transmitted to humans by other animals that may serve as intermediate hosts, facilitating recombination and mutation events with the expansion of genetic diversity.^{3–5} On February 7, 2020, researchers in Guangzhou, China, identified the pangolin as one of the potential sources of 2019-nCoV

FIGURE 5

on the basis of a genetic comparison of CoVs in the samples taken from the animals and from humans who were infected in the outbreak and other findings.^{17,18} Genetic sequences of viruses that were isolated from the scaly animals are 99% similar to that of the circulating virus.

Why most of the children's COVID-19 cases were less severe than adult cases is puzzling. This may be related to both exposure and host factors. Children were usually well cared for at home and might have relatively fewer opportunities to expose themselves to pathogens and/or patients who are sick. Angiotensin-converting enzyme II (ACE2) was known as a cell receptor for SARS-CoV.¹⁹ 2019-nCoV has some amino acid homology to SARS-CoV and may be able to use ACE2 as a receptor. Recent evidence indicates that ACE2 is also likely the cell receptor of 2019-nCoV.^{20,21} It is speculated that children were less sensitive to

2019-nCoV because the maturity and function (eg, binding ability) of ACE2 in children may be lower than in adults.²² Additionally, children often experience respiratory infections (eg, respiratory syncytial virus [RSV]) in winter and may have higher levels of antibody against virus than adults. Furthermore, children's immune systems are still developing and may respond to pathogens differently from adult immune systems. However, we found that the proportion of severe and critical cases was 10.6%, 7.3%, 4.2%, 4.1%, and 3.0% for the age groups <1, 1 to 5, 6 to 10, 11 to 15, and >15 years, respectively. These results suggest that young children, particularly infants, were vulnerable to 2019-nCoV infection. Therefore, the mechanisms for the difference in clinical manifestations between children and adults remains to be determined.

There were more severe and critical cases in the suspected than confirmed

category in this study. However, it remains to be determined if these severe and critical cases in the suspected group were caused by 2019-nCoV or other pathogens (eg, RSV). It may become clearer because the epidemic is quickly unfolding.

We observed slightly more boys than girls (56.6% vs 43.4%) being affected in the COVID-19 outbreak, which is similar to the 2 recent epidemiological studies.^{13,23} However, no significant sex difference was observed in this study. The median age of all children's COVID-19 cases was 7 years (interquartile range: 2–13), but ages ranged from 1 day to 18 years. This finding suggests that all ages of childhood were susceptible to 2019-nCoV.

Temporal distribution of children's COVID-19 cases shows that, in the early stage of the epidemic (ie, between December 2019 and early February 2020), there was a trend of rapid increase of disease onset. Since

early February 2020, the number of children's COVID-19 cases has been declining. This finding indicates that the disease control measures implemented by the government were effective, and it is likely that this epidemic will continue to decline and finally stop in the near future unless sustained human-to-human transmissions occur. Most of the children's COVID-19 cases were concentrated in Wuhan but spread to other areas of Hubei province and farther to other areas of China. It seems that the closer to Wuhan, the more cases in that area, which suggests that population mobility is an important factor of the spread of 2019-nCoV. Heilongjiang province is an exception, which may be because many visitors went there, including those from Wuhan, because of the Ice and Snow Sculpture Festival in Harbin, the provincial capital.

This study has several strengths. First, this is the first nationwide study, to date, with a major focus on the epidemiological characteristics and transmission dynamics of children's COVID-19 in China. It shows that, compared with the adult cases, the severity of children's COVID-19 cases was milder, and the case fatality rate was much lower.^{13,23} Second, the large number of children's COVID-19 cases enabled us to conduct detailed stratified analyses on sex, age, and spatiotemporal distribution. Finally, we included both

confirmed and suspected COVID-19 cases, and it may reveal a comprehensive picture of pediatric patients with COVID-19 in China.

This study also has a number of limitations. First, we were unable to assess clinical characteristics of children's COVID-19 because these data were unavailable at the time of analysis. As an important and urgent issue, clinical features of children's COVID-19 need to be analyzed in further research. It appeared to have more severe and critical cases in the suspected than in the confirmed group (Table 1), which suggests that some suspected cases might be caused by other respiratory infections (eg, RSV). Second, we did not have information on children's exposure history, and thus, the incubation period was not examined in this study. Finally, because the epidemic of COVID-19 is ongoing and rapidly evolving, many children who are affected still remain hospitalized. To gain a better understanding of children's COVID-19, more detailed patient information, particularly clinical outcomes (eg, discharge, transfer to ICU, or death), should be collected in future studies.

CONCLUSIONS

Children of all ages were sensitive to COVID-19, and there was no significant sex difference. Clinical manifestations of children's COVID-19 cases were less severe than those of

adult patients. However, young children, particularly infants, were vulnerable to 2019-nCoV infection. The distribution of children's COVID-19 cases varied with time and space, and most of the cases were concentrated in Wuhan and surrounding areas. Furthermore, the results of this study provide strong evidence for human-to-human transmission because children were unlikely to visit the Huanan Seafood Wholesale Market, where the early adult patients were reported to have obtained 2019-nCoV.

Outbreaks of emerging infections present health professionals with the unique challenge of trying to select appropriate pharmacologic treatments in the clinic with little time available for drug testing and development. Typically, clinicians are left with general supportive care and often untested convalescent-phase plasma as available treatment options. Repurposing of approved pharmaceutical drugs for new indications presents an attractive alternative to clinicians, researchers, public health agencies, drug developers, and funding agencies. Given the development times and manufacturing requirements for new products, repurposing of existing drugs is likely the only solution for outbreaks due to emerging viruses. In the studies described here, a library of 290 compounds was screened for antiviral activity against Middle East respiratory syndrome coronavirus (MERS-CoV) and severe acute respiratory syndrome coronavirus (SARS-CoV). Selection of compounds for inclusion in the library was dependent on current or previous FDA approval or advanced clinical development. Some drugs that had a well-defined cellular pathway as target were included. In total, 27 compounds with activity against both MERS-CoV and SARS-CoV were identified. The compounds belong to 13 different classes of pharmaceuticals, including inhibitors of estrogen receptors used for cancer treatment and inhibitors of dopamine receptor used as antipsychotics. The drugs identified in these screens provide new targets for *in vivo* studies as well as incorporation into ongoing clinical studies.

Middle East respiratory syndrome coronavirus (MERS-CoV) is an emerging virus, and to date no antiviral or therapeutic has been approved for treating patients. Since September 2012, 206 cases, including 86 deaths, have been attributed to infection with MERS-CoV. Currently, supportive care remains the only available treatment option. As the number of cases continues to rise and the geographic range of the virus increases, there is a growing urgency for candidate interventions.

Prior to 2002, coronaviruses were not considered to be significant human pathogens. Other human coronaviruses such as HCoV-229E and HCoV-OC43 resulted in only mild respiratory infections in healthy adults. This perception was shattered in 2002, when severe acute respiratory syndrome coronavirus (SARS-CoV) emerged in Guangdong Province, China. This virus rapidly spread to 29 different countries, resulting in 8,273 confirmed cases and 775 (9%) deaths (1). While SARS-CoV predominantly impacted Southeast Asia, with significant outbreaks throughout China, Hong Kong, Taiwan, Singapore, and Vietnam, the virus was carried outside the region. Importation of the virus into Canada resulted in 251 confirmed cases and 44 deaths (1). The implementation of infection control measures was able to bring the epidemic to an end in 2003.

In 2012, a novel coronavirus, Middle East respiratory syndrome coronavirus (MERS-CoV), was detected in a patient with severe respiratory disease in the kingdom of Saudi Arabia. To date, 636 laboratory-confirmed cases of MERS-CoV infection have been reported, including 193 deaths, across nine countries (WHO Global Outbreak Alert & Response Network, 28 May 2014; <http://www.who.int/csr/outbreaknetwork/en/>). The clinical features of MERS-CoV infection in humans range from asymptomatic to

very severe pneumonia with the potential development of acute respiratory distress syndrome, septic shock, and multiorgan failure resulting in death. Since the first case of MERS-CoV infection was reported in September 2012 and the virus was isolated, significant progress has been made toward understanding the epidemiology, ecology, and biology of the virus (2). Several assays for the detection of acute infection with MERS-CoV by real-time reverse transcription (RT)-PCR have been developed and are now in widespread use (3). Over 30 whole- or partial-genome sequences from different MERS-CoV-infected patients have been posted to GenBank, and phylogenetic trees have been published by several groups (3). Dipeptidyl peptidase 4 (also known as CD26) has been identified as the functional cellular receptor for MERS-CoV (4, 5). Ecological studies have suggested that the virus is of animal origin and is most closely related to coronaviruses found in a number of species of bats, with MERS-CoV viral sequences now found in camels in Saudi Arabia (6–9). Interestingly, a subset of MERS-CoV patients reported close contact with camels. Camels may

constitute an intermediate animal host, since camel serum samples collected in 2003 and 2013 had antibodies to MERS-CoV, indicating that MERS-CoV circulates in camels (10–12). The recent development of an animal model for MERS-CoV with adenovirus vectored human DPP4 in mice will now allow for further pathogenesis studies with various MERS-CoV strains (13).

The emergences of both SARS-CoV and MERS-CoV have demonstrated the importance of coronaviruses as potential emerging human pathogens and highlighted the necessity and value of effective communications within the international science community to facilitate rapid responses to emerging infectious diseases. In July 2013, the International Severe Acute Respiratory & Emerging Infection Consortium (ISARIC) compiled a list of drugs available to clinicians for treatment of MERS-CoV infection based on recent experience in treating SARS-CoV infection and pandemic influenza (14). The most promising and clinically available drugs were ribavirin and interferon (IFN), or a combination of the two, since they demonstrated efficacy in an *in vivo* model for MERS-CoV infection (15, 16). This combination has failed to demonstrate benefit in the small number of severely ill MERS-CoV patients treated (17). Outside ribavirin and IFN, the ISARIC recommendations had few alternatives for treating clinicians. It should be noted that these recommendations are meant to be fluid and based on the best available information at the time. As new data become available, these recommendations may change. Recently, we have shown mycophenolic acid (MPA) and IFN- β to be highly effective against MERS-CoV infection *in vitro*. Interestingly, the activity of MPA was specific to MERS-CoV, with little activity observed against SARS-CoV infection (18, 19).

In the work described here, we took the approach of screening a unique panel of both approved drugs and drugs with a well-defined cellular pathway for *in vitro* efficacy against MERS-CoV infection. This subset was identified previously as having antiviral activity against a series of other viruses (P. J. Glass, G. G. Olinger, Jr., and L. M. Johansen, unpublished data). A subset of drugs was also screened against SARS-CoV with the objective to identify drugs with broad activity against coronaviruses in preparedness for potential future emerging coronaviruses. We utilized this approach with the rationale that drugs that have been approved for use in humans would be more readily accepted as potential therapeutic options for MERS-CoV infection if shown to have antiviral activity. The screening of approved drugs to identify therapeutics for drug repurposing is a valid approach, and several approved drugs have been identified as having activity against many viral diseases (20–22). Here we found that 66 of the screened drugs were effective at inhibiting either MERS-CoV or SARS-CoV infection *in vitro* and that 27 of these compounds were effective against both MERS-CoV and SARS-CoV. These data demonstrate the efficiency of screening approved or clinically developed drugs for identification of potential therapeutic options for emerging viral diseases and also provide an expedited approach for supporting off-label use of approved therapeutics.

MATERIALS AND METHODS

Cell lines and virus. Vero E6 cell line (ATCC 1568; Manassas, VA) was maintained at the Integrated Research Facility (IRF, Frederick, MD) in Dulbecco's modified Eagle's medium (DMEM; Corning, Manassas, VA) plus 10% fetal bovine serum (FBS). The Jordan strain of MERS-CoV (GenBank accession no. [KC776174.1](#), MERS-CoV-Hu/Jordan-N3/2012

[23]), kindly provided by Kanta Subbarao (National Institutes of Health, Bethesda, MD) and Gabriel Defang (Naval Medical Research Unit-3, Cairo, Egypt), was amplified in Vero E6 cells at a multiplicity of infection (MOI) of 0.01. On day 4 after infection, when the cytopathic effect (CPE) was visible, virus-containing supernatants were collected and clarified by centrifugation. The MERS-CoV titers on Vero E6 cells were determined by plaque assay. All procedures using live MERS-CoV were performed under biosafety level 3 conditions at the IRF.

The Vero E6 cell line (ATCC 1568; Manassas, VA) at the University of Maryland, Baltimore (UMB), was maintained in minimal essential medium (MEM; Corning, Manassas, VA) supplemented with 10% FBS (SAFC, Bioscience, Lenexa, KS), 1% penicillin-streptomycin (Gemini Bio-products, West Sacramento, CA), and 1% L-glutamine (Life Technologies, Grand Island, NY). Mouse adapted SARS-CoV (MA15) has been described previously (24). SARS-CoV was amplified in Vero E6 cells for 2 days, when the CPE was visible. SARS-CoV-containing supernatants were collected and clarified by centrifugation. Titers of SARS-CoV on Vero E6 cells were determined by plaque assay. All procedures using live SARS-CoV were performed under biosafety level 3 conditions at UMB.

Reagents. Chlorpromazine hydrochloride (CAS 69-09-0) was purchased from Sigma-Aldrich, St. Louis, MO. Imatinib mesylate (CAS 220127-57-1), gemcitabine hydrochloride (CAS 122111-03-9), and toremifene citrate (CAS 89778-27-8) were purchased from Sequoia Research Products, Pangbourne, United Kingdom. Trifluoromazine hydrochloride (CAS 1098-60-8) was purchased from the U.S. Pharmacopeia, Rockville, MD. Dasatinib (CAS 302962-49-8) was purchased from Toronto Research Chemicals Inc., Toronto, Canada. Dimethyl sulfoxide (DMSO) was used as a solvent for the high-throughput screening assay described below.

Drug library and compound plate preparation. A library of approved drugs, including some drugs with a well-defined cellular target, was assembled and has been previously described (25). A subset of 290 compounds was selected for screening against MERS-CoV and SARS-CoV based on the antiviral activity observed in screens against other RNA viruses (21). For the MERS-CoV and SARS-CoV screens, compounds were added to compound plates using an acoustic compound dispenser (Echo 555; Labcyte, Sunnyvale, CA). The compounds were shot in nanoliter volumes directly onto 96-well plates from master stock solutions. Following addition of compound, 200 μ l of DMEM was added to plates, and plates were frozen at -80°C for a minimum of 24 h prior to shipment to the IRF and UMB investigators. Compound plates were thawed prior to the addition of compound to the infectivity assays described below at the IRF and UMB. For the MERS screen, compounds were plated in 200 μ l of media at 4 times the final concentrations such that the addition of 50 μ l to assay plates resulted in the appropriate final concentration (200- μ l final assay volume). For the SARS screens, drugs were plated in 200 μ l of media at 2 times the final concentrations such that the addition of 50 μ l resulted in the appropriate final concentration (100- μ l final assay volume). All drug plates were blinded to those performing the infectivity assays.

Cell-based ELISA screen for MERS-CoV antiviral agents. For cell-based enzyme-linked immunosorbent assay (ELISA) screen, Vero E6 cells were seeded at 40,000 cells in 100 μ l DMEM plus 10% FBS per well in black-, opaque-, or clear-bottom 96 well-plates. After 24 h, test drugs were transferred from compound plates and added to 3 cell plates in 50 μ l using a 96-well liquidator (Rainin Instrument LLC, Oakland, CA). The DMSO concentration was kept at 0.05% or lower. Duplicate Vero E6 seeded plates were used for detecting inhibition of MERS-CoV, and one plate was used for determining the cytotoxicity of compounds. For infection, duplicate plates were pretreated with drugs for 1 h before the plates were transferred into the containment laboratory to add MERS-CoV strain Hu/Jordan-N3/2012 at an MOI of 0.1 in 50 μ l of DMEM plus 10% FBS. After 48 h, plates were fixed with 10% neutral buffered formalin and removed from biocontainment. MERS-CoV infection was detected with a rabbit polyclonal antibody to the HCoV-EMC/2012 Spike protein (number 40069-RP02; Sino Biological Inc., Beijing, CN) followed by staining

with Alexa Fluor 594 goat anti-rabbit IgG (H+L) antibody (Life Technologies, Grand Island, NY). Fluorescence was quantified on a plate reader (Infinite M1000 Pro; Tecan US, Morrisville, NC) with an excitation wavelength of 590 nm and emission wavelength of 617 nm. The drugs with >50% inhibition of Spike expression and <30% toxicity were then screened with SARS-CoV as described below.

To detect cellular toxicity of drugs in the MERS-CoV screen, one of the three plates that received the test drugs was used to evaluate the cytotoxicity of drugs and was not infected with virus. At 48 h after drug addition, cell plates were analyzed using the CellTiter Glo luminescent cell viability assay kit according to the manufacturer's directions (Promega, Madison, WI), and luminescence was read on the Infinite M1000 Pro plate reader.

SARS-CoV cytopathic effect inhibition assay. For the SARS-CoV screen, 174 of the 290 drugs were screened against SARS-CoV, including all the hits that blocked MERS-CoV (72 drugs). The assay used to screen for inhibition of SARS-CoV replication was different from the one used for MERS-CoV replication due to differences in equipment for analysis at UMB and IRF/NIAID. For the SARS-CoV inhibitor screen at UMB, duplicate Vero E6 cells were seeded into white opaque 96-well plates (Corning Costar) at 1×10^4 cells per well and cultured overnight at 37°C. Cells were treated with the drugs for 2 h at 37°C and then mock infected or infected with SARS-CoV (MA15) at an MOI of 1. Cells were cultured at 37°C for 48 h and then analyzed for cell survival using the CellTiterGlo luminescent cell viability assay (Promega, Madison, WI) according to the manufacturer's instructions and read on a SpectraMax M5 plate reader (Molecular Devices, Sunnyvale, CA). A third identical drug compound plate was used to assess drug toxicity in the absence of SARS-CoV using the same Cell-Titer Glo assay (Promega) as above, with cells incubated in the presence of the drug for 48 h before being assayed.

Data analysis. For the MERS-CoV screen, a minimum of four replicates were performed on two separate days. For the SARS-CoV screen, a minimum of two replicates were performed on two separate days. Outlier data points were defined as values that were greater than the median plus 3 standard errors (σ) and were excluded from calculations.

For MERS screening, raw phenotype measurements (T) from each treated well were converted to normalized fractional inhibition, I , by the formula $I = 1 - (T/V)$, relative to the median, V , of vehicle-treated wells arranged around the plate. For SARS screening with a CPE endpoint, the calculation used to measure the antiviral activity of the compounds was the Percent Normal. The Percent Normal monitors the reduction in cytolysis of cells due to the presence of compound treatment and is determined as follows: Percent Normal = $(T - V)/(N - V)$, where T represents the number of cells infected with SARS-CoV and treated with compound, V represents the number of cells infected with SARS-CoV but vehicle treated, and N represents the number of the normal control cells that are neither infected nor treated with compound.

After normalization, average activity values were calculated between replicate measurements at the same treatment doses along with σ_1 , the accompanying standard error estimates. Drug response curves were represented by a logistic sigmoidal function with a maximal effect level (A_{\max}), the concentration at half-maximal activity of the compound (EC_{50}), and a Hill coefficient representing the sigmoidal transition. We used the fitted curve parameters to calculate the concentration at which the drug response reached an absolute inhibition of 50% (EC_{50}), limited to the maximum tested concentration for inactive compounds.

Compounds were considered active if the antiviral activity observed was >50% I (or Percent Normal) with no or low corresponding cytotoxicity (<30% I).

RESULTS

Overview of screening process. A primary screen of 290 compounds containing both approved drugs and developmental drugs with defined cellular targets was performed with three-point dose-response curves to identify compounds with activity against MERS-CoV using a cell-based ELISA (Fig. 1). The analysis

FIG 1 Flowchart of screening procedure. A library of 290 compounds was screened at three doses for activity against MERS-CoV. Seventy-two compounds that had activity against MERS-CoV were subsequently screened against both MERS-CoV and SARS-CoV. Twenty-seven compounds showed activity (>50% inhibition) against both viruses, while 33 compounds were active against only MERS-CoV. A 102-compound subset was screened against SARS-CoV, leading to 6 compounds that were active against only SARS-CoV.

of the raw screening data indicated that 72 compounds were active against MERS-CoV (>50% inhibition) with no or low cytotoxicity (<30% toxicity). In the secondary screen, the 72 compounds were plated at eight doses for confirmation of antiviral activity against MERS-CoV as well as to determine EC_{50} s in the MERS-CoV ELISA. The 72 compounds were also evaluated for their antiviral activity against SARS-CoV using a cytopathic effect (CPE) inhibition assay. An independent screen using a subset of 102 compounds against SARS-CoV infection identified 6 unique compounds with activity against SARS-CoV.

Overview of drugs active against SARS-CoV, MERS-CoV, or both. Analysis of data from all screening activities resulted in a list of 66 compounds that were active against SARS-CoV, MERS-CoV, or both. In summary, we found six drugs that were active against SARS-CoV only, 33 drugs that were active against MERS-CoV only, and 27 drugs that were active against both SARS-CoV and MERS-CoV. These drugs were grouped based upon their recognized mechanism of action into 13 different therapeutic classes that were active against SARS-CoV, MERS-CoV, or both (Table 1). The high hit rates of 21% (60 of 290) for MERS-CoV inhibitors and 19% (33 of 174) for SARS-CoV inhibitors can be explained by the fact that the library was enriched for compounds that have shown antiviral activity against other viruses (Glass et al., unpublished).

TABLE 1 Compounds with activity against MERS-CoV and/or SARS-CoV^a

Pharmaceutical class	No. of compounds with activity against:			Total no. of drugs for class
	SARS-CoV only	MERS-CoV only	SARS-CoV and MERS-CoV	
Antibacterial agents		1	1	2
Antiparasitic agents		2	4	6
Neurotransmitter inhibitors	2	3	11	16
Estrogen receptor inhibitors		3	2	5
DNA inhibitors		3	1	4
Protein-processing inhibitors		1	3	4
Signaling kinase inhibitors	1		2	3
Cytoskeleton inhibitors		8		8
Lipid, sterol metabolism inhibitors		2	2	4
Anti-inflammatory agents	3			3
Ion channel inhibitors		9		9
Apoptosis inhibitors		1		1
Cathepsin inhibitors			1	1
Total	6	33	27	66

^a Drugs showed inhibition (>50%) against the virus(es) and low cytotoxicity (<30%).

Pharmaceuticals that inhibited both coronaviruses included neurotransmitter inhibitors, estrogen receptor antagonists, kinase signaling inhibitors, inhibitors of lipid or sterol metabolism, protein-processing inhibitors, and inhibitors of DNA synthesis/repair. Antiparasitics or antibacterials were two classes of pharma-

ceuticals in which function was not obviously linked to coronaviruses, or viruses in general, but showed antiviral activity against SARS-CoV and MERS-CoV. We also found that a cathepsin inhibitor, E-64-D, blocked both SARS-CoV and MERS-CoV, though this was not surprising since it is known that cathepsins are important for the fusion step during virus entry of coronaviruses (26).

Interestingly, classes of drugs that seem to inhibit only SARS-CoV or MERS-CoV, but not both, were discovered. Though we identified only a small number of SARS-CoV-only inhibitors, they are primarily anti-inflammatories, which interfere with cell signaling associated with the immune response to virus infection. MERS-CoV was specifically blocked by inhibitors of ion transport, the cytoskeleton (specifically tubulin), and apoptosis.

Specific drugs. Twenty-seven specific drugs inhibited both MERS-CoV and SARS-CoV infection (Table 2; see also Fig. S1 and S2 in the supplemental material). We present a selection of drugs in Fig. 2, 3, and 4 that are particularly interesting because they have similar structures or similar mechanisms of action or have been tested against other viruses. Data on antiviral activity and cytotoxicity for the remaining compounds that inhibit MERS-CoV and SARS-CoV are provided in the supplemental material.

In total, 16 neurotransmitter antagonists were found to have activity against one or both of the coronaviruses (Table 1). Eleven of these antagonists were active against both MERS-CoV and SARS-CoV, two against only SARS-CoV, and three against only MERS-CoV. Two of the neurotransmitter inhibitors that inhibit both MERS-CoV and SARS-CoV are chlorpromazine hydrochloride and trifluorpromazine hydrochloride (Table 2). Both of these drugs inhibit the dopamine receptor, and they have similar chem-

TABLE 2 Specific compounds with activity against MERS-CoV and SARS-CoV

Compound	Pharmaceutical class	MERS-CoV EC ₅₀	SARS-CoV EC ₅₀
Emetine dihydrochloride hydrate	Antibacterial agent	0.014	0.051
Chloroquine diphosphate	Antiparasitic agent	6.275	6.538
Hydroxychloroquine sulfate	Antiparasitic agent	8.279	7.966
Mefloquine	Antiparasitic agent	7.416	15.553
Amodiaquine dihydrochloride dihydrate	Antiparasitic agent	6.212	1.274
E-64-D	Cathepsin inhibitor	1.275	0.760
Gemcitabine hydrochloride	DNA metabolism inhibitor	1.216	4.957
Tamoxifen citrate	Estrogen receptor inhibitor	10.117	92.886
Toremifene citrate	Estrogen receptor inhibitor	12.915	11.969
Terconazole	Sterol metabolism inhibitor	12.203	15.327
Triparanol	Sterol metabolism inhibitor	5.283	
Anisomycin	Protein-processing inhibitor	0.003	0.191
Cycloheximide	Protein-processing inhibitor	0.189	0.043
Homoharringtonine	Protein-processing inhibitor	0.0718	
Benztrapine mesylate	Neurotransmitter inhibitor	16.627	21.611
Fluspirilene	Neurotransmitter inhibitor	7.477	5.963
Thiothixene	Neurotransmitter inhibitor	9.297	5.316
Fluphenazine hydrochloride	Neurotransmitter inhibitor	5.868	21.431
Promethazine hydrochloride	Neurotransmitter inhibitor	11.802	7.545
Astemizole	Neurotransmitter inhibitor	4.884	5.591
Chlorphenoxamine hydrochloride	Neurotransmitter inhibitor	12.646	20.031
Chlorpromazine hydrochloride	Neurotransmitter inhibitor	9.514	12.971
Thiethylperazine maleate	Neurotransmitter inhibitor	7.865	
Trifluorpromazine hydrochloride	Neurotransmitter inhibitor	5.758	6.398
Clomipramine hydrochloride	Neurotransmitter inhibitor	9.332	13.238
Imatinib mesylate	Kinase signaling inhibitor	17.689	9.823
Dasatinib	Kinase signaling inhibitor	5.468	2.100

FIG 2 Antiviral activity of chlorpromazine hydrochloride and triflupromazine hydrochloride. (A) Chemical structures of the compounds. Vero E6 cells were infected with MERS-CoV or SARS-CoV at an MOI of 0.1 or 1, respectively, and treated for 48 h with eight doses of chlorpromazine hydrochloride (B) or triflupromazine hydrochloride (C). Antiviral activity is shown in blue, and cytotoxicity is shown in red. EC₅₀s are indicated. Results are representative of one experiment (means \pm standard error of the means [SEM]; $n = 2$).

ical structures (Fig. 2A), sharing the same core structure, with the only difference being the nature of the halide group: chlorpromazine hydrochloride has a single chlorine, while triflupromazine hydrochloride has three fluorine atoms surrounding a carbon.

Both chlorpromazine hydrochloride and triflupromazine hydrochloride strongly inhibit MERS-CoV and SARS-CoV, with micromolar EC₅₀s (range, 5.76 μM to 12.9 μM) and low toxicity (Fig. 2B and C). No significant difference was observed between the effects

FIG 3 Antiviral activity of dasatinib and imatinib mesylate. Vero E6 cells were infected with MERS-CoV or SARS-CoV at an MOI of 0.1 or 1, respectively, and treated for 48 h with eight doses of dasatinib (A) or imatinib mesylate (B). Antiviral activity is shown in blue, and cytotoxicity is shown in red. EC₅₀s are indicated. Results are representative of one experiment (means \pm SEM; $n = 2$).

FIG 4 Antiviral activity of gemcitabine hydrochloride and toremifene citrate. Vero E6 cells were infected with MERS-CoV or SARS-CoV at an MOI of 0.1 or 1, respectively, and treated for 48 h with eight doses of gemcitabine hydrochloride (A) or toremifene citrate (B). Antiviral activity is shown in blue, and cytotoxicity is shown in red. EC_{50} s are indicated. Results are representative of one experiment (means \pm SEM; $n = 2$).

of these drugs on MERS-CoV and SARS-CoV; for example, triflupromazine hydrochloride inhibits both MERS-CoV and SARS-CoV with approximately the same EC_{50} (5.76 μ M and 6.39 μ M, respectively [Fig. 2C]). The similarity in the structures of chlorpromazine hydrochloride and triflupromazine hydrochloride would suggest that they inhibit MERS-CoV and SARS-CoV using the same mechanism of action. Chlorpromazine hydrochloride has been used to study virus entry by clathrin-mediated endocytosis of several viruses, including West Nile virus (WNV) and influenza virus (27–31). SARS-CoV also utilizes the clathrin-mediated endocytosis pathway for entry (32), suggesting that this drug may act similarly on MERS-CoV and SARS-CoV and have potential as a broad-spectrum coronavirus inhibitor.

We identified three inhibitors of the kinase signaling pathway, two (imatinib mesylate and dasatinib) that are active against both MERS-CoV and SARS-CoV, and one (nilotinib) that inhibits SARS-CoV only. Imatinib mesylate and dasatinib are known inhibitors of the Abelson murine leukemia viral oncogene homolog 1 (ABL1) pathway. The ABL1 pathway is a signaling pathway involved in cell differentiation, cell adhesion, and the cellular stress response. Overactivation of the ABL1 pathway can lead to chronic myelogenous leukemia. Both imatinib mesylate and dasatinib were developed and approved as inhibitors of this pathway for treating human cancers, including chronic myelogenous leukemia (33, 34). Both imatinib mesylate and dasatinib inhibit SARS-CoV and MERS-CoV with micromolar EC_{50} s (range, 2.1 to 17.6 μ M) and low toxicity (Fig. 3A and B). SARS-CoV does appear to be more sensitive to both ABL1 inhibitors; for example, the EC_{50} of dasatinib against SARS-CoV is 2.1 μ M, whereas for MERS-CoV the EC_{50} is 5.4 μ M (Fig. 3A). A third ABL1 inhibitor, nilotinib, was also used in this study. Nilotinib is able to inhibit SARS-CoV with a micromolar EC_{50} and low toxicity (data not shown) but does not significantly inhibit MERS-CoV, with the maximum inhibition of MERS-CoV being 39% at the highest dose tested (data not shown). However, the fact that nilotinib is able to inhibit SARS-

CoV and partially inhibit MERS-CoV further points to the importance of the ABL1 pathway in coronavirus replication. Imatinib mesylate has been shown to block egress of Ebola virus and of poxviruses and entry of coxsackievirus (20, 35, 36). These data suggest that the ABL1 pathway may be important for replication of many different virus families and, therefore, inhibitors of this pathway have the potential to be broad-spectrum antivirals.

Gemcitabine hydrochloride is a deoxycytidine analog that inhibits DNA synthesis and repair. Gemcitabine hydrochloride inhibits both MERS-CoV and SARS-CoV with micromolar EC_{50} s (1.2 μ M and 4.9 μ M, respectively) and low toxicity (Fig. 4A). Interestingly, we identified four DNA synthesis inhibitors that were active against at least one coronavirus (Table 1), suggesting that these drugs have potential as antivirals for coronaviruses. These data also demonstrate the importance of screening large drug sets, rather than targeted screens of suspected inhibitors, as it may not have been immediately obvious that a DNA synthesis inhibitor would have any effect on the replication of an RNA virus.

Toremifene citrate is an estrogen receptor 1 antagonist that inhibits both MERS-CoV and SARS-CoV with micromolar EC_{50} s (12.9 μ M and 11.97 μ M, respectively) and low toxicity (Fig. 4B). Toremifene citrate has been tested against several filoviruses and was shown to block filovirus entry (21, 37). In the screens described here, there were five estrogen receptor inhibitors that blocked at least one coronavirus (Table 1), and two of these blocked both MERS-CoV and SARS-CoV with micromolar EC_{50} s (Table 2) and low toxicity. While the antiviral mechanism against MERS-CoV and SARS-CoV is unknown, these results suggest that estrogen receptor 1 inhibitors have the potential for broad-spectrum antiviral activity.

DISCUSSION

In order to prevent the emergence of a novel virus from growing into a pandemic or established human pathogen, it is critical that public health officials and clinicians be able to diagnose the infec-

tion, control its spread, and treat those afflicted. First and foremost, we need more countermeasures that can be used for the early phase of an epidemic to provide an immediate treatment response while more-appropriate therapies are being developed. Given the time and costs associated with licensure of novel therapeutics, one feasible and rapid response is through repurposing of existing clinically developed products. Repurposing of approved drugs has several advantages, including known safety/tolerability profiles, availability, lower cost, and familiarity of clinicians in working with these drugs. Supplying the international community with robust sets of *in vitro* and *in vivo* data on potential drugs for treatment of emerging viral diseases continues to be a high priority, as it will allow clinicians to make educated decisions on clinically available drugs for testing in intervention trials.

Here we report that screening of a library of 290 drugs either clinically developed or with a well-defined cellular pathway identified 27 compounds with activity against MERS-CoV and SARS-CoV, 33 compounds with activity against MERS-CoV alone, and 6 compounds with activity against SARS-CoV alone. Overall, we have demonstrated that libraries of approved compounds can be used to screen for inhibitors of viruses and have identified a number of potential antivirals with activity against coronaviruses.

The drugs identified here belong to 13 different classes of pharmaceutical drugs. For two of the classes, kinase signaling inhibitors and estrogen receptor antagonists, previous work with other viruses has given insight into how these drugs may affect viral infections. Three tyrosine kinase inhibitors, imatinib mesylate (Gleevec), nilotinib (Tasigna), and dasatinib, were developed to treat human cancers and were later shown to have activity against several viruses, including poxviruses and Ebola virus (20, 36). Mechanism of action studies revealed that Abl1 tyrosine kinase regulates budding or release of poxviruses and Ebola virus, demonstrating that the c-Abl1 kinase signaling pathways play an important role in the egress of these viruses. Here we show that kinase signaling may also be important for replication of two members of the *Coronaviridae* family. Imatinib mesylate and dasatinib inhibit MERS-CoV and SARS-CoV, while nilotinib inhibits only SARS-CoV. The step in viral replication in which these kinases are involved will need to be investigated further. *In vivo* studies performed in the mouse model of vaccinia virus infection showed that imatinib mesylate was more effective than dasatinib in blocking dissemination of the virus, and this was attributed to the immunosuppressive effect of dasatinib (36). Nevertheless, dasatinib may have value for treating coronaviral infections if a dosing regimen that minimizes immunotoxicity while still blocking viral replication can be defined. Imatinib mesylate (Gleevec) and nilotinib (Tasigna) are FDA-approved oral cancer medicines and are considered promising candidates for development into antivirals against poxviruses (38).

Estrogen receptor modulators represent another class of FDA-approved drugs that have potential as antivirals in the clinic. Toremifene citrate, which we have shown blocks both MERS-CoV and SARS-CoV, has previously been shown to inhibit filoviruses (21). Mechanism of action studies showed that the drug acts at a late step of virus entry and may inhibit trafficking of the virus to the late endosome or triggering of fusion for filoviruses (21, 37). Interestingly, the estrogen signaling pathway is not involved in the virus entry step, indicating that these drugs may have off-target effects or the estrogen signaling pathway plays an as-yet-undiscovered

role in filovirus biology. Toremifene citrate also showed activity in the mouse model of Ebola virus infection (21).

Our screen also identified antiviral actives in the pharmaceutical class of neurotransmitter receptor antagonists. These antagonists have been developed for psychiatric care as antipsychotics, antiemetics, anticholinergics, and antidepressants and predominantly act by blocking the dopamine receptor or H₁ receptor (antihistamine). Chlorpromazine was shown to inhibit clathrin-mediated endocytosis of several viruses by preventing the formation of clathrin-coated pits at the plasma membrane (27). This drug is currently approved by the FDA as an antipsychotic and for the treatment of nausea (39) and is occasionally used for short-term use as off-label treatment of severe migraine (40), making it a promising candidate for testing as a broad-spectrum antiviral. Astemizole, an antihistamine that was identified in our screen, is a strong antagonist of the H₁ receptor (see Fig. S1 and S2 in the supplemental material). Interestingly, it has been reported that astemizole is an inhibitor of malaria and showed efficacy in two animal models of malaria with a mechanism of action similar to that of chloroquine (41). Although astemizole was withdrawn from the U.S. market in 1999, it may be worthwhile to reexamine this drug or existing analogs for short-term use in an acute infection. Previous work on chloroquine in coronavirus infections by Barnard et al. has found that while the drug inhibits viral replication *in vitro*, chloroquine did not show efficacy in reducing SARS-CoV virus titers in a nonlethal mouse model (42). Protection studies using a mouse-adapted SARS-CoV will be performed to identify the *in vivo* efficacy of targeted drugs from our screen.

While development of drugs with broad activity against a virus family or even unrelated viruses is advantageous for several reasons such as immediate availability, lower costs, and recycling of products from the strategic national stockpile, drug classes that are more selective in their activity and affect either MERS-CoV or SARS-CoV should also be further investigated. Our screen identified 33 MERS-CoV actives (Table 1), and the two largest classes were cytoskeleton inhibitors (8 drugs) and ion channel inhibitors (11 drugs). Drugs targeting the cytoskeleton specifically interfere with microtubule polymerization and are antimicrotubule developed for treatment of cancer. Some of them, such as nocodazole, have also been used in cell biology labs to synchronize the cell division cycle. Nocodazole's ability to depolymerize microtubules has been used to investigate the entry pathway of WNV, and results show that an intact microtubule network is necessary for trafficking of internalized WNV from early to late endosomes (27). This drug had high activity against MERS-CoV but had no activity against SARS-CoV, suggesting that, in addition to the application as therapeutics, these drugs may also have value in further elucidating differences in the virus replication cycle of MERS-CoV and SARS-CoV.

Two of the 9 ion channel inhibitors, monensin and salinomycin sodium, with activity against MERS-CoV, represent polyether ionophores that are currently well-recognized candidates for anticancer drugs (43, 44). Studies on the mechanism of anticancer activity have shown that these compounds affect cancer cells by increasing their sensitivity to chemotherapy and reversing multidrug resistance (monensin) in human carcinoma. Furthermore, ionophore antibiotics also inhibit chemoresistant cancer cells by increasing apoptosis, and salinomycin was specifically shown to be able to kill human cancer stem cells (45). Interestingly, these compounds affected MERS-CoV but not SARS-CoV, indicating

that MERS-CoV is uniquely susceptible to ionophore activities. Monensin has also been reported to inhibit La Crosse virus and Uukuniemi virus infection by blocking the formation and egress of virus particles (46, 47). Further studies will reveal if these drugs act at a similar step during MERS-CoV infection.

Overall, we identified several pharmaceutical classes of drugs that could be beneficial for treatment of coronaviral infections. Interestingly, chlorpromazine hydrochloride and chloroquine diphosphate were also identified in a similar but independent study described in the accompanying paper by A. H. de Wilde et al. (48). These drugs appear to target host factors rather than viral proteins specifically, and treatment of viral infections in patients aimed at host factors could reconfigure overt manifestations of viral pathogenesis into a less virulent subclinical infection and lower adverse disease outcome (38). The targets identified in this paper provide new candidates for future research studies and clinical intervention protocols.

ACKNOWLEDGMENTS

We thank Laura Pierce, Anatoly Myaskovsky, Kelly DeRoche, and Crag Markwood at Zalicus Inc. for compound plate preparation and data integration. We thank Yingyun Cai and Cindy Allan for outstanding assistance in the development of the drug screen protocol. We thank the IRF Cell Culture staff in preparing the cells used in this study. In addition, we acknowledge Laura Bollinger and Jiro Wada at the IRF for technical writing services and figure preparation for the manuscript.

This work was supported by the Division of Intramural Research of the National Institute of Allergy and Infectious Diseases (NIAID), the Integrated Research Facility (NIAID, Division of Clinical Research), the Battelle Memorial Institute's prime contract with NIAID (contract number HHSN2722007000161) and NIH grant R01AI1095569 (to M.B.F.), and a subcontract (W81XWH-12-2-0064) awarded to L.M.J. from the U.S. Army Research Institute of Infectious Diseases (USAMRIID).

L.M.J. was employed at Zalicus Inc. during the time the research was performed. M.L. is currently employed at Zalicus Inc. No other authors have conflicts of interest.

Abstract No specific antivirals are currently available for two emerging infectious diseases, Middle East respiratory syndrome (MERS) and severe acute respiratory syndrome (SARS). A literature search was performed covering pathogenesis, clinical features and therapeutics, clinically developed drugs for repurposing and novel drug targets. This review presents current knowledge on the epidemiology, pathogenesis and clinical features of the SARS and MERS coronaviruses. The rationale for and outcomes with treatments used for SARS and MERS is discussed. The main focus of the review is on drug development and the potential that drugs approved for other indications provide for repurposing. The drugs we discuss belong to a wide range of different drug classes, such as cancer therapeutics, antipsychotics, and antimalarials. In addition to their activity against MERS and SARS coronaviruses, many of these approved drugs have broad-spectrum potential and have already been in clinical use for treating other viral infections. A wealth of knowledge is available for these drugs. However, the information in this review is not meant

to guide clinical decisions, and any therapeutic described here should only be used in context of a clinical trial. Potential targets for novel antivirals and antibodies are discussed as well as lessons learned from treatment development for other RNA viruses. The article concludes with a discussion of the gaps in our knowledge and areas for future research on emerging coronaviruses.

Key Points

The outbreaks of Middle East respiratory syndrome (MERS) and severe acute respiratory syndrome (SARS) were caused by emerging coronaviruses.

A variety of approaches for developing therapeutics are discussed with emphasis on drugs that have been approved for other indications and could be repurposed for treating emerging coronaviral infections.

The recent MERS and SARS outbreaks highlight the importance of a panel of well-characterized broad-spectrum antivirals for treating emerging viral infections

1 Introduction

An electronic literature search for countermeasures against Middle East respiratory syndrome coronavirus (MERS-CoV) and severe acute respiratory syndrome coronavirus (SARS-CoV) was performed using PubMed and Google

Scholar from 2000 through April 17, 2017. The search (key words: Middle East Respiratory Syndrome, Severe Acute Respiratory Syndrome, inhibitors, antivirals, therapeutics, FDA-approved) produced 1677 citations. References selected discussed (1) pathogenesis and history of disease, (2) clinical countermeasures used during the 2003 SARS and 2012 MERS outbreaks and outcomes, and (3) the efficacy of countermeasures targeting viral components and cellular targets of MERS-CoV and SARS-CoV. The main emphasis was on references for drug repurposing as an alternative to the costly development of novel drugs for emerging coronaviral infections.

1.1 Epidemiology of MERS and SARS

Since 2003, two human coronaviruses, SARS-CoV and MERS-CoV, emerged as global public health threats. SARS-CoV was first identified in February 2003 in Guangdong Province, Peoples Republic of China and was transmitted to humans from infected civets, likely infected from bats [1, 2]. SARS-CoV spread to 29 additional countries and was associated with high morbidity in humans (e.g. atypical pneumonia). Ultimately, SARS was contained in 2004 following a highly effective public health response but resulted in 8098 confirmed cases and 774 deaths (Fig. 1a) [3]. In 2012, MERS emerged in The Kingdom of Saudi Arabia and presented as a severe respiratory disease, with frequent gastrointestinal and renal complications. MERS-CoV, the causative agent of MERS, was later identified as a coronavirus. MERS-CoV has subsequently spread to 27 additional countries (Fig. 1B) [4]. As of September 12, 2017, 2080 confirmed cases of MERS and 722 deaths were reported [5].

Coronaviruses are enveloped, single-stranded, positive-sense RNA viruses (Fig. 2). They are members of the *Coronavirinae* subfamily of viruses and together with the *Torovirinae* subfamily comprise the *Coronaviridae* virus family (order *Nidovirales*). *Coronavirinae* is divided into four genera: alpha coronavirus, beta coronavirus, gamma coronavirus, and delta coronavirus. The coronaviruses share a similar genome organization. The open reading frame 1a and 1b comprise nearly 2/3 of the genome and encode the nonstructural proteins. The multiple structural proteins, including spike, nucleocapsid, envelope, and membrane proteins are encoded by downstream open reading frames (Fig. 2) [6–8]. SARS-CoV and MERS-CoV belong to the beta coronavirus genus. However, SARS-CoV belongs to lineage B, and MERS-CoV belongs to lineage C along with bat coronaviruses HKU4 and HKU5. As MERS-CoV and bat coronaviruses are part of lineage C and MERS-CoV RNA was found in a bat sample in The Kingdom of Saudi Arabia, researchers hypothesize that bats may be a natural reservoir for MERS-CoV [9, 10].

Results from a recent study support that bats may be a reservoir for MERS-CoV; however, camels and goats are thought to be intermediate hosts [11]. In this study, MERS-CoV was isolated from nasal secretions of MERS-CoV-infected dromedary camels that had a short, mild disease progression.

The suspected reservoir for SARS-CoV is the Chinese horseshoe bat [2]. However, the mechanism of emergence and adaptation to make the virus zoonotic is still not definitely understood [2]. SARS-CoV-like isolates from these bats have up to 95% sequence similarity to human and civet SARS-CoV. During the initial outbreak, SARS-CoV was originally isolated from palm civets found in a Chinese market; but, SARS-CoV was not found in the wild palm civet population [12]. Bats harbor many coronaviruses and are considered the main reservoir for later infections in an intermediate host, such as civets or camels, which spread the disease to humans [2]. Human-to-human transmission has been most commonly associated with health-care workers and those with close, unprotected contact with infected patients [13, 14].

1.2 Clinical Features

The clinical features of MERS and SARS are similar and can range from asymptomatic or mild disease to severe pneumonia with acute respiratory distress syndrome (ARDS) and multi-organ failure [15]. Although MERS and SARS are clinically similar, the MERS mortality rate is 40% and SARS's mortality rate is 10% [16]. Approximately 75% of MERS cases were associated with underlying comorbidities with a 60% mortality rate in this subgroup (including cardiopulmonary abnormalities, obesity, and diabetes). In contrast, 10–30% of patients with SARS have comorbidities with a mortality rate of 46% within this subgroup [15, 16].

The development of symptomatic MERS and SARS mostly occurs in adults (median age of 50 years; 40 years for SARS). MERS and SARS symptoms typically follow a mean incubation time of ~ 5 days (range 2–13 and 2–14 days, respectively) and include fever, chills, cough (some associated with blood), shortness of breath, myalgia, headache, nausea, vomiting, diarrhea, sore throat, and malaise [15–17]. Progression from mild to severe disease is more rapid with MERS as compared to SARS with means of 7 and 11 days, respectively [15]. Secondary bacterial infections have occurred in patients with severe MERS; however, the role of these coinfections in MERS pathogenesis has yet to be determined [18–20]. Laboratory abnormalities associated with MERS and SARS patients include elevated lactate dehydrogenase, elevated liver enzymes; thrombocytopenia; lymphopenia and leukopenia [21–23].

Fig. 1 Maps of the severe acute respiratory syndrome (SARS) (a) and Middle East respiratory syndrome (MERS) (b) outbreaks with confirmed case numbers

Radiographic abnormalities consistent with viral pneumonitis and ARDS are common in MERS and SARS. Radiographic progression in the lower lobes has been reported to be more rapid for MERS than SARS [21–23]. For SARS, disease in the lower lobes mimics pneumonia, radiographic progression includes ground-glass opacification and lobe thickening [17]. MERS-CoV (intact virus or

viral genome) is found at higher concentrations in the lower respiratory tract than in the upper respiratory tract in MERS patients and this may account for inefficient inter-human transmission [15, 24]. Currently, no approved therapeutics for patients with MERS or SARS are available, and clinical management has relied primarily on supportive care.

and 1b) and structural proteins (numbered 3–9, and E, M, N, S). *E* envelope, *M* membrane, *N* nucleocapsid, *S* Spike

2 Therapeutic Agents

2.1 Clinical Usage

2.1.1 Treatment of SARS

Effectiveness of antiviral treatments used during the SARS epidemic has been mainly based on case studies and retrospective analysis of patient cohorts. Few randomized, blinded, clinical trials of anti-SARS treatments were performed, which adds complexity when interpreting the available data (Table 1). Ribavirin, a nucleoside analog that prevents RNA and DNA virus replication, was initially used in the treatment of SARS due to its broad-spectrum efficacy. For example, in a Taiwanese study, 51 SARS patients were treated daily with fluoroquinolone antibiotics, [levofloxacin (500 mg) or moxifloxacin (400 mg)] following diagnosis. Out of 51 patients, 44 SARS patients were also treated intravenously (IV) with 2000 mg of ribavirin then orally daily with 1200 mg while 7 SARS patients did not receive ribavirin. Corticosteroids, IV methylprednisolone, or oral prednisolone were administered as needed to treat worsening lung infiltrates and fever [25]. Ribavirin treatment led to hypoxia and anemia and increased risk for death in SARS patients. In a retrospective analysis, a cohort of 229 patients from Hong Kong, Singapore, and Toronto were treated with ribavirin in conjunction with corticosteroids, immunoglobulins, and/or antibiotics [26]; ribavirin did not demonstrate efficacy. Patients in Hong Kong and Singapore were treated with ribavirin at 1200 mg orally at diagnosis, followed by oral treatments with 2400 mg daily, or continual IV ribavirin therapy [8 mg/kg every 8 h (h)]. In Toronto, patients received ribavirin IV treatment with 2000 mg, followed by 1000 mg every 6 h for 4 days, and 300 mg every 8 h for 3 days. Unfortunately, fatality rates were similar between the ribavirin-treated and control groups. Later, researchers demonstrated that the ribavirin dosage required to be effective against SARS-CoV in vitro was not clinically achievable [27]. Ribavirin treatment also resulted in

Table 1 Drug regimens used in the treatment of SARS

Treatment plan	Treatment outcome
Ribavirin (oral/IV)	No increased positive outcome with ribavirin compared to controls [25, 26]
Antibiotics	
± corticosteroids	Increased risk of anemia, hypomagnesemia, hypoxia, or bradycardia with ribavirin compared to ribavirin-naïve patients [25, 246]
± immunoglobulin	
Ribavirin (oral/IV)	Fatality or acute respiratory distress syndrome (ARDS) was reduced significantly from 28.8 to 2.4% [27]
Lopinavir/ritonavir	
± corticosteroids	
IFN- α con-1	Increased oxygen saturation
± corticosteroids	Increased clearance of lung abnormalities
± antibiotics	Slight increase in creatinine kinase concentrations [29, 247]
Fluoroquinolone (IV)	No increased positive outcome [248]
Azithromycin (IV)	
IFN- α (IM)	
± corticosteroids	
± Immunoglobulins	
± thymic peptides/proteins	
Quinolone (IV)	No increased positive outcome [248]
Azithromycin (IV)	
± IFN- α	
± corticosteroids	
Levofloxacin	Increased survival
Azithromycin	Increased clearance of lung abnormalities [248]
± IFN- α	
± corticosteroids	

IFN interferon, *IM* intramuscular, *IV* intravenous, *SARS* severe acute respiratory syndrome

adverse effects including anemia, hypoxemia and decreased hemoglobin levels, and did not improve patient outcome [26]. Due to the increasing adverse effects and lack of efficacy, Health Canada stopped permitting the use of ribavirin for SARS [25].

Additional studies tested the efficacy of ribavirin in conjunction with lopinavir, an anti-retroviral agent. Lopinavir demonstrated in vitro activity against SARS-CoV [28]. In a non-randomized, open-enrollment trial of 152 suspected SARS patients [27], all patients were treated with ribavirin and corticosteroids similar to the previously described studies. In addition, 41 of the confirmed SARS patients were also treated with a combination of lopinavir (400 mg) and ritonavir (100 mg). Mean viral loads in nasopharyngeal swabs within this treatment group decreased to undetectable levels by day 10. Overall, SARS-related symptoms subsided, disease progression was milder, and no adverse effects were reported as compared to the historical control group.

In an open-label, non-randomized study of 22 SARS patients, 9 patients who received subcutaneous (SC) injections of interferon (IFN) α , alfacon-1, for 10 days at an initial dose of 9 μ g/day for 2 days increasing to 15 μ g/day with disease progression. All 9 patients survived with minor adverse effects [29].

2.1.2 Treatment of MERS

The evaluation of treatments in MERS patients has been hampered as high-quality clinical data from randomized clinical trials are limited. Ribavirin (with or without IFN, or corticosteroids) was the primary treatment during the MERS outbreak. In a retrospective analysis, a cohort of 20 patients was treated with oral ribavirin and SC pegylated IFN- α 2a at a dose of 180 μ g/week for 2 weeks (Table 2) [30]. The initial dose of ribavirin was 2000 mg, followed by a 200–1200 mg dose depending on creatinine clearance.

Table 2 Drug regimens used in the treatment of MERS

Treatment plan	Treatment outcome
Ribavirin (oral/IV)	Late treatment administration. Disease progression delayed—all patients died [249]
IFN- α 2b	
Corticosteroids	
Ribavirin (oral/IV)	Treatment initiated 0–8 days after diagnosis
PEGylated IFN- α 2a (IV)	Adverse effects: significant decreases in hemoglobin and absolute neutrophil count (baseline count lower in treatment group) [30]
\pm corticosteroids	
Ribavirin (oral/IV)	No detectable viral RNA in serum after 2 days of therapy
Lopinavir/ritonavir	Adverse effects: ribavirin discontinued due to jaundice, hyperbilirubinemia
IFN- α 2b	Died of septic shock 2 months, 19 days after diagnosis [31]

IFN interferon, IV intravenous, MERS Middle East respiratory syndrome

A group of 24 patients that received supportive care and corticosteroids were considered the control group. At 14 days after confirmed diagnosis of MERS, survival was increased in the treated group (70%) compared to the control group (29%). By 28 days post-diagnosis, 30% of treated subjects survived versus 17% of the control group [30]. In an additional case study, a 69-year-old Greek patient who contracted MERS in Jeddah was treated with oral lopinavir/ritonavir (400/100 mg twice daily), pegylated IFN (180 μ g SC once per week for 12 weeks), and ribavirin (2000 mg initial dose; 1200 mg every 8 h for 8 days, initiated on day 13 post-diagnosis). Two days after treatment initiation, viremia could not be detected; however, viral RNA was detected in several patient samples (feces, respiratory secretions, and serum) up to 14 weeks post-diagnosis. Despite prolonged survival, the patient succumbed from septic shock 2 months post-diagnosis [31]. An ongoing randomized clinical trial in Saudi Arabia is evaluating treatment of MERS patients with IFN- β 1b in combination with lopinavir/ritonavir [32].

2.2 Drugs with Repurposing Potential for Treatment of Coronaviral Infections

Drug repurposing is an attractive alternative drug discovery strategy because it eliminates many steps usually required at the early phase of drug development. Over the past decade, interest in drug repurposing has increased as pharmaceutical companies are challenged with decreasing product pipelines, high costs associated with de novo drug discovery, and the imminent expiration of many drug patents. Some examples for successfully repurposed drugs include Viagra (Pfizer) for erectile dysfunction (original indication: angina) and raloxifene (Eli Lilly) for treatment of invasive breast cancer (original indication: osteoporosis).

The time required for traditional drug development is often discordant with the urgent need for novel therapies for emerging infectious diseases such as SARS and MERS. Outbreaks can occur anywhere in the world and frequently in resource-limited settings. Commonly, the treatment strategies that are available for emerging infectious diseases are less than adequate to improve patient outcome. Although specific antivirals for MERS-CoV and SARS-CoV are in development, drug repurposing could present an important arm in generating additional therapeutics for future coronaviruses. First, if these drugs are confirmed to have beneficial effects in vitro and in animal studies, they could be used to build a panel of approved drugs for use as a first-line of defense for newly emerging coronaviruses. Second, these drugs could be made accessible relatively quickly to patients under Emergency Use Authorization. Extending the choices of treatment by generating a panel of

broad-spectrum antivirals would provide a real improvement to healthcare communities struggling to cope during an outbreak of emerging infections. A great example of how repurposing can benefit in the search of treatments for emerging infections is the drug zidovudine. Zidovudine was originally developed in 1964 as a cancer drug. In 1985, zidovudine was found to be active against human immunodeficiency virus (HIV), and 2 years later it became the first drug to be approved for the treatment of acquired immunodeficiency syndrome (AIDS) [33].

A number of research groups have identified and investigated the usefulness of approved drugs for the treatment of viral infections including coronaviruses. Below, we summarize several drug classes with antiviral activity against MERS-CoV and SARS-CoV that have repurposing potential (Fig. 3, Table 3). Some of the drugs described have activity against other virus families indicating potential broad-spectrum applications and have already been in clinical use for treating other viral infections. We would like to emphasize that none of the therapeutics described in this section are recommended for clinical use outside a clinical trial setting.

2.2.1 Antidiarrheal Agents

Loperamide, an approved anti-diarrheal agent, is on the World Health Organization (WHO) Model List of Essential Medicines and is available in many countries. The drug acts on the opioid receptor and reduces intestinal motility [34]. Results from pharmacokinetic (PK) studies show that oral loperamide is well absorbed from the gut with less than 1% of the drug entering systemic circulation [35]. Loperamide demonstrated anti-MERS-CoV, anti-SARS, and anti-HCoV229E activity in an in vitro screen of approved drugs [36], although the mechanism of action is unknown. Interestingly, loperamide was suggested for limiting gastrointestinal fluid and electrolyte losses in patients with Ebola virus disease (EVD) [37].

2.2.2 Antimalarial Agents

The antimalarial agents, chloroquine (CQ), amodiaquine, and mefloquine have activity against SARS-CoV and MERS-CoV in vitro [36, 38, 39]. CQ is a U.S. Food and Drug Administration (FDA)-approved antimalarial agent that is also used to treat autoimmune disease such as rheumatoid arthritis due to its anti-inflammatory effects [40]. CQ has activity against a number of viruses in vitro and in vivo including flaviviruses [dengue virus (DENV)], Togaviruses [chikungunya virus (CHIKV)], paramyxoviruses (Hendra, Nipah virus), influenza viruses, HIV, and filoviruses [Ebola virus (EBOV)] [41–47].

Fig. 3 Candidate drugs for repurposing for coronaviral infections. Several drug classes (A through I) have been studied, and the steps/processes of the viral replication cycle that they most likely target are indicated. *AKT* serine/threonine kinase, *CAD* cationic amphiphilic drug, *Cyp*s cytochrome P-450s, *E* envelope, *ER* endoplasmic reticulum, *ERGIC* ER–Golgi intermediate compartment, *ERK* extracellular signal-reduction kinase, *IFN* interferon, *MAPK* mitogen-activated protein kinase, *M* membrane, *MPA* mycophenolic acid, *mTOR* mechanistic target of rapamycin, *N* nucleocapsid, *NEFAT* nuclear factor of activated T cells, *ORF* open reading frame, *PI3K* phosphoinositide 3-kinase, *S* Spike

Several mechanisms of action have been identified for the antiviral effect of CQ and suggest that the drug acts nonspecifically at virus entry or at the later stages of virus production. CQ accumulates within acidic organelles such as endosomes, Golgi vesicles, and lysosomes, where the drug is protonated resulting in increased pH within the vesicle [48]. Viruses depend on these acidic organelles for entry, viral replication, and maturation of virus progeny. Similarly, MERS-CoV entry into cells depends on several proteases. Dipeptidyl peptidase 4 (DPP4) acts as functional virus receptor [49], and cellular proteases [e.g. type II transmembrane serine protease (TMPRSS2) and members of the cathepsin family] activate the viral spike (S) glycoprotein [50]. CQ may have an effect on any of these proteases. CQ also affects the glycosylation step within the Golgi that directs trafficking and maturation of viral proteins [51–53]. For SARS-CoV, the antiviral activity of CQ has also been attributed to a deficit in glycosylation of the receptor angiotensin-converting enzyme 2 (ACE2) [54].

The broad-spectrum antiviral activity makes CQ an attractive antiviral for repurposing and treating coronaviral and other emerging viral infections. In vivo activity of CQ in MERS or SARS animal models has not yet been reported. However, the antiviral activity of the drug has been evaluated against other viruses in preclinical and clinical studies with mixed results. CQ plasma steady state concentrations in mice are similar to those reported for humans (10 μ M) and are within range of the EC₅₀ values determined for MERS-CoV (3.6 μ M) and SARS-CoV (2.3 μ M) [43, 55]. Preclinical studies with CQ in mice against other viruses have shown survival benefits for influenza and EBOV infections.

In clinical studies, CQ was effective at reducing viral loads in asymptomatic HIV patients [56, 57], but results of CQ treatment of CHIKV and DENV infections were mixed [58, 59].

In summary, CQ has broad-spectrum potential and the information gained from studies on other viruses can be used to plan the most appropriate strategies for evaluating its specific clinical value for treating for MERS-CoV and SARS-CoV infections. CQ has several advantages including rapid absorption from gastrointestinal tract, low cost,

Candidate antiviral agents

- A** | **Host protease inhibitors**

- I** | **Exogenous IFN- α or - β**
 - betaferon

and very effective biodistribution. CQ may be an excellent candidate for combinatorial treatments with other antivirals. However, considerable challenges remain for the treatment of viral infections including increased understanding of the pharmacodynamics of CQ, achievement of sufficient plasma concentrations in patients, and toxicity concerns [60]. Importantly, hydroxychloroquine, a CQ derivate, may provide an alternative due to lower toxicity and similar pharmacology profile [55].

A related antimalarial drug, amodiaquine, also has activity in vitro against MERS-CoV and SARS-CoV [38]. Previous investigations have demonstrated that amodiaquine inhibits filovirus replication, and the mechanism of action is hypothesized to be similar to that of CQ [43]. Amodiaquine is well tolerated and is commonly used for malaria treatments in many countries. Further, amodiaquine in combination with artesunate was administered to EVD patients during the 2013–2016 epidemic, and the resulting decrease in fatality rates may have been associated with the use of amodiaquine as an antimalarial agent [61]. Nonhuman primate (NHP) studies are currently underway to investigate the effect of amodiaquine treatment on EVD [62].

Mefloquine, a synthetic analog of quinine, is another antimalarial drug with activity against MERS-CoV and SARS-CoV [38]. It belongs to the WHO Model List of Essential Medicines. Mefloquine is known to penetrate the blood-brain barrier and was found to inhibit JC virus infection and replication at concentrations generally achieved in the brains of patients given mefloquine for malaria [63] leading to the clinical evaluation of this drug for the treatment of progressive multifocal leukoencephalopathy [64, 65]. In 2013, the FDA added a boxed warning to the US label of mefloquine regarding the potential for neuropsychiatric side effects. Additional investigations are warranted to determine if amodiaquine or mefloquine have value for repurposing for treatment of MERS or SARS.

2.2.3 Cyclophilin Inhibitors

Cyclophilins are ubiquitous host proteins believed to have multiple roles in trafficking, protein folding and T cell activation [66]. Cyclosporine A (CysA), forms a complex with cyclophilin A, thereby blocking T cell activation. CysA is licensed for use in organ transplantation to suppress the immune response. CysA has also been shown to inhibit coronaviruses including SARS-CoV and MERS-CoV effectively in cell culture [67, 68]; however, the mechanism has yet to be determined. There is increasing evidence that cyclophilins are involved in viral replication of RNA viruses such as hepatitis C virus (HCV) and West Nile virus, and this may also apply to coronaviruses [69].

Although the immunosuppressive properties of CysA are considered a risk for treating viral infections in patients, nonimmunosuppressive analogs of CysA that bind to cyclophilins with higher affinity have been developed and some are in clinical trials as HCV therapeutics [70–72].

2.2.4 Interferons

Interferons (IFNs) are approved by the FDA for other indications such as hepatitis C. Although IFN- α reduced SARS-CoV replication in mice and NHPs [73, 74], efficacy of IFN- α treatment in SARS patients was mixed (see Sect. 2.1.1). From in vitro studies, another type I interferon, IFN- β 1a, may be more effective than IFN- α either alone or in combination with IFN- γ [75–77]. Combinations of IFN- β and - γ were synergistic against SARS-CoV in vitro [77].

With regards to MERS, in vitro and in vivo preclinical studies have indicated that IFN- α 2b alone or in combination with ribavirin, may have a therapeutic effect if given early in disease [78, 79]. In clinical trials, however, IFN- α 2b (given in combination with other treatments) did not lead to a significant benefit to patients (see Sect. 2.1.2). IFN- β 1a ($EC_{50} = 1.37$ IU/mL) was superior in activity against MERS-CoV infection in vitro compared to IFN- α 2a, IFN- α 2b, and IFN- γ ; these IFNs had EC_{50} values of 160.8, 21.4, and 56.5 IU/mL, respectively [80]. IFN- β 1b is currently under evaluation for MERS-CoV in a randomized clinical trial (in combination with lopinavir/ritonavir) [32]. Investigating the IFN- β subtypes (1a and 1b) in combination with other antivirals may be worthwhile as potential synergistic combinations could reduce the effective drug dosage and IFN-associated adverse effects.

2.2.5 Kinase Inhibitors

Many cellular processes are regulated independently of changes in transcription or translation through kinase-mediated cell signaling pathways. As a testament to the biological importance of kinases, there have been over 500 kinases identified along with more than 900 genes encoding proteins with kinase activity [81, 82]. As of April 2015, 28 kinase inhibitors have been granted approval by the US FDA with over half gaining approval from 2012–2015. Further, kinases are the most frequently targeted gene class in cancer therapy, second only to the G protein-coupled receptors as therapeutic targets [83, 84].

The therapeutic potential for host-targeted immunomodulatory agents in viral infections has received considerable attention [85–87]. Recently, Dyall et al. identified two Abelson (Abl) kinase inhibitors (imatinib and dasatinib) that inhibited MERS-CoV and SARS-CoV infection through a cell-screening assay [38]. Both

Table 3 Clinically developed drugs with activity against MERS-CoV and SARS-CoV

Drug class members	Activity against coronaviruses ^a	Activity against other viruses	Clinical status	Known safety issues	Comments
Antidiarrheal agents					
Loperamide hydrochloride	MERS-CoV: 4.8 μ M [36] SARS-CoV: 5.9 μ M HCoV-229E-GFP: 4 μ M [36]		Approved for treatment of diarrhea	Well tolerated, commonly used	WHO list of essential medicines
Antimalaria agents					
Amodiaquine hydrochloride	MERS-CoV: 6.2 μ M [38] SARS-CoV: 1.3 μ M [38]	EBOV [43]; MARV [43]; DENV [250]	Approved for treatment of malaria	Well tolerated, commonly used	
Chloroquine diphosphate	MERS-CoV: 3–6.3 μ M [36, 38] SARS-CoV: 4.1–8.8 μ M [36, 38, 39]	In vitro: CHIKV [251, 252]; DENV [42, 47]; HeV, NiV [46]; HIV-1 [41]; FLUAV [44]; EBOV, MARV [43]; SFV, SINV [45] In vivo: Mixed data on efficacy against EBOV in mice [43, 60]; no efficacy against EBOV in hamsters, guinea pigs [60]; FLUAV : 70% survival in mice [253] In vitro: DENV [42]; HIV-1 [255]; JCV [63]	Approved for treatment of malaria Clinical trials for treatment of CHIKV, DENV, FLUAV, and FLUBV infections showed no impact on disease [58, 59, 254]	Well tolerated, commonly use	WHO list of essential medicines; WHO list of potential EVD treatments; dosing, formulation need to be optimized for treatment of viral infections [54]
Hydroxychloroquine sulfate	MERS-CoV: 8.3 μ M [38] SARS-CoV: 8.0 μ M [38]		Approved for treatment of malaria	Well tolerated, commonly used	WHO list of essential medicines
Mefloquine	MERS-CoV: 7.4 μ M [38] SARS-CoV: 15.6 μ M [38]		Approved for treatment of malaria Clinical trials for treatment of JCV infection: mixed results [64, 65]	Black box warning: potential neuropsychiatric side effects	WHO list of essential medicines
Cyclophilin inhibitors					
Cyclosporin A	MERS-CoV [67] SARS-CoV [68]	HCV [256]; WNV [257]; JEV [258] VSV [259]; HIV-1 [260]	Approved for immunosuppression during organ transplantation	Immunosuppression undesirable for infectious diseases	WHO list of essential medicines; non-immunosuppressive analogs are available [70–72]
Interferons					
IFN- α 2a	MERS-CoV: 160.8 U/mL [80]		Approved for treatment of hepatitis B and C	Well tolerated	

Table 3 continued

Drug class members	Activity against coronaviruses ^a	Activity against other viruses	Clinical status	Known safety issues	Comments
IFN- α 2b	MERS-CoV: 21.4 U/mL [80] SARS-CoV: 6500–4950 U/mL [75]		Approved for treatment of melanoma		
IFN- β 1a, 1b	MERS-CoV: 1.4 U/mL [80] SARS-CoV: 95–105 U/mL [75]		Approved for treatment of multiple sclerosis		
IFN- γ	MERS-CoV: 56.5 U/mL [80] SARS-CoV: 1700–2500 U/mL [115]		Approved for treatment of chronic granulomatous disease		
Kinase inhibitors					
Dabrafenib	MERS-CoV: 45% inhibition at 10 μ M [89]		Approved for treatment of cancers	Well tolerated	
Dasatinib	MERS-CoV: 5.5 μ M [38] SARS-CoV: 2.1 μ M [38]	In vitro: BKPvV [261]; EBOV [100]; HIV-1 [262]; DENV [263] In vivo: VACV: no activity in mice [264] DENV, CPXV, RSV, FLUAV [265]	Approved for treatment of cancers	Well tolerated	ABL1 inhibitor, CAD Immunosuppressive effects in vivo may preclude use as anti-infective
Everolimus	MERS-CoV: 56% inhibition at 10 μ M [89]		Approved immunosuppressant for cancer treatment and prevention of organ rejection; reduced incidence of HHV-5 in cardiac and renal transplant patients [266]	Well tolerated	mTOR inhibitor [267]
Imatinib mesylate	MERS-CoV: 17.7 μ M [38] SARS-CoV: 9.8 μ M [38]	In vitro: BKPvV [261]; HHV [268]; HCV [149]; MPXV, VACV, VARV [264] In vivo: VACV: 100% survival in mice [264] HSV-2 [269]	Approved for treatment of cancers	Well tolerated	ABL1 inhibitor
Miltefosine	MERS-CoV: 28% at 10 μ M [89]		Antimicrobial approved for treatment of leishmaniasis; investigational drug for treatment of amoeba infections	Well tolerated	Akt inhibitor WHO list of essential medicines

Table 3 continued

Drug class members	Activity against coronaviruses ^a	Activity against other viruses	Clinical status	Known safety issues	Comments
Nilotinib	MERS-CoV: 5.5 μ M [38] SARS-CoV: 2.1 μ M [38]				
Selumetinib sulfate	MERS-CoV: \geq 95% inhibition at 10 μ M [89]		In Phase II/III trials for cancer treatment	Well tolerated	MEK inhibitor
Sirolimus	MERS-CoV: 61% inhibition at 10 μ M [89]	HIV-1 [270]; HHV-5 [271]	Approved immunosuppressant in transplant; reduced viral replication in HIV- or HCV-positive transplant patients [272–274]	Well tolerated	mTOR inhibitor
Sorafenib	MERS-CoV: 93% inhibition at 10 μ M [89]	BKPyV [261]; HHV [275]; EV71 [276]; RVFV [277]	Approved for treatment of cancers	Well tolerated	
Trametinib	MERS-CoV: \geq 95% inhibition at 0.1 μ M [89]		Approved for treatment of cancers	Well tolerated	
Wortmannin	MERS-CoV: 40% inhibition at 10 μ M [89]	HSV-2 [269]; HIV-1 [278]	In development for treatment of cancer	Toxicity issues. Derivatives are in Phase I clinical trials	
Neurotransmitter inhibitors					
Astemizole	MERS-CoV: 4.9 μ M [38] SARS-CoV: 5.6 μ M [38]		Previously approved antihistamine	Withdrawn in 1999 because of rare arrhythmias	
Benztropine mesylate	MERS-CoV: 16.6 μ M [38] SARS-CoV: 21.6 μ M [38]	HCV [102], EBOV, MARV [100, 101, 104]	Approved anticholinergic for treatment of Parkinson's disease	Well tolerated	
Chlorphenoxamine	MERS-CoV: 12.7 μ M [38] SARS-CoV: 20.0 μ M [38]		Approved antihistamine and anticholinergic for treatment of Parkinson's Disease	Well tolerated	
Chlorpromazine hydrochloride	MERS-CoV: 4.9–9.5 μ M [36, 38] SARS-CoV: 8.8–13.0 μ M [36, 38]	EBOV [96]; JUNV [94]; SV40 [279]	Approved for treatment of schizophrenia	Well tolerated	CAD

^aAntiviral activity is expressed in terms of EC₅₀ unless otherwise noted

compounds significantly inhibited MERS-CoV and SARS-CoV with micromolar EC_{50} values and low cytotoxicity. Abl2 has been identified as critical for MERS-CoV and SARS-CoV virus entry, and may be the target that imatinib inhibits to block entry of both viruses [88]. A recent systems kinome analysis investigation of in vitro MERS-CoV infection suggested that ERK/MAPK and PI3 K/Akt/mTOR signaling pathways were specifically modulated during infection [89]. Subsequent analysis of licensed kinase inhibitors targeting these pathways demonstrated that kinase inhibitors targeting the ERK/MAPK signal pathway (selumetinib and trametinib) inhibited MERS-CoV infection by $\geq 95\%$ when added pre- or post-infection [89]. Further, trametinib demonstrated significantly stronger inhibitory activity against MERS-CoV than selumetinib suggesting that specific intermediates of the ERK/MAPK signaling pathway may represent crucial foci during early (viral entry) and late (viral replication) events in the viral life cycle. In contrast, sorafenib, an inhibitor of Raf-1 and B-Raf, components of the ERK/MAPK signaling pathway, and vascular endothelial growth factor receptor 2 (VEGFR2), inhibited MERS-CoV infection by $>90\%$ when added to cells prior to infection; however, the inhibitory activity was reduced to $<30\%$ when added post-infection suggesting Raf kinases were primarily involved in early viral life cycle events. In addition, the inhibitory activity dabrafenib, a Raf kinase inhibitor, was also largely ablated when added post-infection. Miltefosine, an alkyl phospholipid, considered to be an inhibitor of protein kinase B (Akt), garnered FDA approval for infectious disease-related treatments (cutaneous or mucosal leishmaniasis) [90]. In 2013, miltefosine became directly available from the US Centers for Diseases Control and Prevention for the treatment of free-living amoeba infections [91]. Pre-treatment of cells with miltefosine reduced MERS-CoV infection by 28%, but had no effect when added post-infection [89]. In contrast, inhibition of mTOR with sirolimus or everolimus reduced MERS-CoV infection by $\sim 60\%$ when added prior pre- or post-infection suggesting a critical role for mTOR in MERS-CoV infection. A recent clinical investigation by Wang et al. [92] evaluated sirolimus and corticosteroids in addition to standard antiviral treatment in a randomized controlled trial in patients with severe H1N1 pneumonia and acute respiratory failure [92]. Importantly, the addition of sirolimus was associated with improved patient outcomes including decreased hypoxia and multi-organ dysfunction, reduced mean times for liberation from mechanical ventilation, and increased clearance of virus. Thus, it may be prudent to extend the study of repurposed kinase inhibitors beyond stand-alone therapeutic investigations and also consider their potential as adjunctive therapies.

2.2.6 Neurotransmitter Inhibitors

Numerous neurotransmitter receptors inhibitors showed activity against MERS-CoV and SARS-CoV infection [38]. These drugs were initially developed as antipsychotics, antihistamines, and sedatives. Five neurotransmitter receptor antagonists belong to the chemical class of phenothiazines: chlorpromazine, trifluorpromazine, thiethylperazine, promethazine and fluphenazine. Phenothiazines were breakthrough medications developed in the 1950s for treating mental health patients and reduced episodes of bizarre behavior, hallucinations, and irrational thoughts [93]. Although phenothiazines primarily block dopamine receptors, they also have anticholinergic, antihistamine, and antiemetic effects.

The phenothiazines, chlorpromazine and trifluorpromazine, are approved antipsychotics. Chlorpromazine has been used off-label for short-term treatment of nausea and migraines. Trifluorpromazine is used to treat severe emesis, but the drug has more serious side effects than chlorpromazine including akathisia and tardive dyskinesia. The antiviral effect of chlorpromazine has been extensively studied, and the drug interferes with clathrin-mediated endocytosis, a process that many viruses exploit for host cell entry. Chlorpromazine inhibits entry of Junin virus [94], West Nile virus [95], EBOV [96], HCV [97], and Japanese encephalitis virus [98] suggesting broad-spectrum activity that could be exploited early during a novel virus outbreak. Chlorpromazine may have similar effects on coronaviruses as the drug effectively inhibits MERS-CoV, SARS-CoV, and human coronavirus 229E expressing green fluorescent protein [36, 38]. However, time-of-addition studies indicate that the inhibitory activity against MERS-CoV is retained whether added pre- or post-infection suggesting that there are additional effects to clathrin-mediated entry impairment [36].

Thiethylperazine is an approved antiemetic. Both chlorpromazine and thiethylperazine have been shown to inhibit alphaviruses, Semliki forest virus (SFV) and chikungunya virus (CHIKV) [45, 99]. As these drugs cross the brain-blood barrier, use of these drugs could be beneficial in the treatment of CHIKV, including common neurologic complications. Promethazine is an antihistamine used as a sedative in many countries under different brand names, but also acts as a weak anti-psychotic activity. Fluphenazine is a common antipsychotic used to treat chronic psychoses (primarily schizophrenia) and belongs to the WHO Model List of Essential Medicines. Promethazine and fluphenazine have shown in vitro activity against MERS-CoV and SARS-CoV and may have value as candidates for repurposing for coronaviral infections [38].

Benztrapine mesylate, an approved anticholinergic used to treat Parkinson's, had activity against MERS-CoV and

SARS-CoV [38]. Benztropine was also identified in other screens of clinically approved drugs for antiviral activities against HCV and EBOV [100–102]. Although the detailed mechanism of action is unknown, HCV studies indicate that benztropine inhibits at a virus entry step, while not interfering with viral genome replication, transcription or production of viral progeny or virus production of viral progeny [102]. It has been argued that a virus entry inhibitor may have value in decreasing the incidence of relapse in chronic HCV patients that receive liver transplants [102]. However, the peak plasma concentrations of benztropine may be too low to be effective for treating an acute infection [103]. Benztropine was also independently identified in two drug screens for EBOV antivirals [100, 101]. A recent report suggests that a step after virus attachment, but prior to viral/cell membrane fusion is targeted by benztropine [104].

Clomipramine, a tricyclic antidepressant, and thiothixene, a thioxanthene antipsychotic, have also been shown to inhibit MERS-CoV and SARS-CoV infection in vitro [38]. In addition, they were found to inhibit EVD VLP entry [101]. Both are approved clinically, and clomipramine belongs to the WHO Model List of Essential Medicines.

Several other neurotransmitter inhibitors, astemizole, promethazine, chlorphenoxamine, and fluspirilene, were active against MERS-CoV and SARS-CoV in cell culture, but we were not able to find reports on activity against other viruses [38]. Astemizole is an H1-histamine receptor antagonist for treating allergic rhinitis that was withdrawn from the market. Cardiac adverse events due to drug overdose have been reported, but are extremely rare [105]. Recently, astemizole has gained renewed interest as an anticancer and antimalarial drug [106, 107].

Chlorphenoxamine is an antihistamine and anticholinergic that is currently in preclinical trials for malaria. Fluspirilene is an approved antipsychotic for treatment of schizophrenia. It is a known autophagy inducer [108]. Autophagy is a cellular degradative pathway that viruses exploit for their propagation [109]. Modulators of autophagy may perturb MERS-CoV or SARS-CoV infection, and investigation of their broad-spectrum potential for the treatment of coronaviral infections would be interesting [110].

2.2.7 Nucleic Acid Synthesis Inhibitors

Several RNA/DNA synthesis inhibitors have broad-spectrum activity against viruses including SARS-CoV and MERS-CoV [38, 80, 111–114]. Inosine monophosphate dehydrogenase (IMPDH) inhibitors such as ribavirin, mycophenolic acid, and mizoribine inhibit an important step in de novo synthesis of nucleic acids although the potency of these drugs against viruses varies. Ribavirin has

been used in combination with IFN in the clinic for treatment of viral infections such as hepatitis C. Treatment regimens with ribavirin are well characterized and have been used in SARS and MERS patients with mixed results (see 2.1). Ribavirin weakly inhibits MERS-CoV in vitro, and conflicting data have been reported for the activity of ribavirin against SARS-CoV [80, 111, 115]. Many of the studies on ribavirin were performed in Vero cells that reportedly have a defect in ribonucleoside uptake, which could explain lack of activity for ribavirin in these cells [116]. Another coronavirus, mouse hepatitis virus (MHV), becomes sensitive to ribavirin when its exoribonuclease activity is inactivated. In presence of exoribonuclease, ribavirin does not inhibit MHV replication [117]. The MHV exoribonuclease has been suggested to function as a ‘proofreading’ viral enzyme that is necessary for high-fidelity replication of MHV. Similarly, the exoribonuclease activity of MERS-CoV and SARS-CoV could possibly counteract inhibitory activity of ribavirin.

Mycophenolic acid (MPA), an immunosuppressant used to prevent organ rejection, has broad-spectrum antiviral activities, and antifungal, antibacterial, anticancer, and antipsoriatic properties [45, 118, 119]. Although MPA has weak inhibitory activity against SARS-CoV in vitro, it has promising activity against MERS-CoV [80, 112]. A potential alternative to MPA, the prodrug mycophenolate mofetil, has improved oral bioavailability [120]. Mycophenolate mofetil evaluated in the common marmoset model of MERS did not reduce disease manifestations compared to that observed in control subjects [121]. However, the MERS marmoset model does not recapitulate human disease due to its rapid onset and pathology associated with exposure methods [122]. Mizoribine, an approved immunosuppressant in organ transplantation with limited adverse side effects, has shown in vitro activity against HCV and bovine viral diarrhoea virus (BVDV), and was considered as an alternative to ribavirin/IFN combinations for treatment of HCV infections [123]. In vivo analysis of ribavirin and other IMPDH inhibitors in SARS-CoV-infected mice have suggested that these agents would be of limited benefit [111].

The chemotherapeutic gemcitabine, has shown in vitro activity against MERS-CoV and SARS-CoV [38]. The drug’s anti-cancer mechanism is attributed to its ability to inhibit ribonucleotide reductase essential for de novo pyrimidine biosynthesis. Gemcitabine has been shown to suppress influenza virus RNA transcription and replication by targeting ribonucleotide reductase and showed anti-retroviral activity in vivo in the mouse model for murine leukemia virus [124, 125].

2.2.8 Protease Inhibitors

MERS-CoV and SARS-CoV require activation of their envelope glycoproteins by host proteases for cell entry by the endosomal or the non-endosomal pathways. Inhibitors of host cell proteases are being investigated as possible antivirals [126]. The serine protease TMPRSS2 mediates entry via the non-endosomal pathway for both MERS-CoV and SARS-CoV [50, 127–129]. Camostat mesylate, which has been used in the treatment of chronic pancreatitis, inhibits TMPRSS2-mediated glycoprotein activation of MERS-CoV, SARS-CoV, and influenza virus [126, 130–132]. K11777, a cysteine protease inhibitor, is in clinical development for treating parasitic infections. K11777 has broad-spectrum activity against coronaviruses (MERS-CoV, SARS-CoV, HCoV-229E), filoviruses (EBOV, Marburg virus), and paramyxoviruses (Nipah virus) [133]. Interestingly, Zhou et al. [133] demonstrated that Camostat and K11777 had inhibitory activity against SARS-CoV whereas EBOV was only inhibited by K11777, suggesting differential host protease requirements for these viruses [133]. E-64-D, an inhibitor of an endosomal cysteine protease currently in Phase III trials for the treatment of muscular dystrophy, inhibits both MERS-CoV and SARS-CoV in vitro [38]. E-64-D also inhibits filovirus cell entry [134, 135]. The dependency of viruses for specific serine or cysteine host proteases must be considered in the selection of protease inhibitors for antiviral therapeutic applications. Therefore, an increased understanding of the relationship between host proteases and viral pathogenesis will determine the most effective treatment options for viral infections.

Lopinavir was identified as an inhibitor of MERS-CoV and SARS-CoV in vitro, and time-of-addition experiments indicate that the drug acts at an early stage of viral entry [36]. Lopinavir, an inhibitor of the HIV protease, is used clinically for the treatment of HIV infections [136]. It is given in combination with ritonavir, an inhibitor of cytochrome P450 3A4, to increase blood concentrations because of the low bioavailability of lopinavir [136]. Lopinavir also inhibits human papilloma virus and is currently under development for the topical treatment of cervical cancer [137]. Treatment with lopinavir/ritonavir resulted in reduced mortality in a NHP model of MERS [121]. Lopinavir has been shown to target the main protease (M^{pro}) of SARS-CoV [138]. However, lopinavir has also been shown to act on other intracellular processes that are involved in coronavirus replication. Additional studies are needed to fully understand the mechanism of action of lopinavir involving cellular proteases. During the 2003 SARS outbreak, patients in open clinical trials were treated with lopinavir/ritonavir in combination with ribavirin had a

milder disease course and reduction in fatality rate compared to that observed with historical controls [27, 28].

2.2.9 Protein Synthesis Inhibitors

Three protein synthesis inhibitors with activity against coronaviruses were identified, emetine, anisomycin and omacetaxine mepesuccinate [38, 139]. Emetine, a natural plant alkaloid, and anisomycin, an antibiotic, both inhibit protein elongation and were identified as anti-protozoals [140, 141]. While emetine is approved for amoebiasis treatment, anisomycin did not move beyond clinical trials [141, 142]. Dehydroemetine, a synthetic emetine derivative, has fewer side effects and is available as an investigational new drug [143, 144]. Anisomycin was originally discovered as a peptidyl transferase inhibitor, but also activates the MAP kinase signaling pathway [145]. In addition to activity against MERS-CoV and SARS-CoV, emetine and anisomycin inhibit the animal picornavirus encephalomyocarditis virus [146]. Anisomycin has in vitro activity against poliovirus [147]. Omacetaxine mepesuccinate, a plant-derived alkaloid, is an anticancer therapeutic that received FDA approval in 2012 for the treatment of chronic myeloid leukemia. Omacetaxine inhibits MERS-CoV, bovine coronavirus, human enteric coronavirus and hepatitis B virus [139, 148]. In spite of omacetaxine broad spectrum anti-coronavirus activity, the drug had no activity against SARS-CoV [38]. Drugs that inhibit coronaviruses by targeting protein synthesis may have potential in the development of combination therapies with drugs that target other antiviral pathways.

2.2.10 Selective Estrogen Receptor Modulators

Recent investigations have demonstrated the potential of estrogen receptor (ER) antagonists for repurposing as anti-coronavirus compounds [38]. For example, toremifene citrate and tamoxifen citrate with activity against SARS-CoV and MERS-CoV were developed and approved as anticancer therapeutics. Both drugs have shown activity against HCV replication in vitro [149, 150]. Mechanistic studies revealed that the ER is functionally associated with HCV replication [150]. ER promotes the interaction between the HCV replication complex and the HCV polymerase NS5B. ER-mediated regulation of HCV genome replication is abrogated by tamoxifen.

Toremifene and tamoxifen also effectively inhibit EBOV infection in vitro [151]. However, in contrast to HCV, mechanistic studies have shown that toremifene-mediated EBOV inhibition is independent of the ER pathway as toremifene was still active against EBOV in cells that did not express ER [151, 152]. Toremifene acts at a late step of virus entry after internalization of EBOV and

may prevent fusion between the viral and endosomal membranes [151–153]. Based on the chemical structure, toremifene is a cationic amphiphilic drug (CAD) that is known to be lysosomotropic and could affect endosomal processes during virus entry [151, 154]. Treatment with toremifene led to 50% survival of EBOV-infected mice confirming that this drug has an effect in vivo as well [151].

In terms of clinical application, toremifene and tamoxifen have good bioavailability, safety and tolerability profiles combined with a long history of use in the clinic. However, prolongation of the QT interval has been noted for toremifene and should not be prescribed to patients with congenital or acquired long QT syndrome, uncorrected hypokalemia or uncorrected hypomagnesemia [155]. Tamoxifen can increase uterine malignancies, stroke and pulmonary embolism in women with ductal carcinoma in situ or at high risk for breast cancer [156]. Despite these side effects, the drugs may have substantial value for short-term treatment of acute coronavirus infections. Advanced patient studies and careful evaluation of the pharmacokinetic profiles may facilitate dosing strategies that limit the risk of adverse events.

2.2.11 Sterol Metabolism Inhibitors

Two sterol synthesis inhibitors, terconazole and triparanol, have shown activity against MERS-CoV and SARS-CoV [38]. Studies with virus-like particles (VLPs) have demonstrated that terconazole inhibits coronavirus cell entry, including MERS-CoV and SARS-CoV. The sterol synthesis pathway has been shown to be required for infection by several viruses including HCV [157, 158]. Terconazole, approved for vaginal yeast infections, can be administered orally, topically or by suppository. Triparanol was approved for lowering plasma cholesterol, but was withdrawn due to numerous side effects. Both are CADs that induce accumulation of cholesterol in late endosomes and have been shown to inhibit EBOV entry [152].

2.3 Drugs in Development

2.3.1 Potential Targets for Inhibition of MERS-CoV and SARS-CoV

In addition to drug repurposing, development of novel antiviral countermeasures is needed for emerging coronaviruses. To this end, design or development strategies have targeted the viral replication cycle and host pathways essential for viral replication (Table 4). Two nucleoside inhibitors of viral RNA-dependent RNA polymerases, GS-5734 and BCX4430, have potential as broad-spectrum

antivirals [159, 160]. Both drugs are active against MERS-CoV and SARS-CoV in cell culture, but in vivo efficacy remains to be investigated. In addition, a new class of nucleosides with a flexible purine base has anti-coronaviral activity, and further optimization could generate potent inhibitors of the coronaviral polymerase [161]. The surface glycoprotein (S) of SARS-CoV and MERS-CoV and other coronaviruses consists of two domains: S1, containing the receptor-binding domain (RBD) needed for extracellular binding; and S2, containing the fusion peptide needed for membrane fusion and release. Endocytosis of SARS-CoV is facilitated by the binding of RBD with the angiotensin converting enzyme 2 (ACE2) receptor on host cells. Membrane-bound cathepsin L cleaves the S protein revealing the S2 fusion protein, which fuses with the membrane and releases the viral RNA. Inhibitors of cathepsin L, the ACE2–SARS–S1 complex, or the S2 fusion peptide could be suitable targets to inhibit SARS-CoV entry [162]. Results from recent studies have identified inhibitors of viral entry, viral proteases, and helicases that potently inhibit both MERS-CoV and SARS-CoV [162]. Proteases, such as papain-like protease and 3C-like protease, could also be useful as antiviral targets for drug development as they are required for cleaving non-structural proteins for viral maturation. Most protease inhibitors are “suicide” protease inhibitors that bind to the target irreversibly. However, reversible protease inhibitors may have greater potential as they are less toxic and better tolerated [113]. Recent studies with helicase inhibitors show that three domain targets, N-terminal metal binding domain, a hinge domain, and a NTP/helicase domain, have potential for the development of new drugs [163].

2.3.2 RNA Interference

Directed RNA interference (RNAi) presents a powerful approach for the development of novel virus-specific therapeutics based on gene silencing [164]. Recent studies have shown that small interfering RNAs (siRNAs) or short hairpin RNAs can inhibit expression of viral genes and thereby block the replication of SARS-CoV in cultured cells [165–172]. Intranasal delivery of a combination of small interfering RNA (siSC2-5) targeting SARS-CoV open reading frame 1 and S protein decreased SARS pathogenesis in NHPs [173]. Potential RNAi candidates identified through computational modeling for MERS-CoV require further in vitro and preclinical investigation [174]. Several RNAi therapeutics for the treatment of viral infections have entered clinical trials including TKM-Ebola, a siRNA/lipid nanoparticle platform targeting EBOV [164, 175, 176]. This technology has great potential for therapeutics for emerging viruses as viral genome

Table 4 Drugs in development for the treatment of Middle East respiratory syndrome (MERS) or severe acute respiratory syndrome (SARS)

Viral/cellular target	Drug class	Drug
MERS-CoV		
3C-like protease	Benzotriazole esters	CE-5 [284]
Papain-like protease	Thiopurines	6-Thioguanine, 6-mercaptopurine [113]
Helicase	Triazole	SSYA10-001 [162]
RNA-dependent RNA polymerase	Nucleotide prodrug	GS-5734 [159]
RNA-dependent RNA polymerase	Nucleoside analog	BCX4430 [160]
Membrane-bound RNA synthesis	Small molecule inhibitor	K22 [285]
Furin inhibitor	Small molecule inhibitor	Decanoyl-RVCR [286]
SARS-CoV		
3C-like protease	Benzotriazole esters	CE-5 [284]
3C-like protease	Anilides	Peptide nitroanilides [287]
3C-like protease	C ₂ -symmetric inhibitors containing diol cores	TL-3 [288]
3C-like protease	Pyrazole analogs	Pyrazolones [289]
3C-like protease	Serine inhibitor	Trifluoromethyl ketones [290]
3C-like protease	Serotonin receptor antagonist	Cinanserin [291]
3C-like protease	Zinc-conjugated inhibitor	JMF 1586 [292]
Papain-like protease	Thiopurines	6-Thioguanine, 6-mercaptopurine [113]
Helicase	Triazole	SSYA10-001 [162]
Helicase	Bananin derivatives	Vanillinbananin, Idobananin [163]
NTPase/Helicase	Aryl diketoacids Dihydroxychromone and hydroxychromone derivatives	ADK analogs [293]; 2-(3-iodobenzyloxy)-6-(3-chlorobenzyloxy)-5-hydroxychromone [294]
RNA-dependent RNA polymerase	Nucleoside analogs	BCX4430 [160], 4-aza-7,9-dideazaadenosine C-nucleosides [295], fleximer nucleoside analogs [161]
Cathepsin L cellular protease	Small molecule inhibitor	Oxocarbamate [296], SSAA09E1 [297]
ACE2–SARS–S1 complex	Small molecule inhibitor	SSAA09E2 [297]
S2-cell membrane fusion	Small molecule inhibitor	SSAA09E3 [297]
ACE2–SARS–S1 complex	Small molecule inhibitor	NAAE [298]

ACE2 angiotensin converting enzyme, *MERS-CoV* Middle East respiratory syndrome coronavirus, *S1* spike protein 1 domain, *S2* Spike protein 2 domain

sequencing can now be completed in a very short time frame that is crucial in situations when an epidemic of a novel emerging viral infection unfolds. The main obstacle for RNAi strategies lies in the identification of suitable viral targets and in the delivery efficiency of nucleic acids to target cells in vivo.

2.3.3 Peptide Entry Inhibitors

Peptides share common physicochemical properties with CADs that facilitate interaction with cell membranes and interference with the fusion of cellular and viral membranes during virus entry. Researchers are making progress

in defining the mechanism of action of peptide entry inhibitors of enveloped viruses such as enfuvirtide, an approved HIV inhibitor [177]. Enfuvirtide is a 36-residue peptide derived from the amphipathic loop/C-helix heptad repeat domain of HIV gp41. A rational approach based on scanning fusion protein sequences for amphipathic sequences has led to the discovery of additional peptide inhibitors for other viruses including MERS-CoV and SARS-CoV [178–180]. Chemical modifications of peptides have increased their in vivo stability and bioavailability, improving their potential for clinical applications as novel broad-spectrum viral entry inhibitors [181–183].

2.4 Antibody Therapy

The success of palivizumab for treatment of respiratory syncytial virus infection has reinvigorated efforts to develop monoclonal antibody-based therapeutics for infectious diseases [184]. ZMapp, a monoclonal antibody cocktail targeting EBOV, has been tested in NHPs with success and was moved to Phase I and II clinical trials in humans during the EVD epidemic [185, 186]. Similarly, a monoclonal antibody against Hendra virus has been administered to humans on a “compassionate use” basis [187–189]. These examples demonstrate the potential for antibody therapy to combat emerging/re-emerging viruses, and similar strategies have been pursued by multiple groups for development of antibodies to MERS-CoV [190–197]. Monoclonal antibodies to MERS-CoV have been sourced from humanized mice libraries or human antibody libraries [192, 194, 197, 198]. Antibodies target the S RBD, S1, or S2 subunits, and have demonstrated efficacy in animal models as reviewed in Ying et al. [199]. Monoclonal antibody therapy can impart a selective pressure for generation of resistant viruses. Although mutants escaping monoclonal antibody pressure tend to be less fit, analysis of the emergence of mutations that confer resistance to the monoclonal antibody will need to be performed.

An alternative to monoclonal antibody therapy is polyclonal antibody therapy using convalescent sera (sera sourced from a nonhuman or humanized animal). Polyclonal antibodies provide an advantage over monoclonal antibodies in that escape mutants are less likely to emerge [200, 201]. Convalescent sera have been recommended for MERS, and a Phase II interventional clinical trial is ongoing to determine efficacy [198]. However, the availability of a suitable donor subject presents a significant complication for this approach. Nonhuman animal sera has been considered, but safety concerns limit this option. Fractionation of nonhuman sera is an alternative; however, antibody-mediated clearance can be limited due to failure of the human Fc receptors to recognize the antibody heavy chain.

An alternative is de-speciating the antibodies by using only the Fab antibody fragment; however, cost and sufficient material may make mass production of Fab fragments difficult. The use of sera from humanized mice or other small laboratory animals is complicated by sample acquisition/volume restraints. Larger laboratory animals may provide a potential alternative. SAB Biotherapeutics has developed a trans-chromosomal bovine platform for the generation of human IgG antibodies [201]. Vaccination of trans-chromosomal cattle with S protein nanoparticles or inactivated, whole virus generated fully humanized

polyclonal antibodies that demonstrated efficacy in the Ad-DPP4 murine model of MERS.

3 Lessons Learned

One of the most important lessons regarding antiviral drug development is that both highly specific and broad-spectrum antivirals bring unique advantages to the table. Antiviral agents can fall anywhere in the spectrum between “broad-spectrum” and “highly specific” [202]. A drug that targets a specific virus or virus family will have narrow activity, high potency, and low toxicity; however, such a drug may also promote resistance [202]. In contrast, broad-spectrum antivirals typically target a host factor or pathway, and often these agents have higher toxicities, lower potencies, and delayed treatment effects. However, the selective pressure for resistance is often lower with broad-spectrum agents.

A large part of our knowledge on antiviral development stems from the studies of chronic viral infections. Antiviral development strategies for DNA viruses have been successful in identifying a single drug that specifically targets a viral protein. This strategy has been less successful for RNA viruses. RNA viruses mutate at a higher rate than DNA viruses resulting in enhanced development of drug resistance.

3.1 AIDS

Despite extensive efforts over the past 30 years, a therapeutic or prophylactic HIV vaccine has remained elusive. Antiviral agents are the only available treatments for AIDS. Over 25 antivirals belonging to 6 different drug classes targeting different stages of viral replication are available (e.g. reverse transcriptase, protease, fusion, entry, integrase) [203]. Combination treatments with 2 to 3 drugs are effective and result in a sustained virologic response [204]. Two aspects have been found to be important for avoiding resistance: (1) selecting drugs with at least two different targets, and (2) selecting drugs that belong to different chemical classes. These considerations may also apply for drug combinations with synergistic effects against MERS- and SARS-CoV.

3.2 Hepatitis C

Broad-spectrum antiviral therapies can be of great value for treating emerging infections when it takes time to develop direct-acting antivirals. For treatment of chronic hepatitis C, clinicians have depended on IFN and ribavirin for a number of years [205]. Eventually, IFN and ribavirin combination was replaced by very effective fixed-

combination therapies using direct-acting antivirals that target multiple steps of the HCV life cycle [206]. IFN and ribavirin contribute significantly to the treatment of viral infections for which no direct-acting antivirals exist. However, they have major side effects [207]. More options for broad-spectrum antivirals with improved safety profiles would be beneficial for use for emerging coronavirus infections.

3.3 Influenza

Influenza viruses are characterized by a high mutation rate of the RNA genome. As available vaccines may not be protective against a novel pandemic strain, antiviral agents are considered an essential component for preparedness. Combinations of direct-acting antivirals are under evaluation for additive or synergistic effects and prevention of resistance [208, 209]. One triple combination (oseltamivir, amantadine and ribavirin) is synergistic and prevents resistance in vivo [210, 211], highlighting the potential of combinatorial therapy.

3.4 Ebola Virus Disease

The recent epidemic of EVD in Western Africa has renewed the urgency for development of treatments against emerging viruses. Although vaccines and direct-acting antiviral treatment are under investigation, none are approved for clinical use [212–216]. The WHO prioritized a panel of drugs approved for other indications that were considered for repurposing under FDA's Emergency Use Authorization [62]. Two of these drugs also have activity against MERS-CoV and SARS-CoV, amodiaquine (antimalarial agent) and toremifene citrate (breast cancer treatment).

Additional broad-spectrum antiviral agents (including repurposed drugs) should be a top priority for future emerging infections including coronavirus infections. A panel of broad-spectrum drugs that have been carefully validated for efficacy and safety and that could be used in combination would supply a minimum of protection for patients and healthcare workers at outbreak locations. This panel of drugs could be used in situations of a known re-emerging pathogen for which specific antiviral agents and vaccines has not been approved or of an unknown novel pathogen that could arise.

4 Gaps in Knowledge and Future Outlook

4.1 Animal Models of MERS and SARS

Effective development of countermeasures depends on developing appropriate animal models that uniformly

recapitulate human disease progression and severity of pathological manifestations. As with most animal models of human disease, no one animal model fully reflects SARS or MERS, therefore researchers are faced with exploring several small animal models or choosing the “best-fit” model. To date, animal models do not fully recapitulate human disease, thus animal models of MERS and SARS need further refinement. Many small animal models have been evaluated as potential MERS and SARS models including mice, hamsters, and ferrets for MERS and Syrian hamsters, and guinea pigs for SARS [217–219]. Four murine models have been reported for MERS. The first model that demonstrated promise involved transduction of the respiratory tract with the putative MERS-CoV receptor, human DPP4 (or CD26) [220]. The major indicator of disease in this model is viral load in the lung at 4 days post-inoculation. Although clinical signs of disease, including weight loss, were limited in this model, it has been used for pathogenesis countermeasure studies [221, 222]. Lethal, disseminated MERS infection has been demonstrated in transgenic mice expressing human DPP4 [223]. Inflammatory processes were observed in the brains of these mice in contrast to human disease in which CNS involvement has not been reported. A transgenic mouse MERS model was developed in which the mouse DPP4 gene was replaced by the human DPP4 gene under control of the endogenous mouse DPP4 promoter. Using this model, MERS-CoV-infected mice developed lung pathology [194]. In addition, administration of human monoclonal antibodies against the spike protein in these transgenic mice provided protection against MERS-CoV infection [194]. Clustered regularly interspaced short palindromic repeat-CRISPR-associated protein 9 (CRISPR-CAS9) gene editing technology was used to modify the mouse DPP4 to match human DPP4 by altering amino acids at positions 288 and 330. Interestingly, wild type virus infection of these mice did not result in an improved model of MERS. However, serial passage of MERS-CoV resulted in MERS-CoV-15. Intranasal exposure of MERS-CoV-15 in 288/330, mice led to weight loss and a severe respiratory disease that included ARDS-like signs and reduced pulmonary function [224].

MERS-CoV infection of rabbits has also been evaluated as a model for MERS. Haagmans et al. [225] demonstrated that MERS-CoV infected rabbits did not develop obvious clinical signs, but infectious virus could be detected in the upper respiratory tract [225]. Furthermore, epithelial cells of the bronchioles and terminal bronchioles respiratory tract were positive for MERS-CoV by immunohistochemistry and in-situ hybridization, which reflects tissue tropism in human disease [225]. Using the rabbit model, Houser et al. [191] demonstrated that human monoclonal antibody 336 given pre-exposure reduced viral RNA lung titer at

3 days post-exposure, but not when given post-exposure [191].

Due to phylogenetic similarities with humans, NHP models of disease have long been considered as necessary for evaluation of countermeasures to infectious diseases. Rhesus monkey and common marmoset have been evaluated as potential models for MERS. Following intratracheal instillation of MERS-CoV in rhesus monkey models, lung pathology was observed [122, 226–228]. Experiments using rhesus monkeys have indicated that they develop limited systemic disease and a transient respiratory disease. Radiologic evaluations have indicated inflammatory infiltrates that develop shortly after exposure. Analysis of lung tissues by reverse transcriptase-quantitative polymerase chain reaction indicated virus replication in the lung.

Similar to MERS, African green monkeys (AGMs), rhesus monkeys, cynomolgus monkeys, and common marmosets have been identified as potential models for SARS [229]. Smits et al. [230] compared SARS CoV infection in young AGMs to cynomolgus monkeys, they observed that neither species developed clinical signs during a 4-day experiment [230]. Gross pathology indicated multi-focal pulmonary consolidation with consolidated grey-red firm lungs. These lesions affected 30% of the lungs in one subject. By comparison, the cynomolgus monkeys developed small patchy macroscopic lesions. Similar to MERS-CoV infection of NHPs, viral load decreases from exposure day to day 4. A comparison between AGMs, rhesus monkeys, and cynomolgus monkeys further support AGMs as the best available NHP model for SARS [231]. AGMs developed the highest viral load and most disease when compared to cynomolgus and rhesus monkeys. Lethal disease was not observed in any of these species; therefore, further development of the SARS model is warranted since lethal respiratory tract disease was the hallmark of SARS.

As an alternative to Old World NHPs, many groups have employed marmosets as models of human infectious disease [232–234]. Common marmosets have been evaluated as a MERS model [121, 122, 235]. These studies have demonstrated that common marmosets develop disease following exposure to MERS-CoV as shown by histopathological analysis, radiological analysis, and RT-qPCR. However, variable results have been reported, and exposure methodology can impact disease progression. Therefore, mock-infected groups must be included to account for pathological artifacts. The virus-specific pathology could be quantified using computed tomography, and future experiments using large group sizes could be used for countermeasure evaluation. Greenough et al. [236] performed a serial euthanasia study of SARS-CoV infected marmosets [236]. Subjects were intratracheally exposed with SARS-CoV. They observed mild inconsistent clinical

signs of disease. Viral loads peaked at day 4 post-infection. Histopathology indicated interstitial pneumonitis with multinucleated syncytia that were described as mild and not observed in all late time-point subjects. Overall, further research is needed to develop animal models of SARS that reflect human disease presentation.

4.2 Combinations with Synergy

Drugs with repurposing potential discussed here (Table 3) have the advantage of easy access, availability and decreased cost of development and provide a wide array of options for combination studies. The pharmacological knowledge available for such compounds may also reduce concerns regarding adverse effects in patients. The generation of a translational database encompassing pharmacodynamics data and infectious disease biology data has been proposed and would greatly facilitate decision making to pursue new drug combinations [237]. Many of the drugs have potential for broad-spectrum antiviral activity and have already been in clinical use for treating other viral infections. As novel drugs in development move from the pre-clinical to clinical phase, they also become available for combination therapy. Care should be taken with the pharmacological evaluation of each combination to avoid possible contraindications of the drugs with regards to disease or adverse effects. Novel broad-spectrum replication inhibitors, such as GS-5734 (Gilead Sciences, in Phase I clinical trial), immunomodulators (nitazoxanide; steroids; statins) along with direct-acting antiviral agents for coronaviruses that are in development represent interesting partners for combinations. Combinations can involve broad-spectrum versus specific antiviral agents; drugs with different mechanism of action; or drugs that target different steps of the viral life cycle. Identifying one or more potent combinations with activity in an animal model would greatly increase preparedness for the next coronavirus outbreak.

4.3 Structure-Based Drug Design

Elucidation of the crystal structure of viral proteins has led to novel approaches for rational drug design. Rational design investigations using protein structure information and *in silico* screening for affinity to active sites of viral proteins holds promise. HIV-1 protease inhibitors have been one of the big successes of rational drug design. Only 6 years after the publication of the HIV-1 protease structure, saquinavir was developed in record time from bench to bedside and was licensed for use against AIDS in 1995 [238–240]. In total, six antivirals against the HIV-1 protease were designed and approved between 1995 and 2000. Similarly, for HCV, computer-aided approaches based on

the known crystal structure of a viral protein have successfully guided the design and synthesis of inhibitors for the HCV NS3/NS4A proteases such as the peptidomimetics, telaprevir and boceprevir [241–243].

Due to the power of computational modeling using crystal structures from known coronaviruses, the crystal structures for the viral proteases, M^{pro} and PL^{pro}, of SARS-CoV and MERS-CoV were determined relatively quickly [244]. These structures have already been used for the discovery of inhibitors with high binding affinity to the active site of the proteases. The structures of additional MERS-CoV or SARS-CoV viral proteins have yet to be determined and would offer additional viral targets for drug discovery.

Structural design can help with development of inhibitors in preparing for future outbreaks of yet unknown emerging coronaviruses. Based on the potential of zoonotic transmission of coronaviruses from bats to humans, crystal structures for the main protease (M^{pro}) of different bat coronavirus families have been proposed for screening and identifying broad-spectrum antiviral agents [244]. Proof-of-principle was shown for the novel protease inhibitor SG85, which inhibits the bat coronavirus HKU4 [244]. In 2012, SG85 was quickly identified as an inhibitor of MERS-CoV through *in silico* docking studies with the M^{pro} of MERS-CoV and the bat coronavirus HKU4.

4.4 Cationic Amphiphilic Drugs: A Novel Class of Antiviral Agents?

Several drugs (e.g. toremifene citrate, terconazole, Fig. 3) belong to a group of compounds termed cationic amphiphilic drugs (CADs) [100, 151, 152, 154, 245]. Phenothiazines (e.g. fluphenazine chlorpromazine, Fig. 3) are CADs that have been shown to inhibit HCV entry at virus-host cell fusion by intercalating into the cholesterol-rich domains of the host cell membrane and increasing membrane fluidity [97]. Drugs that act through this mechanism may present an interesting new class of broad-spectrum antivirals. CADs are known to be lysomotropic and accumulate in acidic compartments where their tertiary amine groups are protonated. The compounds act as mild bases and can neutralize the low pH of the acidic environment of endo/lysosomes. CADs can intercalate into membranes, alter the biophysical properties of membranes and thereby could potentially interfere with fusion of virus with the endo/lysosomal membrane. The concept of interfering with virus entry and budding through physicochemical properties of drugs is intriguing. Many viruses would be susceptible to this type of inhibition and CADs could be used as broad-spectrum antiviral agents. Detailed structure-activity

relationship studies on CADs will be required to determine the chemical core structures and physicochemical properties important for this type of antiviral agent. Future investigations regarding the conservation of this mechanism of action to coronaviruses, as well as other emerging viruses, are warranted.

4.5 Analogs of Developed Drugs

Approved drugs with activity against MERS-CoV or SARS-CoV could be used as lead compounds for further antiviral drug development. Pharmaceuticals usually have undergone multiple rounds of structure-activity relationship studies generating analogs to improve drug activity against the original indication or target. The analogs of drugs with activity against MERS-CoV and SARS-CoV may still be available and could be screened to identify other analogs with increased antiviral activity. Although drug analogs would have to go through the full licensure process, there would be little to no added initial cost associated with producing the structure-activity relationship compounds. Recycling old analogs is one approach that may have value for developing novel drugs for viral infections.

5 Conclusion

A more streamlined process is needed for development of effective treatment measures for emerging and re-emerging pathogens. The availability of a panel of approved broad-spectrum drugs would clearly be beneficial as they could be used for treating disease symptoms and reducing morbidity until more specific acting antivirals and vaccines are developed.

A large number of potential drugs and therapeutics for the treatment of MERS and SARS have been discussed. The greatest challenge will be how best to down-select and evaluate the different approaches. As we have learned from drug development for AIDS and hepatitis, alleviating disease symptoms and increasing life span may be a more achievable goal rather than looking for a treatment that will provide complete recovery. Broad-spectrum antivirals, specific antivirals, and immune modulators each have an important role in treating viral infections either individually or in combination. Effective communication between the different institute partners (government, industry, academic; national, and international partners) is essential. Combining these drug discovery efforts will increase the chance of having one or more potential therapeutic agents at an advanced development stage by the time another outbreak of an emerging coronavirus occurs.

ABSTRACT: Outbreaks associated with emerging and re-emerging viral pathogens continue to increase in frequency and are associated with an increasing burden to global health. In light of this, there is a need to integrate basic and clinical research for investigating the connections between molecular and clinical pathogenesis and for therapeutic development strategies. Here, we will discuss this approach with a focus on the emerging viral pathogens Middle East respiratory syndrome coronavirus (MERS-CoV), Ebola virus (EBOV), and monkeypox virus (MPXV) from the context of clinical presentation, immunological and molecular features of the diseases, and OMICS-based analyses of pathogenesis. Furthermore, we will highlight the role of global investigations of host kinases, the kinome, for investigating emerging and re-emerging viral pathogens from the context of characterizing cellular responses and identifying novel therapeutic targets. Lastly, we will address how increased integration of clinical and basic research will assist treatment and prevention efforts for emerging pathogens.

KEYWORDS: emerging pathogens, kinomics, cell signaling, virology, kinases, high-consequence pathogens

Emerging and re-emerging viruses pose a significant threat to public health and global economies. Moreover, outbreaks caused by emerging and re-emerging viruses continue to increase in frequency as a result of changing socio-economic, environmental, and ecological factors.¹ Notably, the zoonotic viral pathogens, severe acute respiratory syndrome coronavirus (SARS-CoV), Middle East respiratory syndrome coronavirus (MERS-CoV), Ebola virus, chikungunya virus, and Zika virus, have emerged on a global scale in recent years; although less widely publicized, other emerging viral pathogens such as monkeypox virus and Andes virus have led to smaller recurrent outbreaks. A critical challenge for combating these outbreaks is often the discordant relationship between the economic status of outbreak “hotspots” and resource distribution or control capacity within these regions. In addition, the development and delivery of therapeutics for combating such outbreaks have been complicated by both the associated costs in design and development for novel anti-infective therapeutics and the requirements for regulatory approval and licensure.² Importantly, emerging infectious diseases present the additional inherent challenge that they are only “emerging”, and thus limited resources are made available for research until they present a significant risk. For many emerging viral pathogens, the requirement for high-containment facilities has further impeded widespread research. From the perspective of drug development, the limited knowledge and understanding of molecular pathogenesis for these agents is a daunting challenge to overcome when outbreaks emerge.

In the face of an increasing burden of emerging and re-emerging pathogens, it is necessary to overcome the barriers imposed by a paucity of information regarding molecular pathogenesis for these agents. OMICS-based approaches present a mechanism to rapidly generate large amounts of data in regard to host responses and assist in target identification for drug development efforts. In addition, OMICS-based analyses allow for the characterization of molecular events that mitigate cellular responses to viral pathogens from a global perspective across multiple levels of cellular complexity (individual cell types < tissues < organs). High-throughput global analyses of host gene expression, including microarrays and RNA-Seq, provide important information regarding transcriptional responses during infection. Although these validated approaches are among the most widespread of the OMICS-based technologies for infectious disease investigations, they do not provide a direct measure of the activation status of the cell signaling pathways that regulate underlying cellular responses. In contrast, global investigations of cellular kinase activities (the kinome) are able to provide insight into the activation status of cell signaling networks (including those that mediate pathogen recognition and innate immune activation, cell cycle activities, metabolic status, wound healing and repair, and cell death) at the level of

individual kinase-mediated phosphorylation events. In addition, kinome investigations allow for potential identification of kinase drug targets. Kinases are currently one of the top targets for drug design and development, and there is potential for repurposing of kinase inhibitors with existing regulatory approval.

As emerging viral infections often result in severe illness including respiratory failure [severe acute respiratory syndrome (SARS), Middle East respiratory syndrome (MERS), and influenza] and multiorgan failure [Ebola virus disease (EVD)], understanding complex pathogenesis of these infections is required for effective vaccine and therapeutic design and for improved patient care. Healthcare providers caring for patients with severe emerging viral infections are generally focused on clinical care and biosafety as compared to the complex molecular events that underlie pathogenesis. In contrast, basic researchers typically focus on discrete aspects of pathogenesis through a variety of *in vitro* and *in vivo* analyses rather than the complex interplay between these events and the clinical, physiologic, and pathologic abnormalities observed by the clinician. Integrating basic and clinical research is needed to accelerate the translation of knowledge for emerging infections toward vaccine development and therapeutic discovery. Specifically, detailed natural history studies merging multiple data streams including OMICS approaches (high-throughput gene expression and kinomics) and focused translational investigations utilizing relevant models that can be validated

to human disease are needed to clarify disease pathogenesis, advance therapeutic discovery, and facilitate regulatory approval.

Although an integrated approach between basic and clinical research is ideal for investigating the connections between molecular and clinical pathogenesis, there has been a paucity of investigations for which this has been undertaken. Here, we will discuss emerging pathogens for which there is available information regarding the clinical course of disease, host immune responses during natural infection, and molecular information regarding the global cellular responses to infection, with particular attention on host kinome investigations. In this regard we will focus on the emerging viral pathogens MERS-CoV, Ebola virus (EBOV), and monkeypox virus (MPXV) (Figure 1). We will review the clinical presentation and immunological and molecular features of the diseases and summarize available OMICS data informing pathogenesis of these pathogens. Lastly, we will discuss the benefit of improved integration of available clinical knowledge or data regarding the pathologic manifestations of disease with basic research investigations to advance treatment and prevention of severe emerging viral infections.

■ INVESTIGATING MOLECULAR PATHOGENESIS THROUGH KINOME ANALYSIS

Global gene expression investigations have provided information regarding host response to emerging and re-emerging

Figure 2. Generation of kinome peptide array targets and kinome peptide arrays: (1) species-specific proteomic or genomic information from a diverse range of species can be used to identify kinase recognition motifs that are composed of a central phosphorylation target and the surrounding amino acids (normally +4 and −4 amino acids from the central phosphorylated residue); (2) peptides that comprise the kinase recognition motifs identified in (1) are synthesized and covalently linked to a glass surface. Peptide targets are spotted in replicates of three to nine spots on each array to account for intra-array variability. Individual amino acids of the peptides are represented by orange, red, purple, and green spheres.

Figure 3. Kinome analysis of biological samples. Biological samples for kinome analysis can encompass (1) complex biological tissues (lung), (2) focused tissue sections (bronchioles), or (3) individual cell types associated with a particular tissue (alveolar epithelial cells or alveolar macrophages). (4) Biological samples are processed to generate cell lysates that are activated with ATP and applied to the kinome peptide array. (5) Following the application of the cell lysate, activated kinases in the cell lysate will recognize their respective kinase recognition motifs and phosphorylate the central phosphorylated residue of the peptide. (6) Kinome peptide arrays are subsequently stained with a phospho-specific fluorescent stain and imaged followed by comparative bioinformatics analyses. Tissue and cell images were derived and/or modified from Servier Medical Arts under a Creative Commons Attribution 3.0 Unported License.

pathogens at the level of individual genes or gene clusters. However, there is a paucity of information regarding the relationship of cell signaling networks, and in particular their activation status, with the biological/pathological events that occur throughout infection.

It has been well established that many biological processes can be regulated independent of transcriptional or translational changes through post-translational modification (PTM) events. Indeed, kinase-mediated phosphorylation of proteins, in which kinases catalyze the transfer of the γ phosphate group from ATP to the hydroxyl group of a specific Ser, Thr, Tyr residue, is

among the most thoroughly characterized PTM. Virtually all cell signal transduction events are regulated by kinases independent of biological complexity of the host (i.e., prokaryotes and eukaryotes).³ Lending further credence to the biological importance of kinases, >500 kinases have been identified in the human genome, and ~30% of the human proteome is modulated by kinase-mediated phosphorylation events.^{4,5} Thus, considering the central role of kinases in a broad range of cellular processes (including growth and development, metabolism, and immune responses), it has been postulated that the activities of individual kinases may represent more reliable predictors of cellular phenotypes than transcriptional or translational changes.⁶ Indeed, transcriptional or translational-based OMICS approaches are often unable to account for regulatory events including gene silencing, mRNA stability, translational efficiencies, protein turnover, enzyme/substrate subcellular sequestration, or protein activation/repression PTMs.⁷ Given the central role of kinases in the regulation of biological processes, kinases are a logical drug target. As a testament to this, 33 kinase inhibitors have been granted licensure by the U.S. Food and Drug Administration (FDA) for a broad range of malignancies, and there are a continually increasing number of kinase inhibitors that are in various stages of preclinical trials. Furthermore, kinases are the second most frequently targeted gene class in cancer therapy after the G protein coupled receptors.^{8,9} The recent prioritization for the repurposing of approved therapeutics for alternative malignancies by the National Institutes of Health Center for Advancing Translational Sciences (NCATS)^{10,11} also provides considerable impetus for the investigation of licensed kinase inhibitors as infectious disease therapeutics. Concerns exist regarding the therapeutic application of kinase inhibitors as novel therapeutics for infectious disease, in particular to the potential immunosuppressive effects following prolonged treatment. However, it should be appreciated that the application of kinase inhibitors in such cases would need to be targeted in terms of timing and dose, with appropriate molecular biomarkers guiding initiation and cessation. It should also be appreciated that the clinical symptoms associated with many emerging and re-emerging pathogens have been associated with dysregulated host immune responses (in particular pro-inflammatory responses).

Thus, the global analysis of the activation state of host kinases (the kinome) can provide critical insight into the specific activation state of individual kinases, cell signaling pathways, or larger biological networks. In addition, kinome investigations may offer important, and predictive, insight into the cellular mechanisms that regulate phenotypic changes within cells.⁷ As many kinases recognize a particular phosphorylation motif composed of the central phosphoacceptor site and the amino acids +4 and -4 residues from the central phosphorylation site,¹² peptides representing this kinase target motif can be synthesized with relatively high efficiency and low expense. Indeed, kinase target motif peptides have been shown to be appropriate substrates for their respective kinases with V_{\max} and K_m values approaching those of the full-length protein.¹³ Thus, peptide kinome arrays can be constructed in an analogous manner to traditional DNA microarrays where kinase target motif peptides are spotted onto a glass slide representing hundreds to thousands of unique peptide targets for kinases (Figure 2). Following this, samples in the form of cellular lysates from whole organs, tissues, or individual cell types can be applied to the kinome peptide

arrays, allowing for the phosphorylation of specific peptide targets by kinases within the lysate (Figure 3). The development of kinome-specific bioinformatics analysis software, including the Platform for Intelligent, Integrated Kinome Analysis (PIIKA), has provided a mechanism to identify the complex patterns of kinase-mediated phosphorylation events and quantitate the differences between compared conditions.^{14,15}

■ INTEGRATING KINOMICS WITH CLINICAL AND MOLECULAR PATHOGENESIS INVESTIGATIONS FOR EMERGING AND RE-EMERGING PATHOGENS

Middle East Respiratory Syndrome Coronavirus (MERS-CoV). Human coronaviruses are the causative agents of an estimated 30% of upper and lower respiratory tract infections in humans resulting in rhinitis, pharyngitis, sinusitis, bronchiolitis, and pneumonia.^{16,17} Coronaviruses are members of the Coronavirinae subfamily of viruses and together with the Torovirinae subfamily comprise the Coronaviridae virus family (order Nidovirales). Multiple coronavirus family members, including OC43 and 229E, can be found across the globe and largely result in mild illness with more-severe illness limited to children and the elderly.^{18–20} Since the emergence of SARS in 2003 and MERS in 2012, there is increased interest in coronaviruses as global public health threats.

SARS-CoV was first identified in China before spreading to 37 countries resulting in more than 8000 confirmed cases and 775 deaths. No additional cases have been reported since 2004.²¹ In 2012, MERS emerged in Saudi Arabia as a severe respiratory disease with gastrointestinal and renal complications.²² MERS-CoV has subsequently spread to 26 countries (WHO), resulting in 1733 confirmed cases and 628 deaths as of June 2016 (<http://www.who.int/emergencies/mers-cov/en/>). MERS may have emerged from a bat reservoir, likely spilling into humans via dromedary intermediate hosts. Human-to-human spread occurs primarily within healthcare settings, often leading to severe disease. No licensed vaccines or targeted therapies are available.

Clinical Findings during MERS-CoV Infection. Syndromic case-definition for MERS infection requires a compatible clinical syndrome and an epidemiologic risk factor including travel to an affected region or contact with a known or suspected case. Initial symptoms of MERS-CoV infection include fever, chills, cough, shortness of breath, myalgia, and malaise following a mean incubation period of 5 days, which can range from 2 to 14 days.²³ Mildly symptomatic or possibly asymptomatic infections have been reported, and progression to severe disease is associated with pre-existing medical conditions including cardiopulmonary disease, obesity, and diabetes. Most (98%) of reported MERS cases are among adults, with a median age of 50 years. In severe cases respiratory failure requiring mechanical ventilation typically occurs within 7 days of symptom onset.²² Laboratory abnormalities include lymphopenia, leukopenia, thrombocytopenia, elevated serum creatinine levels consistent with acute kidney injury, and elevated liver enzymes.^{23–27} High lactate levels and consumptive coagulopathy have also been reported.^{24,28} Chest radiographic abnormalities are observed in most cases consistent with viral pneumonitis, secondary bacterial pneumonia, or acute respiratory distress syndrome.^{22–24,27,29}

Soluble Immune Mediators Associated with MERS-CoV Infections. Data characterizing immune responses during MERS-CoV infection are limited. Faure et al. evaluated

cytokine levels in serum and bronchoalveolar lavage (BAL) from two MERS patients, one with fatal disease and one who survived.³⁰ Higher levels of retinoic acid-inducible gene 1 (RIG-1), melanoma differentiation-associated protein 5 (MDA5), interferon regulatory factor (IRF)-3 and -7, interleukin (IL) 17A, and IL-23 and lower levels of IL-12 and IFN γ were observed in the fatal case compared with the survivor. More recently, Min et al. performed a temporal analysis of cytokine, chemokine, and growth factor blood levels from 14 patients during the recent outbreak of MERS in South Korea.³¹ The patients were subcategorized into four groups on the basis of disease severity: Group I patients developed fever and recovered. Group II patients developed mild pneumonia without hypoxemia. Group III patients had prolonged and severe pneumonia. Group IV patients had severe pneumonia and acute respiratory distress syndrome. Group IV patients included five fatal cases of MERS; all patients in groups I–III fully recovered from illness. IFN α was elevated in all groups and largely peaked during the second week of illness. Granulocyte-colony stimulating factor (G-CSF) and granulocyte macrophage (GM)-CSF were similarly elevated across all patient groups; however, patients with fatal disease had reduced GM-CSF responses following antiviral treatment as compared to patients that recovered. Patients with pneumonia had relative elevations of IL-1, tumor necrosis factor (TNF)- α , IL-6, and IL-10 during the second and third weeks of illness. Elevated IL-6 and IL-10 appeared to trend positively with the severity of illness. A robust induction of multiple chemokines was found in most patients. Notably, eotaxin and regulated on activation, normal T expressed and secreted (RANTES) was elevated in all patients. In contrast, IL-8, monocyte chemotactic protein (MCP)-3 and macrophage inflammatory protein (MIP)-1 β were more prominent in groups II and III as compared to groups I and IV. Furthermore, elevated interferon gamma induced protein (IP)-10 correlated with the development of pneumonia (groups I–III). Multiple growth factors, including epidermal growth factor (EGF), fibroblast growth factor (FGF)-2, vascular endothelial growth factor (VEGF), and TGF- α , were significantly elevated across all patients; however, EGF was significantly higher in patients that recovered from disease as compared to the fatal cases. Further evaluations are needed to characterize the natural history of immune response during acute MERS-CoV infection and recovery.

Transcriptome Analyses of MERS-CoV. In an effort to better characterize MERS-CoV pathogenesis in the absence of available samples from human patients and, in particular, address pathologic changes associated with infection, multiple animal species have been employed in MERS-CoV investigations. While multiple small animals are not susceptible to MERS-CoV infection,³² rhesus macaques and marmosets develop mild to severe lung pathology following experimental infection. Transcriptome analysis in MERS-CoV-infected rhesus macaques revealed that genes related to antiviral immunity, chemotaxis, and inflammation were overexpressed in lesional versus grossly normal lung tissue at 3 days postinfection.³³ A significantly smaller number of differentially expressed genes was found on day 6 postinfection with no obvious trends following pathway enrichment analysis. Significant changes in the transcriptome profiles of peripheral blood mononuclear cells (PBMCs) were observed at only day 1 postinfection. This global analysis suggests a key role for an initial rapid innate immune and inflammatory response (through pattern recognition receptors) followed by rapid

resolution.³³ A study of MERS-CoV-infected marmosets evaluated lung lesions by RNaseq at days 3–6 postinfection.³⁴ Pathway analyses demonstrated that chemotaxis and cell migration, cell cycle progression, and cell proliferation and fibrogenesis were highly over-represented relative to uninfected controls. To a lesser degree, pathways associated with inflammation, vascularization, endothelial activation, proliferation of smooth muscle, and tissue repair were also over-represented in infected animals. Differences were most significant on days 4 and 6 postinfection during illness progression relative to day 3.

Recently, Menachery and colleagues examined the interaction between MERS-CoV EMC/2012 and the host IFN-stimulated gene (ISG) response by transcriptomics.³⁵ ISG responses in MERS-CoV infected Calu3 cells, a lung adenocarcinoma cell line, had no discernible induction initially upon infection but were up-regulated by 12 h postinfection.³⁵ Down-regulation of a subset of ISGs resulted in altered histone modifications, a potential epigenetic contributor to early impairment of antiviral cellular defenses. In a separate analysis genetically distinct MERS-CoV strains, MERS-CoV SA1 and MERS-CoV Eng1, produced distinct gene expression profiles in Calu-3 cells.³⁶ These analyses may better inform early host-cell antiviral responses and the impact of viral evolution on these and other complex biological responses. Proteomics analysis corroborated these transcriptional data with induction of ISGs observed 18 h postinfection. Significantly reduced levels of STAT1 and PKR compared with uninfected controls were also noted. Differential host transcriptome responses to MERS-CoV SA1 and MERS-CoV Eng1 highlight both the propensity of emerging viral pathogens to evolve rapidly and the importance of additional host response analyses for augmenting and clarifying such complex biological responses.

Kinome Analyses of MERS-CoV Infection. Host responses to MERS-CoV infection through kinome analysis were recently assessed using Huh-7 cells, an immortalized human hepatocyte cell line, that are highly permissive to MERS-CoV infection.³⁷ Temporal analysis of kinome responses by peptide arrays revealed selective modulation of extracellular signal-regulated kinases (ERK)/mitogen-activated protein kinases (MAPK) and phosphatidylinositol-3-kinases (PI3K)/AKT (also known as protein kinase B)/mechanistic target of rapamycin (mTOR) signaling responses. Over-representation analysis (ORA) revealed ERK/MAPK and PI3K/AKT/mTOR signaling responses were consistently up-regulated during infection. Multiple ERK/MAPK family members formed central components of functional networks and signaling pathways throughout infection. Similar results were observed for intermediates of the PI3K/AKT/mTOR signaling pathway at 1 and 24 h postinfection, suggesting that modulation of ERK/MAPK and PI3K/AKT/mTOR signaling may be important for productive MERS-CoV infection.

Downstream analysis of the phosphorylation patterns of pathway intermediates from the ERK/MAPK and PI3K/AKT/mTOR signaling supported observations from the kinome analysis. Both investigations demonstrated that nuclear factor kappa-light-chain-enhancer of activated B cells (NF κ B)-regulated family members were important mediators of MERS-CoV infection.³⁸ IL8- and IFN-mediated signalings were also modulated during MERS-CoV infection, consistent with prior analyses.^{39,40} These results were also in agreement with in vitro transcriptional analysis of MERS-CoV infection.³⁸ Prophylactic or therapeutic addition of FDA-licensed kinase

inhibitors targeting activated kinases in MERS-CoV infection impaired viral replication. These hypothesis-generating data may inform directed investigations into MERS-CoV pathogenesis and, importantly, demonstrate the potential to identify novel host-centric therapeutic targets.

Ebolaviruses. The Filoviridae family of viruses consists of three genera: Ebolavirus, Marburgvirus, and the newly identified Cuevavirus. Structurally, filoviruses have a pleomorphic enveloped, filamentous virion particle that encapsulates a negative-sense single-stranded RNA genome. Ebolaviruses were first described in 1976 following disease outbreaks in the Democratic Republic of Congo and Sudan and are composed of five viral species, including Ebola virus (EBOV), Sudan virus (SUDV), Bundibugyo virus (BDBV), Tai Forest virus (TAFV), and Reston virus (RESTV). Sporadic outbreaks of EBOV, SUDV, BDBV, and TAFV have occurred throughout central Africa for more than three decades, resulting in thousands of infections. Case fatality rates during these outbreaks have routinely exceeded 50%.⁴¹ Isolated outbreaks of RESTV have occurred outside Africa in nonhuman primate facilities in the United States, Italy, and the Philippines, and infection results in high morbidity and mortality in nonhuman primates; however, RESTV has only been associated with asymptomatic infections in humans.⁴² Although ebolaviruses have been historically associated with isolated outbreaks involving small cohorts of infected patients (<500), an outbreak of EVD in West Africa beginning in 2014 has resulted in 28,616 cases and 11,310 deaths (40% CFR) as of June 2016 (<http://www.who.int/csr/disease/ebola/en/>). Although virus transmission has greatly decreased in West Africa, surveillance for sporadic infections continues.

Clinical Findings in EVD. EBOV transmission occurs through exposure of infected body fluids or tissues to mucous membranes or nonintact skin.⁴³ The mean incubation period is 6–10 days, ranging from 2 to 21 days.⁴³ Initial signs and symptoms are nonspecific including fever, myalgia, and malaise and cannot be reliably distinguished from other endemic illnesses in Africa including malaria and enteric infections.⁴³ Whereas mild illness has been described, most patients develop severe disease within days of symptom onset. Massive gastrointestinal fluid losses of up to 5–10 L per day due to vomiting and watery diarrhea may result in progressive dehydration and hypovolemic shock. Even in the setting of adequate fluid and electrolyte replacement, sequential multi-organ failure may occur. EBOV infects multiple organs and cell types throughout the body with the notable exception of lymphocytes that are indirectly depleted early during infection. Organ injury due to direct viral or indirect host-mediated responses results in severe complications including meningo-encephalitis, uveitis, respiratory failure, secretory diarrhea, disordered coagulation, renal failure, hepatic necrosis, and myositis. The clinical presentation, laboratory values, viral kinetics, and clinical management of EVD patients in West Africa, Europe, and the United States during the 2014–2015 outbreak have been recently well-characterized.⁴⁴

Soluble Immune Mediators Associated with EBOV Infections. There is a paucity of information regarding EBOV pathogenesis in humans primarily due to the limited frequency of EVD outbreaks prior to 2014 and limitations presented by sample acquisition from infected patients in the field as well as the overall size of patient cohorts. Largely contradictory findings regarding the immune responses in those who survive or succumb to EVD have further confounded the under-

standing of EBOV pathogenesis in human patients. For example, Villinger et al. reported that serum cytokine concentrations (including IFN α , IFN γ , TNF- α , IL-2, and IL-4) were elevated in patients with fatal infections in comparison to survivors.⁴⁵ In contrast, additional studies have suggested that fatal infections were instead related to general immunosuppression including IFN γ , IL-2, and IL-4.^{46–49} An investigation of SUDV infection in humans by Sanchez et al. demonstrated limited changes in the expression levels of cytokines, Fas antigen, and Fas ligand in PBMCs from infected patients relative to those found for uninfected patients.⁵⁰ Furthermore, an investigation of 42 fatally infected EVD patients by Wauquier et al. has further confounded the role of host immune responses in fatal EVD as hypersecretion of multiple cytokines and growth factors and decreased secretion of T lymphocyte-derived cytokines were associated with fatal disease.⁵¹

Transcriptome Analyses of Ebola Virus Infection. To date, no investigations of host gene expression in EBOV-infected patients have been reported, although limited data are available from animal models of infection or from in vitro investigations.

In a study of PBMCs from EBOV-infected crab-eating macaques, Rubins et al. found few notable changes in the early stages of infection (1–2 days); however, broad changes were observed over days 4–6 post-infection. Pro-inflammatory cytokines (IL-1 β , IL-6, IL-8, and TNF- α) and chemokines (MIP-1 α and MCP1–4) were up-regulated at days 4–6 postinfection relative to healthy controls.⁵² Multiple genes related to apoptosis including Bcl-2 family members, multiple caspases, Fas-associated death domain protein, and TNF superfamily member 10 were also up-regulated at late time points. IFN-regulated genes were up-regulated by day 2 postinfection and remained so through study day 6.

Yan et al. investigated PBMC gene expression in EBOV-infected rhesus macaques with or without anticoagulant administration. Untreated animals displayed up-regulation of immune response genes, B cell receptor signaling intermediates, NK cell mediated cytotoxicity, leukocyte activation, and lymphocyte activation compared with anticoagulant-treated animals during the early stages of infection. The expression levels of these gene clusters fell to pre-infection levels at the late-stage of infection. In contrast, genes related to defense responses, apoptosis, wounding, inflammation, coagulation, and leukocyte activation remained elevated during early- and late-stage infection.

Following the isolation of RESTV from pigs,⁵³ subsequent investigations have demonstrated that pigs were susceptible to both RESTV and EBOV infection with preferential targeting of macrophages in the lungs. Recently, Nfon et al. demonstrated that EBOV infection in pigs resulted in up-regulation of chemokine expression beginning on day 3 postinfection as compared to mock-infected pigs.⁵⁴ The most pronounced changes in gene expression were found on days 5 and 7 postinfection and included the up-regulation of a broad set of cytokines (IL-5, IL-6, IL-8, IL-10, IL-22, IL-26, IL-27, resistin), chemokines (CCL2, CCL10, CCL19, CCL20, AMCF-II, CCL3L1, CCL4), cell adhesion protein (selectin), antimicrobial protein, palate, lung, and nasal epithelium clone proteins, and pro-apoptotic molecules (multiple caspases, caspase recruitment domain-containing protein 6 (CARD), apoptosis-associated tyrosine kinase (AATK), Fas, Fas-associated protein with death domain (FADD), TNF receptor-associated factor 3 (TRAF3), TNF α -induced protein 3-interacting protein 1

(TNIP1)). In addition, expression of multiple genes related to microbial sensing (pattern recognition receptors) or antiviral responses (ISGs) was up-regulated in the lungs of infected animals. Although the localization of the cytokine response of pigs and humans or NHPs differs during the course of EBOV infection (localized responses in the lungs of pigs versus a predominantly systemic response in humans and NHPs), the cytokine profiles of pigs, humans, and NHPs were quite similar. For example, comparison of NHP⁵² and porcine responses⁵⁴ during EBOV infection demonstrated multiple gene expression similarities between the two species (i.e., IL-6, IL-8, caspase family members). It is also likely that direct comparison of both data sets would likely yield many common gene signatures that are conserved in their identity as well as their directionality (up-regulation vs down-regulation).

Macrophages are an early target of EBOV infection and support high-level viral replication. EBOV attachment and entry into human macrophages in vitro induces pro-inflammatory mediators including IL-6, IL-8, and TNF- α as early as 1 h postinfection.⁵⁵ Noncardiogenic pulmonary edema is a recognized complication of EVD, and human autopsy data support that alveolar macrophages are a target of EBOV infection. EBOV infection of alveolar macrophages in vitro resulted in an early, transient increase in cytokine and chemokine expression,⁵⁶ supporting that paracrine-soluble mediators of inflammation may contribute to vascular leakage in the lungs. Gene expression responses of EBOV- and MARV-infected Huh7 cells resulted in the global suppression of antiviral responses, including Toll-like receptor (TLR), IRF3, and protein kinase R (PKR)-mediated pathways.⁵⁷ However, signal transducers and activators of transcription (STAT) phosphorylation in EBOV- and MARV-infected cells were differentially modulated. EBOV-mediated IFN inhibition has been well characterized and is thought to be attributable to EBOV proteins VP24 and VP35.⁵⁸ Interestingly, RESTV infection, which does not induce clinical illness in humans, resulted in the activation of >20% of the IFN-stimulated genes (ISGs).

Kinome Analysis of Ebola Virus. Hepatocytes are an early target of EBOV infection, directly contributing to diffuse hepatic necrosis observed in fatal cases. EBOV infection of Huh7 cells has been evaluated by kinome analyses, shedding light on liver pathogenesis in EVD.⁵⁹ EBOV infection of Huh-7 cells resulted in temporal modulation of the TGF- β signaling pathway as compared to mock-infected cells. Pathway ORA demonstrated that multiple TGF- β -mediated signaling pathways were up-regulated at 1 and 24 h post EBOV infection. Furthermore, these responses were associated with changes in the expression patterns of multiple cellular proteins associated with a mesenchyme-like transition. These included the up-regulation of matrix metalloproteinase 9, N-cadherin, and fibronectin and down-regulation of E-cadherin and claudin 1. In this process cells lose polarity and cell-to-cell adhesion transforming into mesenchymal stem cells that contribute to wound healing or organ fibrosis; however, the role of these events in EBOV infection remains to be elucidated. Additional analysis demonstrated that inhibition of PI3K/AKT, ERK/MAPK, or PKC pathways with kinase inhibitors reduced EBOV replication when administered prophylactically or therapeutically. Supporting this observation, a subset of kinase inhibitors administered to EBOV-infected mice reduced lethality. Defining mechanisms by which kinase inhibitors show benefit

in these models will better clarify their role as potential therapeutics.

Monkeypox Virus. MPXV, a member of the genus *Orthopoxvirus*, causes zoonotic infections with a case fatality rate of ~11%.⁶⁰ MPXV, vaccinia virus (VACV), cowpox virus (CPXV), ectromelia virus, and variola virus (VARV), the etiologic agent of human smallpox, comprise the Orthopoxviridae family of viruses. MPXV was first isolated in 1958 from cynomolgus macaques in Denmark; however, human MPXV infections were not recognized until 1970 following the isolation of the virus from a suspected case of smallpox infection in the Democratic Republic of Congo.⁶¹ MPXV is composed of two distinct clades that are genetically, clinically, and geographically distinct. The Congo Basin MPXV (Central African MPXV) clade is considered to have both higher lethality and morbidity than the West African MPXV clade as demonstrated from comparative infection models in various animal species (including nonhuman primates, mice, prairie dogs, and ground squirrels) and as well natural infection in humans.^{61–63} Fifty-four cases of human MPXV disease were recorded in West and Central Africa from 1970 to 1979. Although no fatalities were reported in West African cases (including Liberia, Nigeria, Ivory Coast, and Sierra Leone), 21% of cases from the Democratic Republic of Congo resulted in fatal disease.⁶¹ Furthermore, West African MPXV was responsible for the 2003 MPXV outbreak in the United States that resulted in 69 diagnosed cases of MPXV and no associated fatalities.⁶⁴ Although human MPXV infections have been recorded in West Africa, the majority of human MPXV infections have occurred in the Congo Basin region of Central Africa, largely in the Democratic Republic of Congo.⁶⁰

Clinical Findings in MPXV Infections. Clinical and epidemiological information regarding human MPXV disease has been derived from enhanced surveillance campaigns in the Congo Basin.⁶¹ From this work, it has been demonstrated that human MPXV infection and illness largely mirror those of discrete, ordinary smallpox.⁶¹ The incubation period for both viruses (VARV and MPXV) is 7–17 days with an initial febrile prodromal period of 1–4 days. This prodromal period is normally accompanied by fever, headache, backache, malaise, and prostration.⁶¹ The rash period for both smallpox and MPXV (including lesion appearance and desquamation) normally occurs 14–28 days postinfection with highly similar appearance, distribution, and progression of lesions.^{60,61} As with smallpox, MPXV-associated rash progresses through macular, papular, vesicular, and pustular phases. A second febrile period occurs when the lesions become pustular and is often associated with deteriorating conditions in the patient. Lymphadenopathy (maxillary, cervical, or inguinal) is often associated with MPXV infections prior to, or concomitant with, rash development but is absent in VARV infections. It has been postulated that this reflects the effective generation of host immune responses during MPXV infection as compared to VARV; however, this has yet to be validated.^{60,61} Severe complications have been noted late in the course of MPXV infection, including pulmonary distress or bronchopneumonia, corneal scarring and permanent vision loss, and encephalitis.⁶⁰ Severe dehydration due to excessive vomiting or diarrhea may also occur. Long-term sequelae in survivors are most commonly associated with pitted scarring.

Soluble Immune Mediators Associated with MPXV Infections. Although MPXV infections in humans have been recorded for over four decades, there has been little information

regarding host immune responses during the course of natural infection. As disease presentation is highly similar during MPXV and VARV infections, it has been postulated that immune responses would likely be highly conserved. Recently, Johnston et al. provided the first empirical evidence for a relationship between cytokine responses and disease severity during MPXV infection.⁶⁵ Serum cytokines were analyzed from 19 patients with confirmed MPXV infections ranging from mild to severe as assessed by the WHO smallpox lesion scoring system.^{66,67} Serum concentrations of IL-1 β , IL-1RA, IL-2R, IL-4, IL-5, IL-6, IL-8, IL-13, IL-15, IL-17, MCP-1, and RANTES were elevated in all disease groups (mild to severe) as compared to normal serum concentrations. IL-10 concentrations were also elevated in all disease groups and were proportional to disease severity. However, patients with serious MPXV disease had significantly higher concentrations of IL-10 compared to all other disease groups. MPXV infection resulted in elevated MIP-1 α and MIP-1 β ; mild cases had significantly elevated levels above the moderate or severe disease groups. Serum concentrations of IL-2R were elevated across all disease groups; however, patients with serious disease had significantly higher IL-2R serum levels than those with mild to severe MPXV disease. GM-CSF levels were significantly elevated only in those with serious MPXV disease as compared to normal serum ranges. On the basis of these observations, MPXV infection resulted in prominent T helper 2 (Th2) and dampened Th1 responses.

Transcriptome Analyses in MPXV Infection. Transcriptome analyses have largely been employed for the in vitro investigation of the molecular pathogenesis of MPXV infection. Alkhalil et al. investigated the host transcriptome responses to MPXV infection during the first cycle of viral replication (3 and 7 h postinfection) in rhesus macaque kidney epithelial cells.⁶⁸ Interestingly, MPXV infection resulted in a strong down-regulation of host transcriptional responses. Of the transcripts that met the authors' criteria for significance, 89% of the transcripts were found to be down-regulated at both post-infection time points. Comparative functional analysis from both time points suggested that the primary biological functions associated with these down-regulated transcriptional responses were largely related to cell morphology, cell development, metabolic responses, and post-translational modifications. Canonical pathway analysis demonstrated a general conservation in the identities of over-represented pathways at both time points including multiple growth factor signaling pathways, p53 signaling, and cell cycle-related pathways. More recently, Bourquain et al. investigated host transcriptome responses in MPXV-infected HeLa cells, a cervical epithelial cell line.⁶⁹ At 6 h post-MPXV infection, only 1.1% of the transcripts analyzed were found to have >2-fold changes in gene expression. In contrast to Alkhalil et al., the majority of these transcripts (~68%) were found to be up-regulated as compared to mock-infected controls. Functional analysis of all transcripts with >2-fold changes in gene expression demonstrated a strong over-representation of genes involved in the negative regulation of MAPK signaling and the intracellular protein cascade. Positive regulation of pathways related to Toll-like receptor signaling, chemotaxis, and regulation of leukocyte migration was also predicted from the data. An investigation by Rubins et al. compared the temporal host transcriptome response to MPXV in multiple human cells targeted by MPXV including primary macrophages, primary fibroblasts, and HeLa cells.⁷⁰ The transcriptome of

MPXV-infected fibroblasts was found to have the most significant changes where MPXV infection resulted in the depletion of ~2000 genes by a factor of ≥ 3 . Interestingly, MPXV infection resulted in the broad repression of many transcripts related to innate immune responses in all cell types tested. In contrast, inactivated MPXV resulted in strong up-regulation of innate immune responses in all of the cell types. It was also noted that MPXV infection resulted in strong cytopathic effects across all of the cell types in contrast to an almost universal repression of innate immune responses.

Kinome Analyses in MPXV Infection. Human MPXV infections and infection models of MPXV in various animal species have demonstrated that the Congo Basin MPXV clade is more virulent than the West African MPXV clade. However, there has been a paucity of information regarding the underlying molecular mechanisms mitigating these virulence differences. Furthermore, previous investigations focusing on gene expression or proteomic changes during MPXV infection have focused solely on Congo Basin MPXV. To address this, host kinome analysis was performed on Congo Basin and West African MPXV-infected human monocytes, a host cell targeted by orthopoxviruses.⁷¹ As the genomes of both MPXV clades demonstrate considerable diversity in the regions coding host response modifier proteins, and in particular in genes associated with anti-apoptotic activities, it was postulated that the virulence differences of the two MPXV clades may be related to differential modulation of host cellular responses. Hierarchical clustering of the kinome data sets suggested limited similarities at the level of host kinase modulation between the two MPXV clades. The Congo Basin MPXV kinome data set clustered most strongly with the kinome data set from CPXV-infected monocytes and moderately with the VACV-infected monocyte data set. Both CPXV and VACV can cause serious disease in humans. The pathway ORA of the kinome data demonstrated that Congo Basin MPXV infection resulted in strong down-regulation of a large proportion of host cell responses, most notably apoptosis, in comparison to West African MPXV. Biological validation through fluorescence-activated cell sorting (FACS) and caspase 3 activity analyses confirmed this phenomenon. From the perspective of individual phosphorylation events, the kinome data also suggested that AKT phosphorylation at Ser473 was increased in Congo Basin MPXV-infected cells as compared to West African MPXV-infected cells. Pharmacologic inhibition of AKT phosphorylation at Ser473 resulted in a >250-fold inhibition of Congo Basin MPXV virus yields, whereas those for West African MPXV were unaffected. Prior investigations with CPXV and VACV demonstrated that pharmacological inhibition of AKT resulted in decreased viral yields for both viruses.⁷² Overall, this investigation provided significant insight into the host cellular response differences between the two MPXV clades.

■ CONCLUSIONS

Emerging and re-emerging pathogens are a continual threat to global health. In recent years, disease outbreaks associated with SARS and the 2009 influenza pandemic have also demonstrated that these pathogens can have considerable effects on local, national, and international economies. As a consequence, regional outbreaks of emerging and re-emerging pathogens can have deleterious effects on global stability. Thus, it is prudent that a concerted effort is employed to assimilate data that bridge both clinical and molecular information in investigations

Table 1. Kinase Inhibitors Tested against EBOV, MERS-CoV, or MPXV

kinase inhibitor	host target	impact of inhibitor on viral replication (reduction in viral replication considered to be >40% inhibition)	impact of inhibitor on animal survival	reference
MERS-CoV				
Rapamycin	mTOR	in vitro reduction in viral replication with prophylatic and therapeutic treatment	no data available	37
GF109203X	PKC	in vitro reduction in viral replication with prophylatic and therapeutic treatment	no data available	37
Ro-31-8220	PKC	in vitro reduction in viral replication with prophylatic and therapeutic treatment	no data available	37
U0126	MEK1, MEK2	in vitro reduction in viral replication with prophylatic treatment	no data available	37
Wortmannin	PI3K	in vitro reduction in viral replication with prophylatic treatment	no data available	37
GW5074	c-Raf1	in vitro reduction in viral replication with prophylatic treatment	no data available	37
Imatinib	c-Abl1 family	in vitro reduction in viral replication with prophylatic treatment	no data available	79
SB203580	p38 MAPK	in vitro reduction in viral replication with prophylatic treatment	no data available	37, 38
Dasatinib (BMS-354825)	Src, Abl family kinases	in vitro reduction in viral replication with prophylatic treatment	no data available	79
PP2	Src family kinases	no significant inhibition of viral replication	no data available	37
Bay 11-7082	IKB α	no significant inhibition of viral replication	no data available	37
PKC-412	PKC	no significant inhibition of viral replication	no data available	37
AG490	EGFR; ERBB2	no significant inhibition of viral replication	no data available	37
L-NAME	nitric oxide synthase	no significant inhibition of viral replication	no data available	37
EBOV				
AG879	ErbB2 and FLK-1 (VEGF receptor)	in vitro reduction in viral replication with prophylatic and therapeutic treatment	improvement in mouse survival	59
LY294002	PI3K	in vitro reduction in viral replication with prophylatic and therapeutic treatment	improvement in mouse survival	59, 80
SB431542	activin receptor-like kinase receptors, ALK5, ALK4 and ALK7	in vitro reduction in viral replication with prophylatic and therapeutic treatment	improvement in mouse survival	59
SU1498	VEGF receptor 2	no significant inhibition of viral replication	improvement in mouse survival	59
Rottlerin	PKC	in vitro reduction in viral replication with prophylatic and therapeutic treatment	improvement in mouse survival	59
Wortmannin	PI3K	in vitro reduction in viral replication with prophylatic and therapeutic treatment	no data available	59
Indirubin-3-monoxamine	glycogen synthase kinase 3 β	in vitro reduction in viral replication with prophylatic and therapeutic treatment	no data available	59
SP600125	JNK	in vitro reduction in viral replication with prophylatic and therapeutic treatment	no data available	59
GF109203X	PKC	in vitro reduction in viral replication with prophylatic and therapeutic treatment	no data available	59
Genistein	EGFR	in vitro inhibition of vsv-ebov pseudotype transduction with prophylatic treatment	no data available	81
Tyrphostin	tyrosine kinases	in vitro inhibition of vsv-ebov pseudotype transduction with prophylatic treatment	no data available	81
KN-93	CAMK2	in vitro reduction in infectivity	no data available	80

of these pathogens. These efforts will not only provide considerable context in regard to the molecular events that potentiate clinical manifestations of pathogenesis but also better inform the design and implementation of novel therapeutics. To this end, global analyses of host molecular responses can provide considerable insight into the complex molecular events that underlie cellular responses. Indeed, transcriptome analyses have provided important information regarding host transcriptional responses during emerging and re-emerging pathogen infection. These investigations often provide critical insight into the kinetics of host immune responses during the course of infection as well as mechanistic information regarding the cellular intermediates involved in these processes. However, the role of PTMs in the regulation of these events cannot be captured by traditional transcriptome technologies. In particular, the role of kinase-mediated regulation of cell signaling pathways has remained poorly understood. Given the central role of kinases in the regulation of cellular processes (e.g., homeostasis, metabolism, proliferation, and stress responses), it is of inherent importance that future investigations also address the role of the kinome in the cellular response to pathogen insult. Furthermore, kinomics also provides a mechanism for the identification of novel therapeutic targets based on the direct assessment of the activation state of cell signaling pathways. For example, pro-inflammatory responses during early stages of infection, and in particular the dysregulation of specific cytokines or cell signaling events that contribute to these, may represent potential therapeutic targets in the early stages of high-consequence viral pathogen infection. However, the selection of immunomodulatory therapeutics that target these dysregulated host responses is complicated by the regulatory events (i.e., kinase-mediated cell signaling events) that occur upstream of changes in gene expression. In addition, mRNA is subject to a variety of regulatory processes (including gene silencing, mRNA stability, translational efficiencies, protein turnover, enzyme/substrate subcellular sequestration, and/or protein activation/repression PTMs). Thus, from the standpoint of therapeutic discovery, the sole reliance on technologies for the global investigations of host responses that do not account for these regulatory processes or the role of PTMs in the modulation of cellular responses could impede the identification of efficacious therapeutics.

To this end, kinome analysis may also facilitate the identification of immunomodulatory therapeutics that have gained licensure through analysis of a quantifiable biological event (kinase-mediated phosphorylation) or for identifying novel host therapeutic targets for which therapeutics could be designed/developed. Furthermore, kinase inhibitors may serve as primary or adjunctive therapies for emerging infectious diseases. In addition, preclinical data and the increasing number of kinase inhibitors that have gained regulatory approval for cancer and other maladies suggest this approach is feasible and efficacious. From the perspective of this review, kinome investigations have identified several therapeutic targets and

licensed kinase inhibitors that have impaired viral replication in vitro and reduced the severity of disease in vivo (Table 1). For example, it has been demonstrated that the ERK/MAPK and PI3K/AKT/mTOR signaling pathways have a role in viral propagation during MERS-CoV infection.³⁷ Indeed, licensed kinase inhibitors that targeted these pathways (i.e., everolimus, selumetinib, and trametinib) resulted in decreased viral replication in vitro when added prior to, or following, infection. Furthermore, the pharmacologic inhibition of PI3K and PKC following EBOV infection provided partial protection in a lethal model of EVD in mice.⁵⁹ It should be noted that although the modulation of an individual kinase may have suppressive effects on infection (i.e., viral replication), this might not provide the level of inhibition required to completely negate viral escape. In addition, given the ability of many cell signaling pathways to signal through both canonical and noncanonical mechanisms, inhibition at a single intermediary point within a pathway may not provide the overall level of inhibition required to negate a deleterious response (i.e., viral replication, changes in cellular phenotypes, etc.). Thus, although previous investigations have demonstrated that individual kinases or cell signaling pathways may represent novel targets for anti-infective therapies, it is prudent that future investigations also examine combinations of inhibitors for efficacy and anti-infective activities. Furthermore, the targeting of cell signaling pathways at or near the origin point for the cell signaling cascade should also be examined as these likely represent stronger inhibitory targets given the generally reduced branching of cell signaling networks at or near the cell receptor.

In addition to host-directed therapeutic targeting, kinomics also confers the ability to identify novel inhibitors of pathogens through detailed characterization of the viral life cycle. Host-mediated PTMs, and in particular kinase-mediated phosphorylation, have been implicated in the viral life cycle and pathogenesis for several members of the order Mononegavirales, including EBOV.^{73–75} Thus, therapeutic targeting of kinases may represent a novel therapeutic strategy that can be employed to modulate host-centric or pathogen-centric molecular events during infection. For example, in silico prediction of viral protein phosphorylation sites provides a mechanism for the construction and, ultimately, the annotation of viral protein PTMs that are critical to the viral life cycle. Furthermore, the use of kinome peptide arrays has extended beyond the human kinome and now extends to a variety of animal species.^{76–78} It has been suggested that the interspecies phenotypic variability may reflect differences in phosphorylation sites found within the proteome.⁷⁸ Thus, the development of species-specific kinome peptide arrays provides additional utility for kinome analysis as peptide arrays representing traditional laboratory animal species (mouse, guinea pig, nonhuman primate) can be employed to detail the species-specific host response. The results from such analyses, and the overlap between these and those described previously from the analysis of human infections, may inform

the selection of appropriate animal models that meet regulatory approval through the FDA Animal Efficacy Rule.²⁹

Taken together, it is of inherent importance that future investigations of emerging and re-emerging pathogens address the complex nature of biological responses. Thus, molecular investigations of pathogenesis should be guided by available knowledge regarding the clinical and pathologic manifestations of disease. Indeed, technologies that provide further granularity into the precise molecular events that potentiate cellular responses during the course of infection will assist investigations of emerging and re-emerging pathogens and the identification of novel therapeutic targets. To this end, kinomics-based analyses of host responses provide a mechanism to directly address the cellular events at the level of specific cell signaling phenomena that underlie the biological responses and, ultimately, the clinical presentation of disease for emerging infectious pathogens.

Abstract

Mask wearing has been advocated by public health officials as a way to reduce the spread of COVID-19. In the United States, policies on mask wearing have varied from state to state over the course of the pandemic. Even as more and more states encourage or even mandate mask wearing, many citizens still resist the notion. Our research examines mask wearing policy and adherence in association with COVID-19 case rates. We used state-level data on mask wearing policy for the general public and on proportion of residents who stated they always wear masks in public. For all 50 states and the District of Columbia (DC), these data were abstracted by month for April – September 2020 to measure their impact on COVID-19 rates in the subsequent month (May – October 2020). Monthly COVID-19 case rates (number of cases per capita over two weeks) >200 per 100,000 residents were considered high. Fourteen of the 15 states with no mask wearing policy for the general public through September reported a high COVID-19 rate. Of the 8 states with at least 75% mask adherence, none reported a high COVID-19 rate. States with the lowest levels of mask adherence were most likely to have high COVID-19 rates in the subsequent month, independent of mask policy or demographic factors. Mean COVID-19 rates for states with at least 75% mask adherence in the preceding month was 109.26 per 100,000 compared to 249.99 per 100,000 for those with less adherence. Our analysis suggests high adherence to mask wearing could be a key factor in reducing the spread of COVID-19. This association between high mask adherence and reduced COVID-19 rates should influence policy makers and public health officials to focus on ways to improve mask adherence across the population in order to mitigate the spread of COVID-19.

Introduction

The global pandemic of SARS-CoV-2 has overwhelmed health care systems, marked by peak numbers of hospital and intensive care unit admissions and deaths [1,2]. Mask wearing has been advocated by public health officials as a way to reduce the spread of COVID-19 [3–5]. In the United States, policies on mask wearing have varied from state to state over the course of the pandemic [6]. For the period of April 1 through October 31, 2020, less than half of states

Competing interests: The authors have declared that no competing interests exist.

had issued a mandate for mask wearing in public and nearly a third had not made any recommendation. Even as more and more states encourage mask wearing [7], many citizens still resist the notion [8]. Individuals' mask wearing behaviors are not only influenced by recommendations and mandates issued by state leaders, but also by print, televised, and social media [9]. Thus, adherence to mask wearing in public remains a challenge for mitigating the spread of COVID-19.

Public health policy-making requires navigating the balance of public good and individual rights [10]. The adoption of universal masking policies is increasingly polarized and politicized, demanding that public health authorities balance the values of health and individual liberty. Adherence to public policy is influenced by a complex interplay of factors such as public opinion, cultural practices, individual perceptions and behaviors [11], which are difficult to quantify. The politicization of COVID-19 epidemiology [9,12] has further complicated policy-making, messaging, and uptake. Nevertheless, adherence is essential for policy effectiveness. Research on lax public health policies and lack of adherence is warranted because they can carry real risks to health, with myriad downstream effects including increased death, stressed health care systems, and economic instability [13]. We examined the impact of state-based mask wearing policy and adherence on COVID-19 case rates during the summer and early fall of 2020 in order to quantify this effect.

Methods

For all 50 states and D.C., data on mask wearing and physical distance policies, mask adherence, COVID-19 cases, and demographics were abstracted from publicly available sources. We utilized the COVID-19 US State Policy Database, created by Dr. Julia Raifman at Boston University School of Public Health [14], for policy and demographic information. We abstracted data on whether the state issued a mandate of mask use by all individuals in public spaces, and if so, the dates of implementation and whether the mandate was enforced by fines or criminal charge/citation(s). For policies on physical distancing, we recorded whether a stay-at-home order was issued and, if so, when. For mask adherence levels, we utilized the Institute of Health Metrics and Evaluation (IHME) COVID-19 Projections online database [15], which holds data collected by Facebook Global in partnership with the University of Maryland Social Data Science Center [16]. We abstracted daily percentages of the population who say they always wear a mask in public. To calculate monthly COVID-19 case rates, we abstracted the number of new cases reported by the U.S. Centers for Disease Control and Prevention (CDC) [17] and state population sizes in 2019 [18].

Mask wearing policy

We categorized the existence of a mask policy as “None” if there was no requirement for face coverings in public spaces, “Recommended” if required in all public spaces without consequences, and “Strict” if required in all public spaces with consequences in the form of fine(s) or citation(s). We combined the Recommended and Strict groups into “Any” policy. States and D.C. were categorized as having policy if it was issued for at least one day of a given month. Although Hawaii's governor did not issue a mask wearing policy until after October 2020, we considered that state to have a policy because mayors of the four populous counties had mandated mask wearing earlier in the pandemic.

Mask wearing adherence

We calculated the average mask use percentage by month for April–September, 2020. For each month, the distributions of mask adherence across all 50 states and D.C. were categorized into

quartiles, meaning the cut-off values for each quartile may be different from one month to another. Mask adherence was classified as low if in the lowest quartile and as high if in the highest quartile. We also identified states with average mask adherence $\geq 75\%$ in a given month.

COVID-19 rates

We calculated the number of new cases in each month, for each state and D.C. Rates were the number of new cases divided by the population in 2019. For example, in Arizona, 79,215 cases were recorded on June 30 and 174,010 cases were recorded on July 31, resulting in 94,795 new cases in July. We divided the monthly number by 2.2 to obtain the number in a two-week period (43,088). The 2-week rate in July in Arizona = 43,088 cases/7,278,717 population in 2019 = 0.00592 or 592 per 100,000. We classified a state and D.C. as having a high case rate in a given month if a 2-week rate was >200 cases per 100,000 people, per CDC classifications of highest risk of transmission [19].

Covariates

Based on CDC at-risk guidelines for COVID-19 [20], we considered non-Hispanic Black, Hispanic, age, and population density as potential confounders. Data on population distributions from the COVID-19 US State Policy Database [13] came from the US Census. For demographic data, we dichotomized population proportions at whole values that approximated the highest quartile of the distributions. Specifically, we created the following categories: $>15\%$ non-Hispanic Black, $>15\%$ Hispanic, median age >40 years, and population density >200 people per square mile, which corresponded to 74.5%, 78.4%, 82.4%, and 78.4% of the distributions, respectively. Policy data on physical distancing were dichotomized as any versus no stay-at-home order during the April 1 to October 31, 2020 interval.

Statistical analysis

Our analyses took into consideration the delayed effect of mask wearing and policies on COVID-19 health outcomes. Thus, policy and adherence levels in a given month were contrasted with lagged COVID-19 case rates in the subsequent month. Both mask policy and mask adherence for states and D.C. were cross-tabulated with high case rates in the subsequent month. Logistic regression models were used to estimate the odds ratio and 95% confidence intervals for high case rates in the subsequent month associated with average mask adherence (as a continuous variable). Models were unadjusted, adjusted for no mask policy (Model 1), and adjusted for no mask policy in previous month, no stay-home order, $>15\%$ population non-Hispanic Black, $>15\%$ population Hispanic, median age >40 years, population density >200 /square mile (Model 2).

Results and discussion

States in COVID-19 high-risk categories are listed in Table 1. Because stay-at-home order, mask wearing policy, mask adherence, and COVID-19 rates can vary from month to month, we listed those states with consistent classifications across the period April through September (or May through October for COVID-19 rates). Eleven states had no stay-at-home order, 15 had no mask policy, and four states had low adherence throughout this six-month period.

The list of states with high COVID-19 rates by month shows the initial wave in northeastern states in May, followed by a wave in southern states, and then spreading across the U.S. over the next four months (Table 2). Of the 15 states with no mask policy from April through

Table 1. States with high COVID-19 population risk characteristics.

High risk category	States
>15% non-Hispanic Black	AL, AR, DC, DE, FL, GA, HI, LA, MD, MS, NC, SC, TN, VA
>15% Hispanic	AZ, CA, CO, CT, FL, IL, NJ, NM, NV, NY, RI, TX
Median age >40 years	CT, DE, FL, ME, MT, NH, NJ, PA, RI, VT, WV
Pop. density > 200/mile ²	CA, CT, DC, DE, FL, HI, MA, MD, NH, NY, OH, PA, RI
No stay at home order	AR, CT, IA, KY, ND, NE, OK, SD, TX, UT, WY
No mask policy Apr-Sep	AZ, FL, GA, IA, ID, MO, MT, ND, NE, NH, OK, SC, SD, TN, WY
<25%ile mask adherence Apr-Sep	IA, KS, ND, SD

September, 14 reported high COVID-19 rates in at least one month from May to October. Because high COVID rates were reported by only eight states in May and four states in June, we did not examine mask adherence or policy in the preceding April or May. Thus, subsequent comparisons of states with high COVID-19 rates by month focused on July, August, September and October. Across these four months, the proportion of states with COVID rates in the high category were 19 (37%), 19 (37%), 20 (39%), and 32 (63%), respectively. Eight states were reported to have at least 75% mask adherence in any month between June and September (AZ, CT, HI, MA, NY, RI, VT, VA); none reported a high COVID-19 rate in the subsequent month.

For mask adherence, the cut-off values for the low and high quartiles were 31% and 46% in June, 53% and 72% in July, 55% and 71% in August, and 55% and 68% in September. The proportions of states with high COVID-19 rates are shown for those in the low and high quartiles of mask adherence in the preceding month (Fig 1). Most states in the low quartile had high COVID-19 rates in the subsequent month. Indeed all 13 states in the low mask adherence group in September had high COVID-19 rates in October. In contrast, just one state in July, August, and September and three in October in the high quartile had high COVID-19 rates in the subsequent month. When we looked at states with $\geq 75\%$ mask adherence (Arizona, Connecticut, Hawaii, Massachusetts, Michigan, New York, Rhode Island, Vermont), we found none had experienced a high COVID-19 rate in the subsequent month. Mean COVID-19 rates for states with $\geq 75\%$ mask adherence in the preceding month was 109.26 per 100,000 compared to 249.99 per 100,000 for those with less adherence.

The proportions of states and D.C. with high COVID-19 rates were greatest for those with no mask wearing policy for the general public in the preceding month (Fig 2). Among states and D.C. with no mask wearing policy, 50 to 73% had high COVID-19 rates in the subsequent month. In contrast, 25% or fewer states with a mask wearing policy had high COVID-19 rates,

Table 2. States with high COVID-19 rates.

COVID-19 >200 cases /100,000	States
May	DC, DE, IL, MA, MD, NE, NJ, RI
June	AR, AZ, FL, SC
July	AL, AR, AZ, CA, FL, GA, ID, IA, KS, LA, MO, MS, NC, NV, OK, SC, TN, TX, UT
August	AL, AR, CA, FL, GA, ID, IA, IL, KS, LA, MO, MS, ND, NV, OK, SC, SD, TN, TX
September	AL, AR, GA, ID, IA, IL, KS, KY, MO, MS, MT, NE, ND, OK, SC, SD, TN, TX, UT, WI
October	AL, AK, AR, CO, DE, ID, IA, IL, IN, KS, KY, MI, MN, MO, MS, MT, NC, NE, ND, NM, NV, OH, OK, RI, SC, SD, TN, TX, UT, WI, WV, WY
Jul, Aug, Sep or Oct and no mask policy Jun-Sep	AZ, FL, GA, IA, ID, MO, MT, ND, NH, OK, SC, SD, TN, WY

except in September when over half experienced high rates. Fourteen of the 15 states with no mask wearing policy for the general public for the entire four month period (June through September) reported a high COVID-19 rate. High COVID-rates were less frequent in states and D.C. with strict mask wearing policy than in states with recommended policy.

Looking more closely at October when COVID-19 rates increased across the US, we found average adherence was only 47% in September for the 11 states without a mask policy and high

Fig 2. Proportion of states with high COVID-19 rates among those no, any, strict, and recommended mask wearing policy in the preceding month.

October COVID-19 rates. In contrast, average adherence was 68% in the 15 states with lower COVID-19 rates in October and any mask policy in September. Of note, there were no states with $\geq 75\%$ in September.

Odds ratios and 95% confidence intervals for average mask adherence and mask policy for the general public are associated with high COVID-19 rates in the subsequent month (Table 3). Mask adherence was associated with lower odds of high COVID-19 rates, even after

Table 3. State-level odds ratios and 95% confidence intervals (CI) for high versus lower COVID-19 rates in the subsequent month.

adjustment for mask policy and for demographic factors. For every 1% increase in average adherence in June, the fully adjusted odds ratios for high COVID-19 in July was 0.95, indicating a protective effect against high COVID-19 rates. Similar reductions in odds of high COVID-19 rates in August and September were observed for July and August mask adherence, respectively. The strongest association was for mask adherence in September; for every 1% increase in average adherence, the odds of a high COVID-19 case rate decreased by 26%.

Crude and adjusted odds ratios for any mask policy in relation to high COVID-19 rates in the subsequent month were below 1.0; but confidence intervals were wide. For mask policy and adherence in September in relation to high COVID-19 rates in October, collinearity caused the odds ratio to flip.

We were not able to measure statistical interactions between mask policy and adherence due to instability arising from small numbers. We did estimate odds ratios for mask adherence within subgroups of states with and without mask policy. Odds ratios indicating protection against high COVID-19 rates remained for all months and policy subgroups, ranging from 0.82 to 0.93 for states with any policy and from 0.60 to 0.95 for states with no policy.

Interpretation

We show supporting evidence for reducing the spread of COVID-19 through mask wearing. This protective effect of mask wearing was evident across four months of the pandemic, even after adjusting the associations for mask policy, distance policy, and demographic factors. We observed some benefit of mask policy on COVID-19 rates, but the findings were unstable. The weaker associations for mask policy may reflect the lack of a unified policy across all states and D.C. and the inconsistent messaging by the media and government leaders. Indeed, issuing such a policy is not the same as successfully implementing it. Our observed associations should influence policy-makers and contribute to public health messaging by government officials and the media that mask wearing is a key component of COVID-19 mitigation.

Our observation that states with mask adherence by $\geq 75\%$ of the population was associated with lower COVID-19 rates in the subsequent month suggests that states should strive to meet this threshold. The difference in mean COVID-19 rates between states with $\geq 75\%$ and $< 75\%$ mask adherence was 140 cases per 100,000. It is worth noting that no states achieved this level of mask adherence in September, which might account in part for the spike in COVID-19 rates in October. Of course, many other factors could be at play, like the possibility of cooler weather driving non-adherent persons to indoor gatherings.

Our study accounted for temporality by staggering COVID-19 outcome data after adherence measures. Nevertheless, it is possible that average mask adherence in a given month does not capture the most effective time period that influences COVID-19 rates. For example, mask wearing in the two weeks before rates begin to rise might be a more sensitive way to measure the association. If this is true, we would expect associations between mask adherence and high COVID-19 rates to be even stronger. It is also possible that survey respondents misreported their mask wearing adherence; whether they would be more or less likely to over or under-report is open to speculation, but residents in states with mask wearing policy might over-report adherence to appear compliant. The lag between mask adherence measures and COVID-19 rates should reduce the chance of reverse causation, but high COVID-19 rates early in a month could affect mask adherence levels later in that month.

It is important to note that state level distributions of demographic factors do not account for concentrations or sparsity of populations within a given state. Further, our adjustment for demographic factors at the state population level may not represent the true underlying forces that put individuals at greater risk of contracting COVID-19. Though demographic factors

were measured as proportions of the population, even if they were considered to be indicators for individual level characteristics, they do not denote an inherent biologic association with the outcome and more likely reflect structural inequities that lead to higher rates of infection in minoritized populations. Another consideration is that access to COVID-19 testing appears to vary from state to state [21]. Our study was also limited by the lack of information on accessibility of COVID-19 testing; if less accessible testing is associated with less mask adherence, the associations we report here may be under-estimates.

Our analysis of state and D.C.-level data does not account for variations in policy, adherence, and demographic factors at smaller geographic levels, such as county-levels. Further analyses of more granular geographic regions would be a logical next step. Indeed, associations between mask policy, adherence and other factors may be obscured in states with many high density and low density areas.

Conclusions

In conclusion, we show that mask wearing adherence, regardless of mask wearing policy, may curb the spread of COVID-19 infections. We recommend renewed efforts be employed to improve adherence to mask wearing.

Following the detection of the new coronavirus¹ severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and its spread outside of China, Europe has experienced large epidemics of coronavirus disease 2019 (COVID-19). In response, many European countries have implemented non-pharmaceutical interventions, such as the closure of schools and national lockdowns. Here we study the effect of major interventions across 11 European countries for the period from the start of the COVID-19 epidemics in February 2020 until 4 May 2020, when lockdowns started to be lifted. Our model calculates backwards from observed deaths to estimate transmission that occurred several weeks previously, allowing for the time lag between infection and death. We use partial pooling of information between countries, with both individual and shared effects on the time-varying reproduction number (R_t). Pooling allows for more information to be used, helps to overcome idiosyncrasies in the data and enables more-timely estimates. Our model relies on fixed estimates of some epidemiological parameters (such as the infection fatality rate), does not include importation or subnational variation and assumes that changes in R_t are an immediate response to interventions rather than gradual changes in behaviour. Amidst the ongoing pandemic, we rely on death data that are incomplete, show systematic biases in reporting and are subject to future consolidation. We estimate that—for all of the countries we consider here—current interventions have been sufficient to drive R_t below 1 (probability $R_t < 1.0$ is greater than 99%) and achieve control of the epidemic. We estimate that across all 11 countries combined, between 12 and 15 million individuals were infected with SARS-CoV-2 up to 4 May 2020, representing between 3.2% and 4.0% of the population. Our results show that major non-pharmaceutical interventions—and lockdowns in particular—have had a large effect on reducing transmission. Continued intervention should be considered to keep transmission of SARS-CoV-2 under control.

Following the identification of the new coronavirus SARS-CoV-2 in Wuhan (China) in December 2019 and its global spread, large epidemics of COVID-19 have ensued in Europe. In response to the rising numbers of cases and deaths and to preserve health systems, European countries—as with those in Asia—have implemented measures to control their epidemics. These large-scale non-pharmaceutical interventions vary between countries, but include social distancing (such as banning large gatherings), border closures, school closures, measures to isolate symptomatic individuals and their contacts, and large-scale lockdowns of populations with all but essential internal travel banned. Understanding whether these interventions have had the desired effect of controlling

the epidemic, and which interventions are necessary to maintain control, is critical given their large economic and social costs. The key aim of these interventions is to reduce R_t , a fundamental epidemiological quantity that represents the average number of infections generated at time t by each infected case over the course of their infection.

In China, strict movement restrictions and other measures (including case isolation and quarantine) began to be introduced from 23 January 2020, which achieved a downward trend in the number of confirmed new cases during February and resulted in zero new confirmed indigenous cases in Wuhan by 19 March 2020. Studies have estimated how the values of R_t changed during this time in different

Article

areas of China, from around 2–4 during the uncontrolled epidemic to below 1 (refs. ^{1,2}).

Estimating R_t for SARS-CoV-2 presents challenges, owing to the high proportion of infections that are not detected by health systems^{1,3,4} and to the regular changes in testing policies, which resulted in different proportions of infections being detected over time and between countries. Initially, most countries had the capacity to test only a small proportion of suspected cases and reserved tests for severely ill patients or for high-risk groups (for example, the contacts of positively tested individuals).

An alternative way to estimate the course of the epidemic is to calculate backwards from observed deaths to the number of infections. We introduce a Bayesian mechanistic model linking the infection cycle to observed deaths, inferring the total population infected (attack rates) as well as R_t . We assess whether there is evidence that interventions have so far been successful at reducing R_t to values below 1. We simulate a hypothetical counterfactual scenario in which R_t remains at starting levels to estimate the deaths that would have occurred without interventions.

Reported deaths are likely to be far more reliable than case data—although reported death data still have limitations. First, early deaths attributable to COVID-19 may have been missed. Second, there is variation in the reporting of deaths by country and over time. Third, reporting delays are expected and can be both systematic and random in nature. We attempt to overcome these data limitations by using a consolidated data source, incorporating noise in our observational model, partially pooling of information between countries and performing a sensitivity analysis under scenarios of underreporting to test our conclusions (Supplementary Information).

Our model relies on fixed estimates of some epidemiological parameters, such as the onset-to-death distribution, the infection fatality rate and the generation distribution, that are based on previous work^{5,6}; we perform a sensitivity analysis on these parameters. Our parametric form of R_t assumes that changes in R_t are an immediate response to interventions rather than gradual changes in behaviour, and it does not include importation or subnational variation. We assume that individual interventions have a similar effect in different countries, and that the efficacy of these interventions remains constant over time. Our framework infers R_t from mortality data, while accounting for time lags since infections occurred. As a result, even with perfect data and partial pooling, we cannot perfectly predict the current value of R_t . However, the credible intervals on R_t show the self-consistent behaviour that is a hallmark of a fully Bayesian analysis throughout the entire period we study, exhibiting appropriate shrinkage as more data become available (Supplementary Videos 1–3).

Italy was the first European country to begin major non-pharmaceutical interventions, and other countries followed soon afterwards (Extended Data Fig. 4). The onset of interventions ranged between 2 March and 29 March 2020. We analysed data on mortality from COVID-19 in 11 European countries until 4 May 2020, at which point lockdowns were relaxed in Italy and Spain. For each country, we model the number of infections, the number of deaths and R_t (Fig. 1). R_t is modelled as a piecewise constant function that changes only when an intervention occurs. Each country has its own individual starting R_t before interventions took place. For all countries, interventions are assumed to have the same relative effect on R_t and are informed by mortality data across all countries. The only exception is that we use partial pooling to introduce country-specific effects of the effectiveness of the last intervention introduced in the study period in a country (which is usually lockdown).

Estimated infections, R_t and effect sizes

In all countries, we estimate there are orders-of-magnitude fewer infections detected (Fig. 1, Extended Data Figs. 1, 2) than true infections, most

likely owing to mild and asymptomatic infections as well as limited testing capacities and changes in testing policy. In Italy, our results suggest that—cumulatively—2.8 (2.2–3.5) million people (all parenthetical ranges refer to 95% credible intervals) have been infected as of 4 May 2020, which gives an attack rate of 4.6% (3.6–5.8%) of the population (Table 1). In Spain (which has also experienced a large number of deaths), we estimate that 5.5% of the population (2.6 (2.1–3.3) million people) have been infected to date. Germany, the most populous country in our study, is estimated to have one of the lowest attack rates at 0.85% with 710,000 (550,000–930,000) people infected. Belgium has the highest estimated attack rates of 8%, followed by Spain with 5.5%. Although there have been few reliable national serological studies⁷, initial small-scale surveys in Austria⁸ and Denmark⁹ closely align with our estimates. A much larger study in Spain is very closely aligned with our estimates¹⁰. To some extent, these initial results validate our choice of infection fatality rate.

Averaged across all countries, we estimate the initial R_t to be 3.8 (2.4–5.6), consistent with previous analyses¹¹. These estimates are informed by our choice of generation-interval distribution and the initial growth rate of observed deaths. A shorter assumed generation time results in lower starting R_t (Supplementary Discussion 3). The initial values of R_t are also uncertain, owing to (a) importation (rather than local transmission) being the dominant source of new infections in the early period of the epidemic and (b) possible under-ascertainment in deaths, particularly before testing became widespread. We perform sensitivity analyses around these parameters (Supplementary Discussions 10, 11).

We estimate large reductions in R_t in response to the combined non-pharmaceutical interventions. Our results—which are driven more by countries with advanced epidemics and larger numbers of deaths—suggest that these interventions have together had a substantial effect on transmission, as measured by changes in the estimated R_t . At the time of this study, we find current estimates of R_t to range from a posterior mean of 0.44 (0.26–0.61) for Norway to a posterior mean of 0.82 (0.73–0.93) for Belgium, with an average of 0.66 across the 11 countries—an 82% reduction compared to the pre-intervention values. For all countries, we find that current interventions have been sufficient to drive R_t below 1 (probability $R_t < 1.0$ is greater than 99% across all countries we consider) and achieve control of the epidemic. These conclusions are corroborated by studies from individual countries—France¹², Spain¹³, Germany¹⁴ and the UK¹⁵—over a similar period, which arrive at very similar estimates despite different methodologies and data. For example, a previous study¹² estimates an R_t of 0.67 for France using hospitalization records (we estimate 0.68); for Germany, the Robert Koch Institute reports R_t of 0.76 using electronically notified cases¹⁴ (we estimate 0.71). The retrospective stability of our model (Supplementary Videos 1–3) is variable when the implementations of interventions are very dissimilar; an example of this is seen in Sweden, where interventions were dissimilar to other countries and led initially to large uncertainty. Our model uncertainty is also dependent on the magnitude of R_t ; this occurs because infections are a nonlinear function of R_t and are sensitive to small increases. Uncertainty shrinks greatly when R_t is reduced. Examples of this effect are seen in all countries, but it is most pronounced in Belgium and France; these countries show large uncertainties in the number of infections in the early period of the epidemic. Our choice of parameterizing R_t using piecewise constant functions means that we cannot capture the fine-scale variation that could be achieved by using additional covariates.

Lockdown has an identifiable large effect on transmission (81% (75–87%) reduction) (Fig. 2). The close spacing of interventions in time (Extended Data Fig. 4) means that the individual effects of the other interventions are not identifiable (Fig. 2). Our partial pooling model requires only one country to provide a signal for the effect of a given intervention, and this effect is then shared across all countries. Although this sharing can potentially lead to initial over- or under-estimation of the effect of an intervention, it also means that a

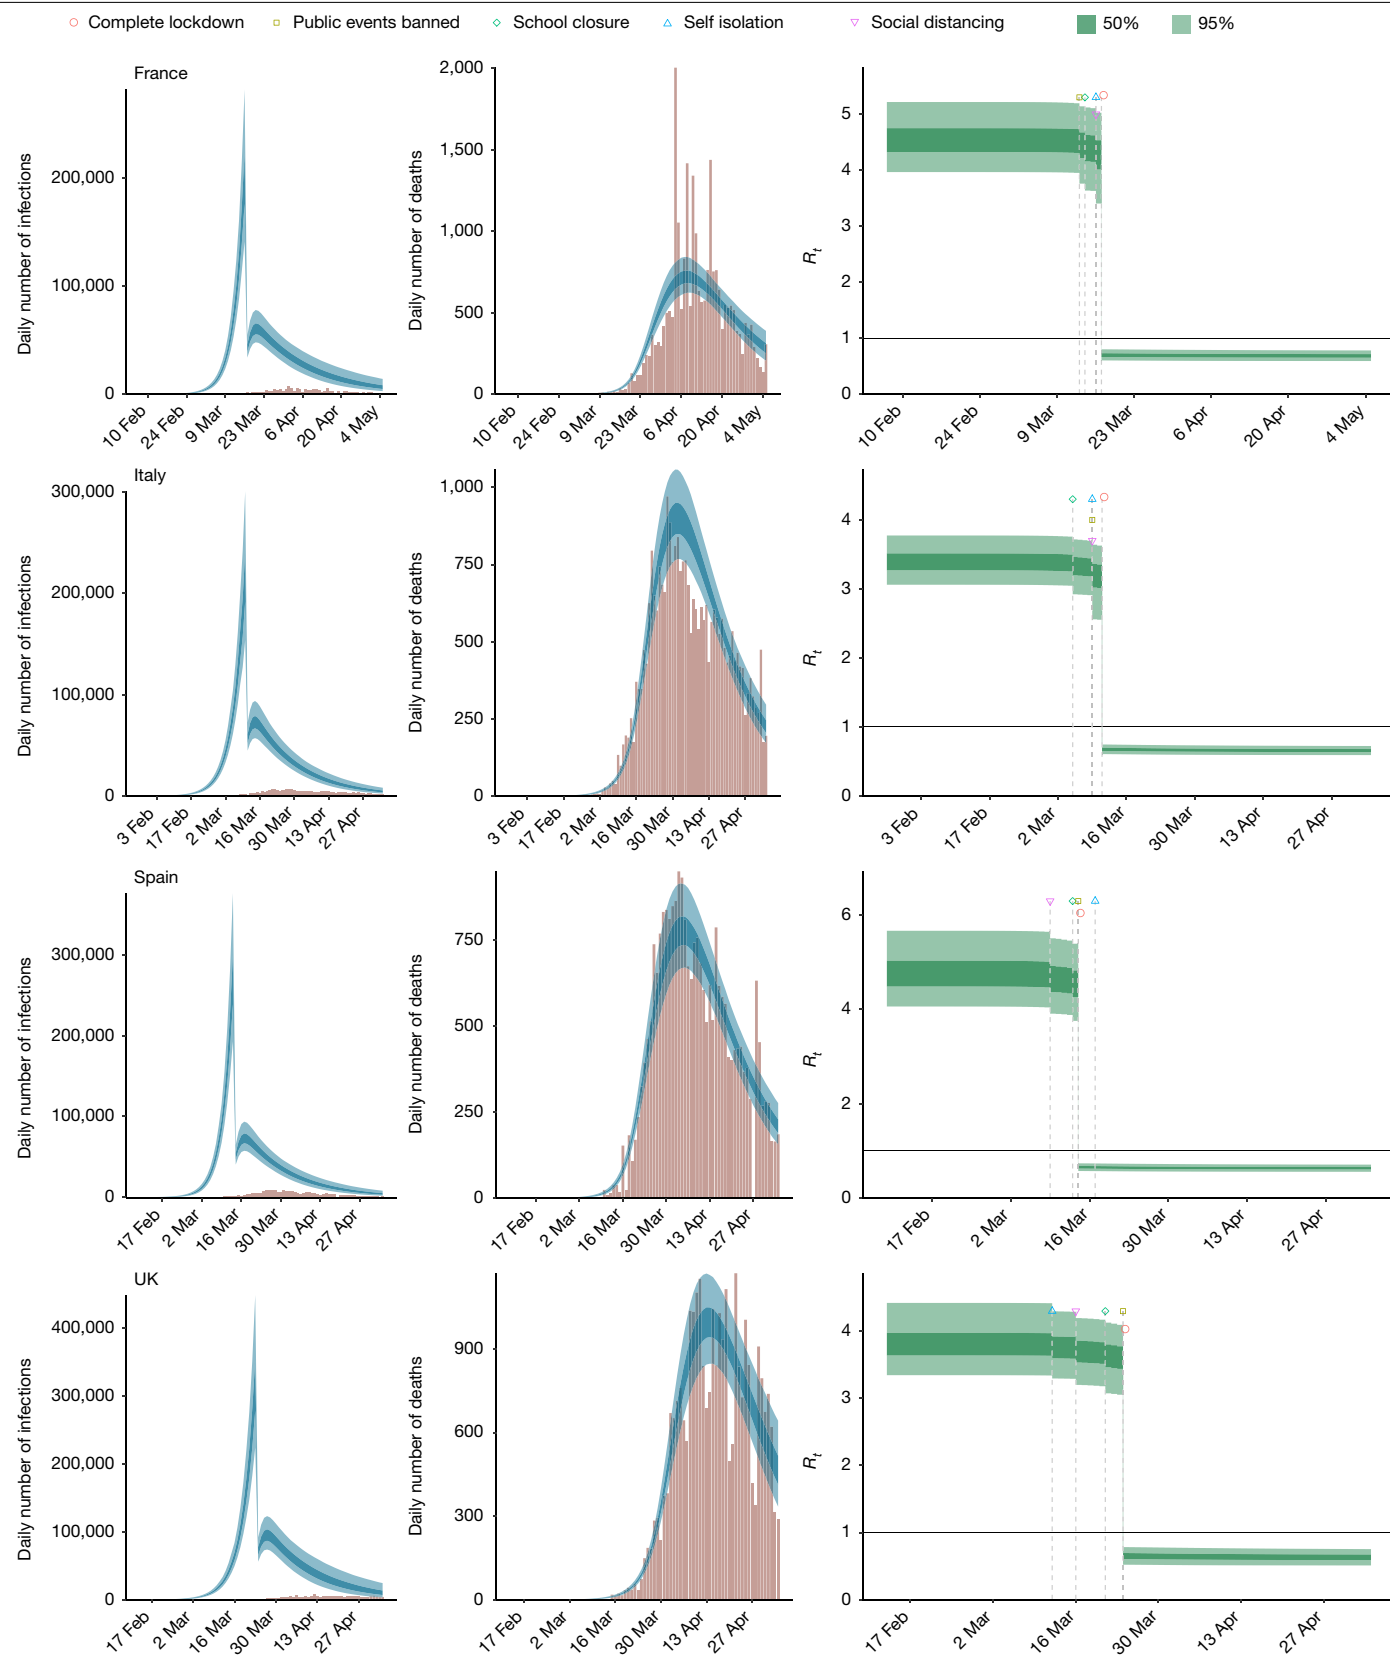

Fig. 1 | Country-level estimates of infections, deaths and R_t for France, Italy, Spain and the UK. Left, daily number of infections. Brown bars are reported infections; blue bands are predicted infections; dark blue, 50% credible interval; light blue 95% credible interval. The number of daily infections estimated by our model drops immediately after an intervention, as we assume that all infected people become immediately less infectious through the

intervention. Afterwards, if R_t is above 1, the number of infections will start growing again. Middle, daily number of deaths. Brown bars are reported deaths; blue bands are predicted deaths; credible intervals are as in the left plot. Right, R_t . Dark green, 50% credible interval; light green, 95% credible interval. Icons are interventions, shown at the time at which they occurred.

Table 1 | Total population infected by country

Country	Percentage of total population infected (mean (95% credible interval))
Austria	0.76% (0.59–0.98%)
Belgium	8% (6.1–11%)
Denmark	1.0% (0.81–1.4%)
France	3.4% (2.7–4.3%)
Germany	0.85% (0.66–1.1%)
Italy	4.6% (3.6–5.8%)
Norway	0.46% (0.34–0.61%)
Spain	5.5% (4.4–7.0%)
Sweden	3.7% (2.8–5.1%)
Switzerland	1.9% (1.5–2.4%)
UK	5.1% (4.0–6.5%)

Posterior model estimates of the attack rate by country (percentage of total population infected) as of 4 May 2020. Results are derived from a model representing 11 countries with a total population of 375 million and 128,928 reported COVID-19-related deaths up to 4 May 2020.

consistent signal for all countries can be estimated before that signal is present in data from an individual country¹⁶. Therefore, this sharing is potentially useful for generating early warnings, by leveraging what happened in countries with earlier epidemics to inform countries with more-recent epidemics.

Estimated effect of interventions on deaths

Extended Data Table 1 shows total deaths forecast from the beginning of the epidemic up to and including 4 May 2020 under our fitted model and under the counterfactual model, which predicts what would have happened if no interventions were implemented (and $R_t = R_0$; that is, the initial R_t estimated before interventions came into effect).

By comparing the deaths predicted under the model with no interventions to the deaths predicted in our intervention model, we calculated the total deaths averted in our study period. We find that across 11 countries 3.1 (2.8–3.5) million deaths have been averted owing to interventions since the beginning of the epidemic; Extended Data Fig. 5 compares the actual total deaths to the counterfactual total deaths. The counterfactual model without interventions is illustrative only, and reflects the assumptions of our model. We do not account for changes in behaviour; in reality, even in the absence of government interventions we would expect R_t to decrease and therefore would overestimate deaths in the no-intervention model. Conversely, we do not consider the effect on the infection fatality rate as a result of an overwhelmed health system in which patients may not be able to access critical care facilities, which would underestimate the number of counterfactual deaths. In the Supplementary Information, we show further counterfactual estimates under differing assumptions of the generation distribution and onset-to-death distribution and all scenarios broadly show the same trends. Given this agreement across differing scenarios, we believe our estimates for the counterfactual deaths averted to be plausible.

Discussion

During the ongoing transmission of SARS-CoV-2 in Europe, we analyse trends in the numbers of deaths to assess the extent to which transmission has been reduced. Representing the infection process associated with COVID-19 using a semi-mechanistic, joint Bayesian hierarchical model, we can reproduce trends observed in the data relating to deaths and produce empirically driven predictions that are valid over short time horizons.

We estimate that there have been many more infections than are currently reported. The high level of under-ascertainment of infections

Fig. 2 | Effectiveness of interventions on R_t . Our model includes five covariates for governmental interventions, adjusting for whether the intervention was the first one undertaken by the government in response to COVID-19 (red) or was subsequent to other interventions (green). Mean relative percentage reduction in R_t is shown with 95% posterior credible intervals. If 100% reduction is achieved, $R_t = 0$ and there is no more transmission of COVID-19. Lockdown is significantly different from the other interventions; the other interventions are not significantly different from each other, probably owing to the fact that many interventions occurred on the same day or within days of each other (as shown in Extended Data Fig. 4). Results are derived from a model that represents 11 countries with a total population of 375 million and 128,928 reported COVID-19-related deaths up to 4 May 2020.

that we estimate here is probably due to the focus on testing in hospital settings, which misses milder or asymptomatic cases in the community. Despite this, we estimate that only a relatively small minority of individuals in each country have been infected (Table 1). Our estimates imply that the populations in Europe are not close to herd immunity (about 70% if R_0 is 3.8)¹⁷. Furthermore, with values of R_t below 1 in all countries, the rate of acquisition of herd immunity will slow down rapidly. Our estimates for attack rates during our study period are consistent with those reported from national serological studies⁷. Similarly, comparable studies estimating R_t all agree that the number as of 4 May 2020 is less than 1.

To our knowledge, our modelling approach is unique in pooling information from multiple countries at once. Using this approach means that we require a central consolidated data source (such as data from the European Centre of Disease Control (ECDC)), and also that trends in some countries will be affected by those countries with more data. We argue that this effect is beneficial, in that it helps to minimize idiosyncrasies in the data¹⁶, as well as to improve consistency of estimates over time. Although our qualitative conclusions surrounding the effect of interventions and the finding that R_t is less than 1 are robust to our choice of whether to incorporate pooling or not, the ability to use a greater extent of available data and share information across countries in a statistically principled manner markedly improves the consistency of model predictions across the study period (Supplementary Videos 1–3).

Most interventions were implemented in rapid succession in many countries, and as such it is difficult to disentangle the individual effect sizes of each intervention. In our analysis, we find that only the effect of lockdown is identifiable, and that it has a substantial effect (81% (75–87%) reduction in R_t). Taking into account country-specific effects, the effect size of lockdown remains large across all countries (Supplementary Fig. 29).

We acknowledge the limitations of existing mortality data relating to COVID-19—in particular, deaths outside hospitals may be underreported. However, by using the ECDC data, we rely on a comprehensive data source that is refined and updated each day in a systematic process. Our sensitivity analysis of underreporting and statistical-measurement noise suggests that we may slightly

underestimate the attack rates in some countries, but this does not change our overall conclusions pertaining to R_t . However, even if the data were complete, our method cannot surmount the time lag between infections and deaths and can only fully identify trends in infections 2–3 weeks earlier. Extensions of our model could use case, hospitalization or intensive care data, but reconciling the different biases inherent in these sources while ensuring parsimony is challenging and would require additional assumptions.

The modern understanding of infectious disease, combined with a global publicized response, has meant that nationwide interventions could be implemented with widespread adherence and support. Given the observed infection fatality ratios and the epidemiology of COVID-19, major non-pharmaceutical interventions have had an effect in reducing transmission in all of the countries we have considered. In all countries in this study, we find that these interventions have reduced R_t below 1, and have contained their epidemics at the current time. When looking at simplistic counterfactual models over the whole epidemic, the number of potential deaths averted is substantial. We cannot say for certain that the current measures will continue to control the epidemic in Europe; however, if current trends continue there is reason for optimism.

Methods

Data

Our model uses daily consolidated death data from the ECDC for 11 European countries currently experiencing the COVID-19 epidemic: Austria, Belgium, Denmark, France, Germany, Italy, Norway, Spain, Sweden, Switzerland and the UK. The ECDC provides information on confirmed cases and deaths attributable to COVID-19. For population counts, we use the United Nations Population Division age-stratified counts¹⁸.

We also catalogue data on the nature and type of major non-pharmaceutical interventions. We looked at the government webpages from each country as well as their official public health webpages to identify the latest advice or laws being issued by the government and public health authorities. We collected the following: school closure ordered; case-based measures; public events banned; social distancing encouraged; lockdown decreed; and the time of the first and last intervention. A full list of the timing of these interventions and the sources we have used is provided in the Supplementary Notes, Supplementary Table 2.

By using the ECDC data, we rely on a consolidated data source compiled by the ECDC, who include many sources of data each day, constantly refining and updating data using a comprehensive and systematic process. However, despite the rigorous protocols, countries may vary in the specifics of the data that they report to the ECDC. For example, there is variation in reporting (that is, community versus hospital) and time lags. Despite these issues, we use ECDC data to ensure as much consistency as possible across all countries.

Model

A visual summary of our model is presented in Extended Data Fig. 3; details are provided in the Supplementary Methods.

We fit our model to observed deaths according to ECDC data from 11 European countries. The modelled deaths are informed by an infection-to-death distribution (Supplementary Fig. 1; derived from assumptions about the time from infection to the onset of symptoms and about the time from the onset of symptoms to death), and the population-averaged infection fatality ratio (adjusted for the age structure and contact patterns of each country, as discussed in the Supplementary Methods, Supplementary Table 3).

Given these distributions and ratios, modelled deaths are a function of the number of infections. The number of infections is modelled as the product of R_t with a discrete convolution of the previous infections. Individual components of this convolution sum are weighted by the generation time distribution (the average time from the infection of one person to the time at which they infect another; Supplementary Fig. 2). In our work, we approximate the generation time distribution using the serial interval distribution. R_t is a function of the initial R_t before interventions and the effect sizes from interventions, in which interventions are modelled as piecewise constant functions.

Following the Bayesian hierarchy from bottom to top gives us a full framework to see how interventions affect infections, which can result in deaths. A schematic of our model is shown in Extended Data Fig. 3. To maximize the ability to observe the effect of interventions on deaths, we fit our model jointly for all 11 European countries, and use partial pooling of information between countries with both individual and shared effects on R_t . Partial pooling operates on the last intervention, which is—in most cases—lockdown. The effect of partial pooling can be seen in Supplementary Discussion 12, Supplementary Fig. 29. We chose a balanced prior that encodes the prior belief that interventions have an equal chance of having an effect or not, and ensure a uniform prior on the joint effect of all interventions (Supplementary Fig. 3). We evaluate the effect of our Bayesian prior distribution choices and evaluate our Bayesian posterior calibration to ensure our results are statistically robust.

We perform extensive model validation and sensitivity analyses. We validate our model by cross-validation over a 14-day period (Supplementary Discussion 1, Supplementary Table 1) and we show the fits for holdout samples in Supplementary Figs. 5–15. We check the convergence of the Markov chain Monte Carlo sampler (Supplementary Fig. 4). We consider the sensitivity of our estimates of R_t to the mean of the generation distribution (Supplementary Discussion 3, Supplementary Figs. 16, 17). We further show that the choice of generation distribution does not change our counterfactual conclusions (Supplementary Fig. 18). Using univariate analyses and uninformative priors, we find (Supplementary Fig. 19) that all effects on their own serve to decrease R_t (Supplementary Discussion 4). We compare our model to a non-parametric Gaussian Process model (Supplementary Discussion 5). To assess the effect of individual countries on the results, we perform a ‘leave one country out’ sensitivity analysis (Supplementary Discussion 6, Supplementary Figs. 20, 21). To validate our starting values of R_t , we compare our model against an exponential-growth linear model (Supplementary Discussion 7, Supplementary Fig. 22). Instead of a joint analysis, we consider fits of our model to individual countries (Supplementary Discussion 8, Supplementary Figs. 23–26). We perform a sensitivity analysis with respect to the onset-to-death distribution (Supplementary Discussion 9, Supplementary Fig. 27). We validate our probabilistic seeding scheme through an importance-sampling leave-one-out cross-validation (Supplementary Discussion 10). We consider a model extension with a constant, probabilistic under-reporting (Supplementary Discussion 11), finding that R_t does not change substantially (Supplementary Fig. 28).

Our model is different to other approaches (such as EpiEstim¹⁹) that use the discrete renewal equation. We use the renewal equation as a latent process to model infections and propose a generative mechanism to connect these infections to death data. Simply applying the renewal equation directly to death data requires positing a mechanism in which deaths in the past can cause future deaths (see, for example, ref.²⁰). In addition, for R_t , we are able to use a functional relationship in which non-pharmaceutical interventions can have a direct effect on R_t .

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

COVID-19 in children and adolescents in Europe: a multinational, multicentre cohort study

Florian Göttinger*, Begoña Santiago-García*, Antoni Noguera-Julián, Miguel Lanaspá, Laura Lancella, Francesca I Calò Carducci, Natalia Gabrovská, Svetlana Velizarova, Petra Prunk, Veronika Osterman, Uros Krivec, Andrea Lo Vecchio, Delane Shingadia, Antoni Soriano-Arandes, Susana Melendo, Marcello Lanari, Luca Pierantoni, Noémie Wagner, Arnaud G L'Huillier, Ulrich Heininger, Nicole Ritz, Srinil Bandi, Nina Krajcar, Srđan Roglić, Mar Santos, Christelle Christiaens, Marine Creuven, Danilo Buonsenso, Steven B Welch, Matthias Bogyi, Folke Brinkmann, Marc Tebrügge, on behalf of the ptbnet COVID-19 Study Group†

Summary

Background To date, few data on paediatric COVID-19 have been published, and most reports originate from China. This study aimed to capture key data on children and adolescents with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection across Europe to inform physicians and health-care service planning during the ongoing pandemic.

Methods This multicentre cohort study involved 82 participating health-care institutions across 25 European countries, using a well established research network—the Paediatric Tuberculosis Network European Trials Group (ptbnet)—that mainly comprises paediatric infectious diseases specialists and paediatric pulmonologists. We included all individuals aged 18 years or younger with confirmed SARS-CoV-2 infection, detected at any anatomical site by RT-PCR, between April 1 and April 24, 2020, during the initial peak of the European COVID-19 pandemic. We explored factors associated with need for intensive care unit (ICU) admission and initiation of drug treatment for COVID-19 using univariable analysis, and applied multivariable logistic regression with backwards stepwise analysis to further explore those factors significantly associated with ICU admission.

Findings 582 individuals with PCR-confirmed SARS-CoV-2 infection were included, with a median age of 5·0 years (IQR 0·5–12·0) and a sex ratio of 1·15 males per female. 145 (25%) had pre-existing medical conditions. 363 (62%) individuals were admitted to hospital. 48 (8%) individuals required ICU admission, 25 (4%) mechanical ventilation (median duration 7 days, IQR 2–11, range 1–34), 19 (3%) inotropic support, and one (<1%) extracorporeal membrane oxygenation. Significant risk factors for requiring ICU admission in multivariable analyses were being younger than 1 month (odds ratio 5·06, 95% CI 1·72–14·87; $p=0·0035$), male sex (2·12, 1·06–4·21; $p=0·033$), pre-existing medical conditions (3·27, 1·67–6·42; $p=0·0015$), and presence of lower respiratory tract infection signs or symptoms at presentation (10·46, 5·16–21·23; $p<0·0001$). The most frequently used drug with antiviral activity was hydroxychloroquine (40 [7%] patients), followed by remdesivir (17 [3%] patients), lopinavir–ritonavir (six [1%] patients), and oseltamivir (three [1%] patients). Immunomodulatory medication used included corticosteroids (22 [4%] patients), intravenous immunoglobulin (seven [1%] patients), tocilizumab (four [1%] patients), anakinra (three [1%] patients), and siltuximab (one [1%] patient). Four children died (case-fatality rate 0·69%, 95% CI 0·20–1·82); at study end, the remaining 578 were alive and only 25 (4%) were still symptomatic or requiring respiratory support.

Interpretation COVID-19 is generally a mild disease in children, including infants. However, a small proportion develop severe disease requiring ICU admission and prolonged ventilation, although fatal outcome is overall rare. The data also reflect the current uncertainties regarding specific treatment options, highlighting that additional data on antiviral and immunomodulatory drugs are urgently needed.

Funding ptbnet is supported by Deutsche Gesellschaft für Internationale Zusammenarbeit.

Introduction

In late December, 2019, WHO was notified of an unusual cluster of pneumonia cases in Wuhan, China. The disease, later termed COVID-19, spread quickly beyond the borders of China, with the first cases in Europe being recorded on Jan 25, 2020.¹

Subsequent investigations identified a novel beta-coronavirus now designated as severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2).² Currently, there

are no antiviral treatment options with proven efficacy, but several randomised controlled trials are investigating agents such as hydroxychloroquine, lopinavir–ritonavir, favipiravir, and remdesivir (eg, NCT04336904, NCT04328285, and NCT04280705). Other trials are focusing on immunomodulators, including tocilizumab and anakinra (eg, NCT04317092 and NCT04330638).

To date, data on COVID-19 in children and adolescents remain scarce, despite the number of confirmed COVID-19

Research in context

Evidence before this study

We searched MEDLINE on May 7, 2020, through the PubMed interface to identify publications describing clinical studies in children with COVID-19. To ensure a broad search, the search terms used were "(child OR children OR pediatric OR paediatric) AND COVID-19". No additional limits were set. This search yielded 809 papers: 104 case reports or case series; 38 epidemiological reports; 66 guidelines and consensus statements; 184 reviews, perspectives, or editorials without original data; and 53 letters; 332 were unrelated to children with COVID-19. 22 papers presented original data, but exclusively in adults. Only ten papers reported clinical studies in children with COVID-19: eight papers originated from China, one from Spain, and one from Italy. The study by Tagarro and colleagues was reported in letter format, and only included 41 children with confirmed severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection in Madrid. The study from Italy by Parri and colleagues was also reported as a letter and included 100 cases across several Italian hospitals. However, the study only featured a single patient who required mechanical ventilation, and consequently very few data on children with COVID-19 at the severe end of the disease spectrum.

Added value of this study

To our knowledge, this study is the first multinational, multicentre study in children with COVID-19, and provides a detailed overview on SARS-CoV-2 infection in children in

Europe during the initial peak of the pandemic, which was facilitated by a collaboration of 82 units across 25 European countries. The study has several key findings. First, the data show that COVID-19 is generally a mild disease in children, including infants. Second, the study found that a substantial proportion (8%) of children develop severe disease, requiring intensive care support and prolonged ventilation. Several predisposing factors for requiring intensive care support were identified. Third, the study confirms that fatal outcome is rare in children. There was considerable variability in the use of drugs with antiviral activity as well as immunomodulatory medication, reflecting current uncertainties regarding specific treatment options.

Implications of all the available evidence

This study confirms previous reports from China suggesting that the case-fatality rate of COVID-19 in children is substantially lower than in older adult patients. However, some children develop severe disease and require prolonged intensive care support, which should be accounted for in the planning of health-care services and allocation of resources during the ongoing pandemic. Finally, the findings highlight that data on antiviral and immunomodulatory drugs are urgently needed from well designed, randomised controlled trials in children, to enable paediatricians to make evidence-based decisions regarding treatment choices for children with severe COVID-19.

cases now exceeding 8 million globally.^{3,4} Most published data originate from China, which cannot necessarily be extrapolated to children in Europe and elsewhere.⁵⁻¹² Also, existing papers from China contain very few clinical data on children, and most lack details regarding supportive measures required by children with COVID-19. Similarly, recent epidemiological reports from Europe and North America contain little clinically relevant information.^{13,14} Determining the level of support required by children is essential for paediatric service planning during the ongoing COVID-19 pandemic.

By use of a well established research network, predominately comprising paediatric infectious diseases specialists and paediatric pulmonologists, the aim of this study was to rapidly capture key data on COVID-19 in children in Europe on a large scale, to aid physicians in Europe and in other geographical locations with service planning and allocation of resources.

Methods

Study design and participants

For this cohort study, European members of the Paediatric Tuberculosis Network European Trials Group (ptbnet)—which currently includes 304 clinicians and researchers, most of whom are based at tertiary or quaternary paediatric infectious diseases or paediatric

pulmonology units, across 128 paediatric health-care institutions in 31 European countries¹⁵⁻²⁰—were invited to contribute cases of confirmed SARS-CoV-2 infection that had been managed at or managed remotely by their health-care institution (including individuals admitted to other hospitals or identified during community screening) before or during the study period. Any individual aged 18 years or younger with SARS-CoV-2 infection confirmed by RT-PCR was eligible for inclusion. A standardised data collection spreadsheet was used by collaborators to record data from their centre. All data were reviewed by three of the investigators (FG, BS-G, and MT), and any inconsistencies and other data queries were clarified with the reporting collaborators. Units that did not see any cases before or during the study period were asked to report the absence of cases fulfilling the inclusion criteria at the end of the study period. The study was done over a 3·5-week period, from April 1 to April 24, 2020.

The study was reviewed and approved by the ptbnet steering committee, and the human research ethics committees of the University of Bochum, Germany (19-6545-BR), the Hospital Gregorio Marañón, Spain (CEIM HGUGM-177/20), and the city of Vienna, Austria (EK 20-071-VK). The study was conducted in accordance with the Declaration of Helsinki and its subsequent

amendments. No personal or identifiable data were collected during the conduct of this study.

Study definitions

A confirmed case was defined as a patient in whom SARS-CoV-2 was detected in any clinical sample (respiratory tract, blood, stool, or cerebrospinal fluid) by RT-PCR. PCR testing was done as part of routine clinical care, and therefore done according to local testing guidelines in place at the time. Date of symptom onset was defined as the day when the first symptom or sign occurred, and date of diagnosis as the day when SARS-CoV-2 was first detected. Pyrexia was defined as a body temperature at least 38·0°C. The index case was defined as the most likely source case based on history; if multiple family members were affected, the person who displayed symptoms first was recorded. Diagnosis of upper respiratory tract infection was based on clinical signs and symptoms, encompassing any of the following: coryza, pharyngitis, tonsillitis, otitis media, or sinusitis. Lower respiratory tract infection was based on clinical signs and auscultation findings. Inotropic support was defined as administration of dopamine, dobutamine, epinephrine, or norepinephrine by continuous infusion.

Statistical analysis

Non-parametric two-tailed Mann-Whitney *U* tests were used to compare continuous variables and χ^2 or Fisher's exact tests to compare categorical variables, as appropriate. In children younger than 2 years, age was calculated as fraction of a whole year (365 days); from 2 years of age, age was rounded to the nearest year. The 95% CI around the case-fatality rate (CFR) was calculated with the Wald method. Normality of data distribution was assessed with the Shapiro-Wilk test. The clinical endpoint was the need for admission to an intensive care unit (ICU; either neonatal or paediatric intensive care). The association of baseline characteristics and clinical findings with ICU admission was initially evaluated using univariable logistic regression. Subsequently, multivariable logistic regression analysis with the backward stepwise method was used to explore variables that were independently associated with ICU admission. Only variables that were significant in univariable analyses were introduced into the model. Factors associated with drug treatment for COVID-19 were also explored with univariable analysis. All probabilities are two tailed. $p < 0.05$ was considered statistically significant. All analyses were done with Prism (version 8.0; GraphPad, La Jolla, CA, USA) and SPSS (version 25.0; IBM, Armonk, NY, USA).

Role of the funding source

The funders had no role in the study design, data collection, data analysis, data interpretation, or writing of the manuscript. The corresponding author had full access to all the data and had the final responsibility for the decision to submit for publication.

Results

585 cases of SARS-CoV-2 infection were reported from 77 health-care institutions located in 21 European countries: Austria, Belgium, Bulgaria, Croatia, Denmark, Estonia, Germany, Greece, Hungary, Ireland, Italy, Lithuania, Norway, Portugal, Slovakia, Slovenia, Spain, Sweden, Switzerland, Turkey, and the UK (figure 1). Three cases did not meet the inclusion criteria (one 21-year-old individual and two individuals diagnosed with COVID-19 based on serological testing, but PCR negative). Five participating units in the Netherlands, Moldova, Ukraine, and Russia reported not having encountered any cases.

582 individuals with PCR-confirmed SARS-CoV-2 infection were included in the final analyses. 454 (78%) were contributed by tertiary or quaternary health-care institutions, whereas 54 (9%) had been diagnosed in secondary and 74 (13%) in primary health-care settings.

The median age of the study population was 5·0 years (IQR 0·5–12·0), ranging from 3 days to 18 years (table). Age was non-normally distributed ($W=0.8710$; $p<0.0001$), with 170 (29%) participants younger than 12 months (figure 2). The sex ratio was 1·15 males to every female. The most common source of infection was a parent, considered the index case in 324 (56%) individuals; for 24 (4%) individuals, the most probable index case was a sibling. In the remaining 234 (40%) individuals, the

Data are n (%), n/N (%), or median (IQR), unless stated otherwise. p values shown are based on univariable analyses, and calculated separately to the odds ratios. Odds ratios refer to the likelihood of admission to ICU, and were not calculated where one of the required values is zero. ICU=intensive care unit. ARDS=acute respiratory distress syndrome. *At diagnosis of COVID-19. †Only includes children aged 5 years or older in whom those data were recorded.

Table: Baseline characteristics in the entire cohort and by requirement of ICU admission

index case was a person outside of the immediate family or unknown. 363 (62%) individuals were admitted to hospital and 48 (8%) required admission to an ICU for additional support, corresponding to 13% of those admitted to hospital.

437 (75%) individuals had no pre-existing medical conditions. Among the remaining 145 (25%) individuals,

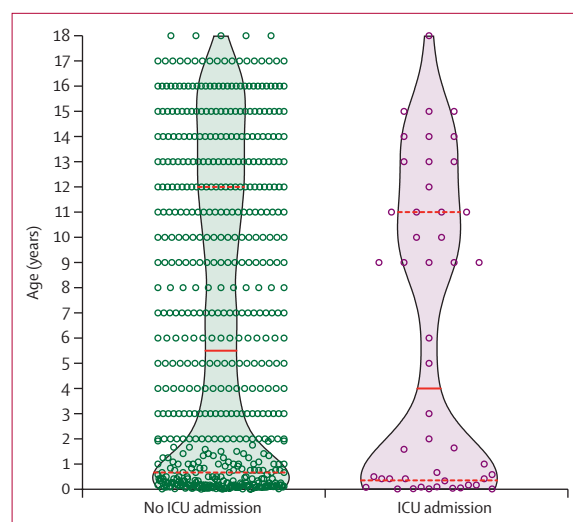

Figure 2: Violin plots showing the age distribution of patients by requirement of ICU support
Each circle represents a patient. The solid lines represent the medians and dashed lines represent IQRs. ICU=intensive care unit.

the most common conditions were chronic pulmonary disease (29 individuals, of whom 16 had asthma and six bronchopulmonary dysplasia), followed by malignancy (27 individuals, of whom 14 had leukaemia or lymphoma and 11 had solid tumours), neurological disorders (26 individuals, of whom nine had epilepsy and eight had cerebral palsy), congenital heart disease (25 individuals), chromosomal abnormalities (ten individuals, of whom eight had trisomy 21), and chronic kidney disease (nine individuals; table). 17 (3%) individuals had two or more pre-existing medical conditions.

29 (5%) individuals were receiving immunosuppressive medication at the time of COVID-19 diagnosis (table). Three (1%) had a previously diagnosed immunodeficiency, comprising common variable immunodeficiency, congenital neutropenia, and Schimke immuno-osseous dysplasia. 25 (4%) individuals were receiving chemotherapy at the time of their diagnosis or had received chemotherapy in the preceding 6 months. Three (1%) had previously undergone human stem cell transplant.

Pyrexia was the most common sign at presentation, observed in 379 (65%) individuals (table). Approximately half had signs or symptoms of upper respiratory tract infection and approximately a quarter had evidence of lower respiratory tract infection; 128 (22%) had gastrointestinal symptoms. 40 (7%) individuals with gastrointestinal symptoms had no respiratory symptoms; the majority (65%; n=26) of these individuals had pyrexia. 92 (16%) individuals were asymptomatic.

Dates when SARS-CoV-2 infection was confirmed by RT-PCR in the study population are summarised in figure 3. The median interval between symptom onset and diagnosis was 2 days (IQR 1–4; range 0–23); in the

majority (n=391; 67%) of cases, the interval was no more than 3 days. In eight cases, SARS-CoV-2 infection was confirmed before any signs or symptoms were present—mainly neonates born to SARS-CoV-2-positive mothers and household members of symptomatic adults with confirmed COVID-19.

A chest x-ray was done in 198 (34%) patients. Of those, 93 (47%) had changes consistent with pneumonia (table). Ten (5%) had changes suggestive of acute respiratory distress syndrome (ARDS), all of whom required mechanical ventilation. In 29 (5%) patients, additional viruses were detected in respiratory samples, comprising enterovirus or rhinovirus (n=18), influenza virus (n=5), parainfluenza virus (n=3), adenovirus (n=3), respiratory syncytial virus (RSV; n=2), bocavirus (n=2), and coronavirus NL63, coronavirus HKU1, coronavirus OC43, and human metapneumovirus (n=1 each). In 22 patients one virus was detected in addition to SARS-CoV-2; in six patients, two additional viruses were detected simultaneously; and in one patient, three were detected. Patients with one or more viral co-infections were more likely to have signs or symptoms of upper or lower respiratory tract infection at presentation compared with those in whom no additional viral agent was identified (appendix p 1). Furthermore, individuals with viral co-infection were significantly more likely to require ICU admission, respiratory support, or inotropic support.

507 (87%) individuals did not require respiratory support at any stage. 75 (13%) patients required oxygen support: 31 (5%) were started on continuous positive airway pressure (CPAP) and 25 (4%) on mechanical ventilation (including 14 who had been managed with CPAP initially). The median duration of mechanical ventilation was 7 days (IQR 2–11; range 1–34). One (<1%) patient was started on extracorporeal membrane oxygenation. 19 (3%) patients required support with inotropes.

When comparing individuals by their requirement of ICU admission, we found that patients who required ICU admission were younger than those who did not (ie, individuals in the community and those admitted to hospital but not needing ICU support), but this was not statistically significant (table; figure 2). In univariable analysis, being younger than 1 month of age, male sex, pre-existing medical conditions, pyrexia, signs or symptoms of lower respiratory tract infection, radiological changes suggestive of pneumonia or ARDS, and viral co-infection were associated with ICU admission (table). In multivariable analysis, the factors that remained associated with ICU admission were being younger than 1 month (odds ratio [OR] 5.06, 95% CI 1.72–14.87; p=0.0035), male sex (2.12, 1.06–4.21; p=0.033), signs or symptoms of lower respiratory tract infection at presentation (10.46, 5.16–21.23; p<0.0001), and presence of pre-existing medical conditions (3.27, 1.67–6.42; p=0.0015).

The most commonly used drug with antiviral activity was hydroxychloroquine, used in 40 (7%) patients, followed

Figure 3: Violin plot illustrating the dates SARS-CoV-2 infection was confirmed by RT-PCR in the study population, by country

Countries with fewer than five paediatric cases reported are not shown. Solid lines represent the medians and dashed lines represent IQRs. The date of the first case in each country is based on data reported by the European Centre for Disease Prevention and Control. SARS-CoV-2=severe acute respiratory syndrome coronavirus 2.

*First case of any age.

by remdesivir, which was used in 17 (3%) patients. Lopinavir–ritonavir was used in six (1%) patients and oseltamivir in three (1%), two of whom had influenza virus co-infection. Three (1%) patients received two drugs with antiviral activity and one (<1%) patient received three; all four patients had ARDS on chest x-ray. No patient received chloroquine, favipiravir, zanamivir, or ribavirin. With regard to immunomodulatory medication, 22 (4%) patients received systemic corticosteroids, seven (1%) intravenous immunoglobulin, four (1%) tocilizumab, three (1%) anakinra, and one (<1%) siltuximab. In univariable analysis, factors associated with treatment initiation of drugs with antiviral or immunomodulatory activity comprised pre-existing malignancy (OR 6.3, 95% CI 2.8–14.2), cardiac disease (4.2, 1.8–10.0), or respiratory disease (6.5, 3.0–14.2); immunosuppressive therapy at presentation (6.5, 3.0–14.2) or recent chemotherapy (6.1, 2.6–14.1); radiological findings suggestive of pneumonia (4.5, 2.3–8.6) or ARDS (22.3, 2.7–180.5); and viral co-infection (5.5, 2.5–12.2; all p<0.0001; appendix p 2).

Four patients, all older than 10 years, had a fatal outcome (CFR 0.69%, 95% CI 0.20–1.82), with death

See Online for appendix

For the European Centre for Disease Prevention and Control COVID-19 data see <https://ecdc.europa.eu/public/extensions/COVID-19/COVID-19.html>

occurring at 3, 9, 11, and 17 days after symptom onset. Two patients had no known pre-existing medical conditions; one had a cardiorespiratory arrest before arrival at the hospital and resuscitation was unsuccessful and the other died while being mechanically ventilated in ICU. The third patient had undergone human stem cell transplant 15 months earlier. The fourth patient was managed palliatively (without intubation), due to the severity of their pre-existing medical conditions. The remaining 578 patients were alive when the study closed. 93 (16%) individuals never developed clinical symptoms. In 460 (80%) individuals, all symptoms had resolved without apparent sequelae, whereas 25 (4%) were still symptomatic or were requiring respiratory support when the study closed.

Discussion

To our knowledge, this is the first multinational, multicentre study on paediatric COVID-19, and also the largest clinical study in children outside of China to date. The inclusion of such a substantial number of cases was made possible by involving a large number of specialist centres across Europe via a well established collaborative paediatric tuberculosis research network, allowing this study to provide one of the most detailed accounts of COVID-19 in children and adolescents published to date.

It is important to highlight that this study has primarily captured data from children and adolescents who were seen or managed within the hospital setting, and that the majority of participating units were part of tertiary or quaternary health-care institutions. Consequently, the study population is likely to primarily represent individuals at the more severe end of the disease spectrum. Notably, a recent letter summarising 171 PCR-confirmed cases in Wuhan suggests that close to 20% of children and adolescents with SARS-CoV-2 infection are asymptomatic.¹⁰ At the time our study was conducted, testing capacity for SARS-CoV-2 in many European countries was lower than clinical demand, and therefore many children with symptoms consistent with COVID-19 in the community were not tested and consequently not diagnosed. Nevertheless, our data indicate that children and adolescents are overall less severely affected by COVID-19 than adults, particularly older patients. Previous, large-scale data suggest that the CFR in adults older than 70 years is close to 10%,⁶ potentially due to immunosenescence.²¹ It is reassuring that our data show that severe COVID-19 is uncommon in young children, including infants, despite their immune maturation being incomplete,^{22,23} with only few requiring mechanical ventilation. It was striking that all children who died in our cohort were older than 10 years.

The Centers for Disease Control and Prevention (CDC) reported 2572 confirmed cases of COVID-19 in individuals younger than 18 years in the USA as of April 2, 2020, representing only 1.7% of the total number of recorded cases ($n=149\,760$).¹⁴ The Australian Health Protection Agency has reported that children accounted for only 4%

of confirmed COVID-19 cases in Australia.²⁴ Unfortunately, in the CDC report, clinical data were only available in a small proportion of patients ($n=291$; 11%). In concordance with our observations, fever and cough were the predominant clinical features at presentation (present in 56% and 54% of individuals, respectively), with similar rates observed in a study from Italy.²⁵ In our cohort almost a quarter of patients had gastrointestinal symptoms, some of whom had no respiratory symptoms, and a substantial proportion of children were entirely asymptomatic.

The CDC report also mentions three deaths,¹⁴ but it is unclear how many patients were still hospitalised by the time of publication, so it is difficult to come to firm conclusions regarding the CFR in US children. Our data indicate that the CFR in children and adolescents across Europe is less than 1%. Considering that many children with mild disease will never have been brought to medical attention, and therefore not diagnosed, it is highly probable that the true CFR is substantially lower than the figure of 0.69% observed in our cohort. This hypothesis is further supported by an epidemiological study from China, in which the CFR in individuals aged 19 years or younger was only 0.1% (one death in 965 confirmed cases).⁶ Furthermore, our data indicate that sequelae related to COVID-19 are likely to be rare in children and adolescents. However, after the closure of our study, reports of a hyperinflammatory syndrome affecting children that is temporally, and potentially causally, associated with SARS-CoV-2 infection have emerged, which has subsequently been named paediatric inflammatory multisystem syndrome temporally associated with SARS-CoV-2 (PIMS-TS; sometimes known as MIC-S).^{26,27} Further research will be required to characterise this emerging disease entity in detail, and determine the long-term outcome of affected children.

Importantly, our data show that severe COVID-19 can occur both in young children and in adolescents, and that a significant proportion of those patients require ICU support, frequently including mechanical ventilation. A small study from Madrid also found that four (10%) of 41 children with SARS-CoV-2 infection required admission to ICU.²⁸ In our cohort, being younger than 1 month, male sex, presence of lower respiratory tract infection signs or symptoms at presentation, and presence of a pre-existing medical condition were associated with increased likelihood of requiring ICU admission. Our results also show that the majority of children who are intubated due to respiratory failure require prolonged ventilation, often for 1 week or more. This contrasts with observations in children with RSV infection who, on average, only require mechanical ventilation for 5–7 days,²⁹ but is not dissimilar to observations in children with influenza.³⁰ This has important implications for service planning, as although the overall demand for ICU support might be lower in children than in adults, each patient is likely to occupy ICU space for an extended period of time. At this time of intense strain on health-care services worldwide, it is vital

that adequate resources are allocated to paediatric services to sustain the provision of high-quality care for children.

The observation that, in our study, individuals with viral co-infection (ie, infected with SARS-CoV-2 and one or more other viral agents) were more likely to require ICU support than those in whom SARS-CoV-2 was the only viral agent identified might have implications for the winter period 2020–21, when the incidence of other viral respiratory tract infections, including RSV and influenza virus infections, is bound to increase. This could result in a greater proportion of paediatric patients with COVID-19 requiring ICU support than in the cohort described here, as the influenza season 2019–20 was already over in Europe before the study commenced.

Our data also reflect the uncertainties regarding drug treatment options for COVID-19. In some countries, including Spain and Italy, national guidelines were encouraging the use of hydroxychloroquine for selected cases, as reflected in our data, while in other countries, recommendations were more guarded regarding the use of antiviral agents in the absence of robust human data. An expert consensus statement from the USA has emphasised that antiviral treatment should be reserved for patients at the severe end of the disease spectrum, ideally within a clinical trial.³¹ Overall, the expert panel appeared to favour the use of remdesivir over other agents, based on the currently available data from in-vitro and animal studies, including in non-human primates, and recent data from compassionate use in humans.^{32,33} The panel members' opinion was split regarding the use of lopinavir–ritonavir, given the disappointing results of a recently published randomised controlled trial.³⁴

The main limitation of this study relates to the number of variables for which data were collected. In the context of the ongoing COVID-19 pandemic, to ensure high levels of participation and avoid diverting substantial time away from clinical front-line duties, a decision was made not to collect detailed data on laboratory parameters or ICU interventions. A further limitation was that a variety of in-house and commercial PCR assays were used across different participating centres, precluding an assessment of diagnostic test performance. Also, the number of children receiving antiviral or immunomodulatory treatment was too small to draw meaningful conclusions regarding their effectiveness, which will be addressed by the aforementioned randomised trials. A further limitation is that different countries were using different thresholds to screen for SARS-CoV-2 at the time the study was done, with some recommending screening of all children admitted to hospital or conducting community screening, whereas others were using more selective testing strategies. Despite those limitations, to our knowledge, this study provides the most comprehensive overview on COVID-19 in children and adolescents to date.

In conclusion, our data, originating from a large number of specialist centres across Europe, show that COVID-19 is

usually a mild disease in children, including infants. Nevertheless, a small proportion of children and adolescents develop severe disease and require ICU support, frequently needing prolonged ventilatory support. However, fatal outcome is rare overall. Our data also reflect the current uncertainties regarding specific treatment options, highlighting that more robust data on antiviral and immunomodulatory drugs are urgently needed.

Contributors

MT conceived of the study. FG, BS-G, SBW, MB, FB, and MT designed the study. FG, BS-G, and MT cleaned and analysed the data, constructed the figures, and wrote the first draft of the manuscript. All authors contributed data to the study, contributed to the data interpretation, critically reviewed the manuscript, and approved the final manuscript for submission.

ABSTRACT

BACKGROUND

Since December 2019, when coronavirus disease 2019 (Covid-19) emerged in Wuhan city and rapidly spread throughout China, data have been needed on the clinical characteristics of the affected patients.

METHODS

We extracted data regarding 1099 patients with laboratory-confirmed Covid-19 from 552 hospitals in 30 provinces, autonomous regions, and municipalities in mainland China through January 29, 2020. The primary composite end point was admission to an intensive care unit (ICU), the use of mechanical ventilation, or death.

RESULTS

The median age of the patients was 47 years; 41.9% of the patients were female. The primary composite end point occurred in 67 patients (6.1%), including 5.0% who were admitted to the ICU, 2.3% who underwent invasive mechanical ventilation, and 1.4% who died. Only 1.9% of the patients had a history of direct contact with wildlife. Among nonresidents of Wuhan, 72.3% had contact with residents of Wuhan, including 31.3% who had visited the city. The most common symptoms were fever (43.8% on admission and 88.7% during hospitalization) and cough (67.8%). Diarrhea was uncommon (3.8%). The median incubation period was 4 days (interquartile range, 2 to 7). On admission, ground-glass opacity was the most common radiologic finding on chest computed tomography (CT) (56.4%). No radiographic or CT abnormality was found in 157 of 877 patients (17.9%) with nonsevere disease and in 5 of 173 patients (2.9%) with severe disease. Lymphocytopenia was present in 83.2% of the patients on admission.

CONCLUSIONS

During the first 2 months of the current outbreak, Covid-19 spread rapidly throughout China and caused varying degrees of illness. Patients often presented without fever, and many did not have abnormal radiologic findings. (Funded by the National Health Commission of China and others.)

IN EARLY DECEMBER 2019, THE FIRST PNEUMONIA cases of unknown origin were identified in Wuhan, the capital city of Hubei province.¹ The pathogen has been identified as a novel enveloped RNA betacoronavirus² that has currently been named severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which has a phylogenetic similarity to SARS-CoV.³ Patients with the infection have been documented both in hospitals and in family settings.⁴⁻⁸

The World Health Organization (WHO) has recently declared coronavirus disease 2019 (Covid-19) a public health emergency of international concern.⁹ As of February 25, 2020, a total of 81,109 laboratory-confirmed cases had been documented globally.^{5,6,9-11} In recent studies, the severity of some cases of Covid-19 mimicked that of SARS-CoV.^{1,12,13} Given the rapid spread of Covid-19, we determined that an updated analysis of cases throughout mainland China might help identify the defining clinical characteristics and severity of the disease. Here, we describe the results of our analysis of the clinical characteristics of Covid-19 in a selected cohort of patients throughout China.

METHODS

STUDY OVERSIGHT

The study was supported by National Health Commission of China and designed by the investigators. The study was approved by the institutional review board of the National Health Commission. Written informed consent was waived in light of the urgent need to collect data. Data were analyzed and interpreted by the authors. All the authors reviewed the manuscript and vouch for the accuracy and completeness of the data and for the adherence of the study to the protocol, available with the full text of this article at NEJM.org.

DATA SOURCES

We obtained the medical records and compiled data for hospitalized patients and outpatients with laboratory-confirmed Covid-19, as reported to the National Health Commission between December 11, 2019, and January 29, 2020; the data cutoff for the study was January 31, 2020. Covid-19 was diagnosed on the basis of the WHO interim guidance.¹⁴ A confirmed case of Covid-19 was defined as a positive result on high-

throughput sequencing or real-time reverse-transcriptase–polymerase-chain-reaction (RT-PCR) assay of nasal and pharyngeal swab specimens.¹ Only laboratory-confirmed cases were included in the analysis.

We obtained data regarding cases outside Hubei province from the National Health Commission. Because of the high workload of clinicians, three outside experts from Guangzhou performed raw data extraction at Wuhan Jinyintan Hospital, where many of the patients with Covid-19 in Wuhan were being treated.

We extracted the recent exposure history, clinical symptoms or signs, and laboratory findings on admission from electronic medical records. Radiologic assessments included chest radiography or computed tomography (CT), and all laboratory testing was performed according to the clinical care needs of the patient. We determined the presence of a radiologic abnormality on the basis of the documentation or description in medical charts; if imaging scans were available, they were reviewed by attending physicians in respiratory medicine who extracted the data. Major disagreement between two reviewers was resolved by consultation with a third reviewer. Laboratory assessments consisted of a complete blood count, blood chemical analysis, coagulation testing, assessment of liver and renal function, and measures of electrolytes, C-reactive protein, procalcitonin, lactate dehydrogenase, and creatine kinase. We defined the degree of severity of Covid-19 (severe vs. nonsevere) at the time of admission using the American Thoracic Society guidelines for community-acquired pneumonia.¹⁵

All medical records were copied and sent to the data-processing center in Guangzhou, under the coordination of the National Health Commission. A team of experienced respiratory clinicians reviewed and abstracted the data. Data were entered into a computerized database and cross-checked. If the core data were missing, requests for clarification were sent to the coordinators, who subsequently contacted the attending clinicians.

STUDY OUTCOMES

The primary composite end point was admission to an intensive care unit (ICU), the use of mechanical ventilation, or death. These outcomes

were used in a previous study to assess the severity of other serious infectious diseases, such as H7N9 infection.¹⁶ Secondary end points were the rate of death and the time from symptom onset until the composite end point and until each component of the composite end point.

STUDY DEFINITIONS

The incubation period was defined as the interval between the potential earliest date of contact of the transmission source (wildlife or person with suspected or confirmed case) and the potential earliest date of symptom onset (i.e., cough, fever, fatigue, or myalgia). We excluded incubation periods of less than 1 day because some patients had continuous exposure to contamination sources; in these cases, the latest date of exposure was recorded. The summary statistics of incubation periods were calculated on the basis of 291 patients who had clear information regarding the specific date of exposure.

Fever was defined as an axillary temperature of 37.5°C or higher. Lymphocytopenia was defined as a lymphocyte count of less than 1500 cells per cubic millimeter. Thrombocytopenia was defined as a platelet count of less than 150,000 per cubic millimeter. Additional definitions — including exposure to wildlife, acute respiratory distress syndrome (ARDS), pneumonia, acute kidney failure, acute heart failure, and rhabdomyolysis — are provided in the Supplementary Appendix, available at NEJM.org.

LABORATORY CONFIRMATION

Laboratory confirmation of SARS-CoV-2 was performed at the Chinese Center for Disease Prevention and Control before January 23, 2020, and subsequently in certified tertiary care hospitals. RT-PCR assays were performed in accordance with the protocol established by the WHO.¹⁷ Details regarding laboratory confirmation processes are provided in the Supplementary Appendix.

STATISTICAL ANALYSIS

Continuous variables were expressed as medians and interquartile ranges or simple ranges, as appropriate. Categorical variables were summarized as counts and percentages. No imputation was made for missing data. Because the cohort of patients in our study was not derived from random selection, all statistics are deemed to be

descriptive only. We used ArcGIS, version 10.2.2, to plot the numbers of patients with reportedly confirmed cases on a map. All the analyses were performed with the use of R software, version 3.6.2 (R Foundation for Statistical Computing).

RESULTS

DEMOGRAPHIC AND CLINICAL CHARACTERISTICS

Of the 7736 patients with Covid-19 who had been hospitalized at 552 sites as of January 29, 2020, we obtained data regarding clinical symptoms and outcomes for 1099 patients (14.2%). The largest number of patients (132) had been admitted to Wuhan Jinyintan Hospital. The hospitals that were included in this study accounted for 29.7% of the 1856 designated hospitals where patients with Covid-19 could be admitted in 30 provinces, autonomous regions, or municipalities across China (Fig. 1).

The demographic and clinical characteristics of the patients are shown in Table 1. A total of 3.5% were health care workers, and a history of contact with wildlife was documented in 1.9%; 483 patients (43.9%) were residents of Wuhan. Among the patients who lived outside Wuhan, 72.3% had contact with residents of Wuhan, including 31.3% who had visited the city; 25.9% of nonresidents had neither visited the city nor had contact with Wuhan residents.

The median incubation period was 4 days (interquartile range, 2 to 7). The median age of the patients was 47 years (interquartile range, 35 to 58); 0.9% of the patients were younger than 15 years of age. A total of 41.9% were female. Fever was present in 43.8% of the patients on admission but developed in 88.7% during hospitalization. The second most common symptom was cough (67.8%); nausea or vomiting (5.0%) and diarrhea (3.8%) were uncommon. Among the overall population, 23.7% had at least one coexisting illness (e.g., hypertension and chronic obstructive pulmonary disease).

On admission, the degree of severity of Covid-19 was categorized as nonsevere in 926 patients and severe in 173 patients. Patients with severe disease were older than those with nonsevere disease by a median of 7 years. Moreover, the presence of any coexisting illness was more common among patients with severe disease than among those with nonsevere disease (38.7% vs.

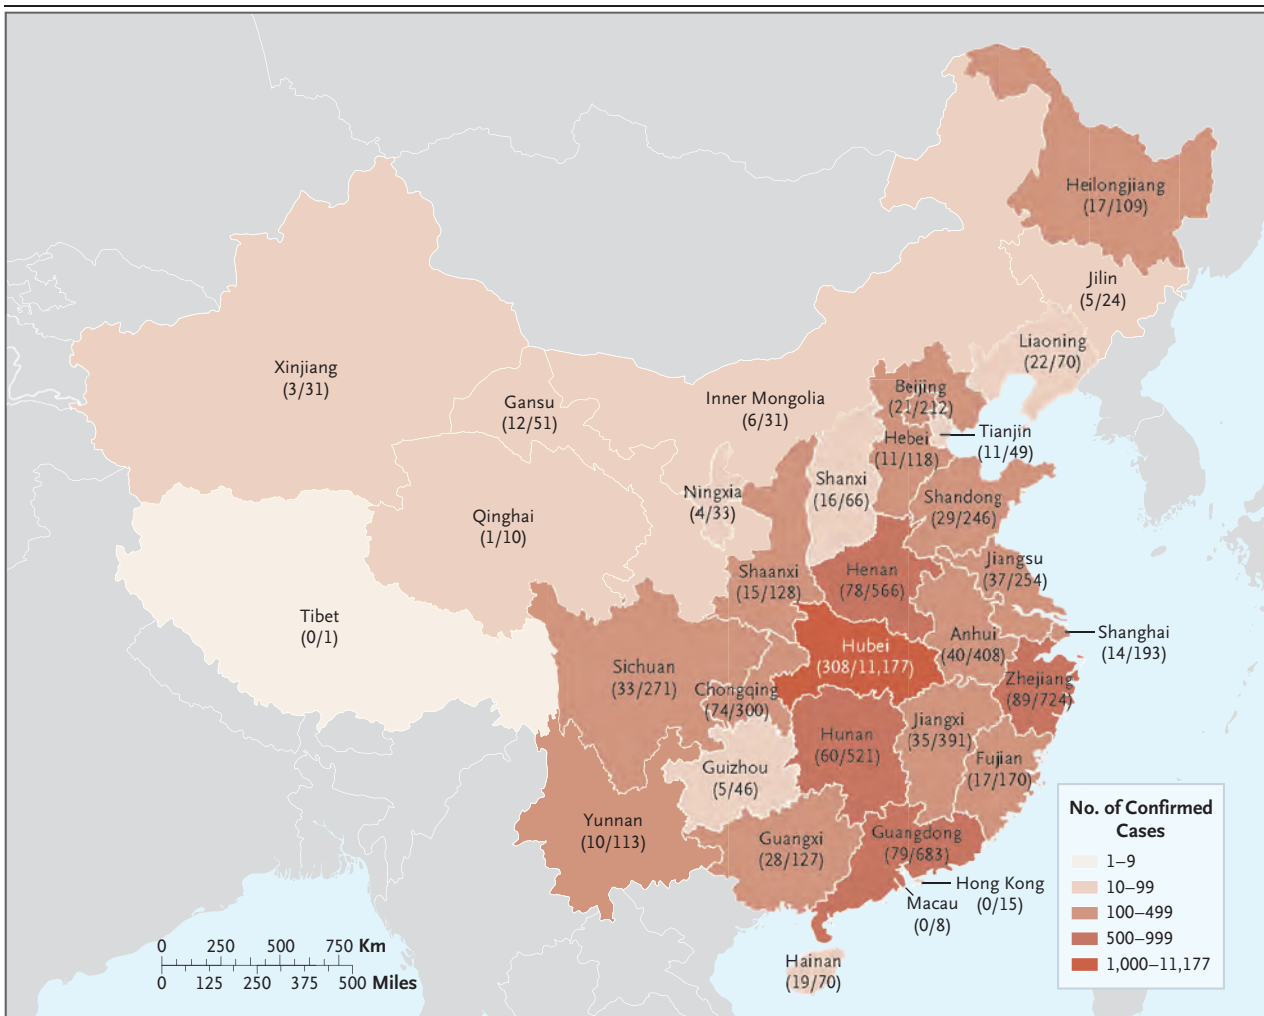

Figure 1. Distribution of Patients with Covid-19 across Mainland China.

Shown are the official statistics of all documented, laboratory-confirmed cases of coronavirus disease 2019 (Covid-19) throughout China, according to the National Health Commission as of February 4, 2020. The numerator denotes the number of patients who were included in the study cohort and the denominator denotes the number of laboratory-confirmed cases for each province, autonomous region, or provincial municipality, as reported by the National Health Commission.

21.0%). However, the exposure history between the two groups of disease severity was similar.

RADIOLOGIC AND LABORATORY FINDINGS

Table 2 shows the radiologic and laboratory findings on admission. Of 975 CT scans that were performed at the time of admission, 86.2% revealed abnormal results. The most common patterns on chest CT were ground-glass opacity (56.4%) and bilateral patchy shadowing (51.8%). Representative radiologic findings in two patients with nonsevere Covid-19 and in another

two patients with severe Covid-19 are provided in Figure S1 in the Supplementary Appendix. No radiographic or CT abnormality was found in 157 of 877 patients (17.9%) with nonsevere disease and in 5 of 173 patients (2.9%) with severe disease.

On admission, lymphocytopenia was present in 83.2% of the patients, thrombocytopenia in 36.2%, and leukopenia in 33.7%. Most of the patients had elevated levels of C-reactive protein; less common were elevated levels of alanine aminotransferase, aspartate aminotransferase,

creatinine kinase, and D-dimer. Patients with severe disease had more prominent laboratory abnormalities (including lymphocytopenia and leukopenia) than those with nonsevere disease.

CLINICAL OUTCOMES

None of the 1099 patients were lost to follow-up during the study. A primary composite end-point event occurred in 67 patients (6.1%), including 5.0% who were admitted to the ICU, 2.3% who underwent invasive mechanical ventilation, and 1.4% who died (Table 3). Among the 173 patients with severe disease, a primary composite end-point event occurred in 43 patients (24.9%). Among all the patients, the cumulative risk of the composite end point was 3.6%; among those with severe disease, the cumulative risk was 20.6%.

TREATMENT AND COMPLICATIONS

A majority of the patients (58.0%) received intravenous antibiotic therapy, and 35.8% received oseltamivir therapy; oxygen therapy was administered in 41.3% and mechanical ventilation in 6.1%; higher percentages of patients with severe disease received these therapies (Table 3). Mechanical ventilation was initiated in more patients with severe disease than in those with nonsevere disease (noninvasive ventilation, 32.4% vs. 0%; invasive ventilation, 14.5% vs. 0%). Systemic glucocorticoids were given to 204 patients (18.6%), with a higher percentage among those with severe disease than nonsevere disease (44.5% vs. 13.7%). Of these 204 patients, 33 (16.2%) were admitted to the ICU, 17 (8.3%) underwent invasive ventilation, and 5 (2.5%) died. Extracorporeal membrane oxygenation was performed in 5 patients (0.5%) with severe disease.

The median duration of hospitalization was 12.0 days (mean, 12.8). During hospital admission, most of the patients received a diagnosis of pneumonia from a physician (91.1%), followed by ARDS (3.4%) and shock (1.1%). Patients with severe disease had a higher incidence of physician-diagnosed pneumonia than those with nonsevere disease (99.4% vs. 89.5%).

DISCUSSION

During the initial phase of the Covid-19 outbreak, the diagnosis of the disease was complicated by the diversity in symptoms and imaging

findings and in the severity of disease at the time of presentation. Fever was identified in 43.8% of the patients on presentation but developed in 88.7% after hospitalization. Severe illness occurred in 15.7% of the patients after admission to a hospital. No radiologic abnormalities were noted on initial presentation in 2.9% of the patients with severe disease and in 17.9% of those with nonsevere disease. Despite the number of deaths associated with Covid-19, SARS-CoV-2 appears to have a lower case fatality rate than either SARS-CoV or Middle East respiratory syndrome-related coronavirus (MERS-CoV). Compromised respiratory status on admission (the primary driver of disease severity) was associated with worse outcomes.

Approximately 2% of the patients had a history of direct contact with wildlife, whereas more than three quarters were either residents of Wuhan, had visited the city, or had contact with city residents. These findings echo the latest reports, including the outbreak of a family cluster,⁴ transmission from an asymptomatic patient,⁶ and the three-phase outbreak patterns.⁸ Our study cannot preclude the presence of patients who have been termed “super-spreaders.”

Conventional routes of transmission of SARS-CoV, MERS-CoV, and highly pathogenic influenza consist of respiratory droplets and direct contact,¹⁸⁻²⁰ mechanisms that probably occur with SARS-CoV-2 as well. Because SARS-CoV-2 can be detected in the gastrointestinal tract, saliva, and urine, these routes of potential transmission need to be investigated²¹ (Tables S1 and S2).

The term Covid-19 has been applied to patients who have laboratory-confirmed symptomatic cases without apparent radiologic manifestations. A better understanding of the spectrum of the disease is needed, since in 8.9% of the patients, SARS-CoV-2 infection was detected before the development of viral pneumonia or viral pneumonia did not develop.

In concert with recent studies,^{1,8,12} we found that the clinical characteristics of Covid-19 mimic those of SARS-CoV. Fever and cough were the dominant symptoms and gastrointestinal symptoms were uncommon, which suggests a difference in viral tropism as compared with SARS-CoV, MERS-CoV, and seasonal influenza.^{22,23} The absence of fever in Covid-19 is more frequent than in SARS-CoV (1%) and MERS-CoV infection

Table 1. Clinical Characteristics of the Study Patients, According to Disease Severity and the Presence or Absence of the Primary Composite End Point.*

Characteristic	All Patients (N=1099)	Disease Severity		Presence of Primary Composite End Point†‡

* Lymphocytopenia was defined as a lymphocyte count of less than 1500 per cubic millimeter. Thrombocytopenia was defined as a platelet count of less than 150,000 per cubic millimeter. To convert the values for creatinine to milligrams per deciliter, divide by 88.4.

† Data regarding the ratio of the partial pressure of arterial oxygen to the fraction of inspired oxygen (PaO₂:Fio₂) were missing for 894 patients (81.3%).

‡ Data regarding hemoglobin were missing for 226 patients (20.6%).

§ Data were missing for the measurement of sodium in 363 patients (33.0%), for potassium in 349 patients (31.8%), and for chloride in 392 patients (35.7%).

Table 3. Complications, Treatments, and Clinical Outcomes.

Variable	All Patients (N = 1099)	Disease Severity			Presence of Composite Primary End Point	
		Nonsevere (N = 926)	Severe (N = 173)		Yes (N = 67)	No (N = 1032)
Complications						
Septic shock — no. (%)	12 (1.1)	1 (0.1)	11 (6.4)		9 (13.4)	3 (0.3)
Acute respiratory distress syndrome — no. (%)	37 (3.4)	10 (1.1)	27 (15.6)		27 (40.3)	10 (1.0)
Acute kidney injury — no. (%)	6 (0.5)	1 (0.1)	5 (2.9)		4 (6.0)	2 (0.2)
Disseminated intravascular coagulation — no. (%)	1 (0.1)	0	1 (0.6)		1 (1.5)	0
Rhabdomyolysis — no. (%)	2 (0.2)	2 (0.2)	0		0	2 (0.2)
Physician-diagnosed pneumonia — no./total no. (%)	972/1067 (91.1)	800/894 (89.5)	172/173 (99.4)		63/66 (95.5)	909/1001 (90.8)
Median time until development of pneumonia (IQR) — days*						
After initial Covid-19 diagnosis	0.0 (0.0–1.0)	0.0 (0.0–1.0)	0.0 (0.0–2.0)		0.0 (0.0–3.5)	0.0 (0.0–1.0)
After onset of Covid-19 symptoms	3.0 (1.0–6.0)	3.0 (1.0–6.0)	5.0 (2.0–7.0)		4.0 (0.0–7.0)	3.0 (1.0–6.0)
Treatments						
Intravenous antibiotics — no. (%)	637 (58.0)	498 (53.8)	139 (80.3)		60 (89.6)	577 (55.9)
Oseltamivir — no. (%)	393 (35.8)	313 (33.8)	80 (46.2)		36 (53.7)	357 (34.6)
Antifungal medication — no. (%)	31 (2.8)	18 (1.9)	13 (7.5)		8 (11.9)	23 (2.2)
Systemic glucocorticoids — no. (%)	204 (18.6)	127 (13.7)	77 (44.5)		35 (52.2)	169 (16.4)
Oxygen therapy — no. (%)	454 (41.3)	331 (35.7)	123 (71.1)		59 (88.1)	395 (38.3)
Mechanical ventilation — no. (%)	67 (6.1)	0	67 (38.7)		40 (59.7)	27 (2.6)
Invasive	25 (2.3)	0	25 (14.5)		25 (37.3)	0
Noninvasive	56 (5.1)	0	56 (32.4)		29 (43.3)	27 (2.6)
Use of extracorporeal membrane oxygenation — no. (%)	5 (0.5)	0	5 (2.9)		5 (7.5)	0
Use of continuous renal-replacement therapy — no. (%)	9 (0.8)	0	9 (5.2)		8 (11.9)	1 (0.1)
Use of intravenous immune globulin — no. (%)	144 (13.1)	86 (9.3)	58 (33.5)		27 (40.3)	117 (11.3)
Admission to intensive care unit — no. (%)	55 (5.0)	22 (2.4)	33 (19.1)		55 (82.1)	0
Median length of hospital stay (IQR) — days†	12.0 (10.0–14.0)	11.0 (10.0–13.0)	13.0 (11.5–17.0)		14.5 (11.0–19.0)	12.0 (10.0–13.0)

Clinical outcomes at data cutoff — no. (%)					
Discharge from hospital	55 (5.0)	50 (5.4)	5 (2.9)	1 (1.5)	54 (5.2)
Death	15 (1.4)	1 (0.1)	14 (8.1)	15 (22.4)	0
Recovery	9 (0.8)	7 (0.8)	2 (1.2)	0	9 (0.9)
Hospitalization	1029 (93.6)	875 (94.5)	154 (89.0)	51 (76.1)	978 (94.8)

* For the development of pneumonia, data were missing for 347 patients (31.6%) regarding the time since the initial diagnosis and for 161 patients (14.6%) regarding the time since symptom onset.

† Data regarding the median length of hospital stay were missing for 136 patients (12.4%).

(2%),²⁰ so afebrile patients may be missed if the surveillance case definition focuses on fever detection.¹⁴ Lymphocytopenia was common and, in some cases, severe, a finding that was consistent with the results of two recent reports.^{1,12} We found a lower case fatality rate (1.4%) than the rate that was recently reportedly,^{1,12} probably because of the difference in sample sizes and case inclusion criteria. Our findings were more similar to the national official statistics, which showed a rate of death of 3.2% among 51,857 cases of Covid-19 as of February 16, 2020.^{11,24} Since patients who were mildly ill and who did not seek medical attention were not included in our study, the case fatality rate in a real-world scenario might be even lower. Early isolation, early diagnosis, and early management might have collectively contributed to the reduction in mortality in Guangdong.

Despite the phylogenetic homogeneity between SARS-CoV-2 and SARS-CoV, there are some clinical characteristics that differentiate Covid-19 from SARS-CoV, MERS-CoV, and seasonal influenza infections. (For example, seasonal influenza has been more common in respiratory outpatient clinics and wards.) Some additional characteristics that are unique to Covid-19 are detailed in Table S3.

Our study has some notable limitations. First, some cases had incomplete documentation of the exposure history and laboratory testing, given the variation in the structure of electronic databases among different participating sites and the urgent timeline for data extraction. Some cases were diagnosed in outpatient settings where medical information was briefly documented and incomplete laboratory testing was performed, along with a shortage of infrastructure and training of medical staff in non-specialty hospitals. Second, we could estimate the incubation period in only 291 of the study patients who had documented information. The uncertainty of the exact dates (recall bias) might have inevitably affected our assessment. Third, because many patients remained in the hospital and the outcomes were unknown at the time of data cutoff, we censored the data regarding their clinical outcomes as of the time of our analysis. Fourth, we no doubt missed patients who were asymptomatic or had mild cases and who were treated at home, so our study cohort may represent the more severe end of Covid-19. Fifth,

many patients did not undergo sputum bacteriologic or fungal assessment on admission because, in some hospitals, medical resources were overwhelmed. Sixth, data generation was clinically driven and not systematic.

Covid-19 has spread rapidly since it was first identified in Wuhan and has been shown to have a wide spectrum of severity. Some patients with Covid-19 do not have fever or radiologic abnormalities on initial presentation, which has complicated the diagnosis.

High SARS-CoV-2 Attack Rate Following Exposure at a Choir Practice — Skagit County, Washington, March 2020

Lea Hamner, MPH¹; Polly Dubbel, MPH¹; Ian Capron¹; Andy Ross, MPH¹; Amber Jordan, MPH¹; Jaxon Lee, MPH¹; Joanne Lynn¹; Amelia Ball¹; Simranjit Narwal, MSc¹; Sam Russell¹; Dale Patrick¹; Howard Leibrand, MD¹

On May 12, 2020, this report was posted as an MMWR Early Release on the MMWR website (<https://www.cdc.gov/mmwr>).

On March 17, 2020, a member of a Skagit County, Washington, choir informed Skagit County Public Health (SCPH) that several members of the 122-member choir had become ill. Three persons, two from Skagit County and one from another area, had test results positive for SARS-CoV-2, the virus that causes coronavirus disease 2019 (COVID-19). Another 25 persons had compatible symptoms. SCPH obtained the choir's member list and began an investigation on March 18. Among 61 persons who attended a March 10 choir practice at which one person was known to be symptomatic, 53 cases were identified, including 33 confirmed and 20 probable cases (secondary attack rates of 53.3% among confirmed cases and 86.7% among all cases). Three of the 53 persons who became ill were hospitalized (5.7%), and two died (3.7%). The 2.5-hour singing practice provided several opportunities for droplet and fomite transmission, including members sitting close to one another, sharing snacks, and stacking chairs at the end of the practice. The act of singing, itself, might have contributed to transmission through emission of aerosols, which is affected by loudness of vocalization (1). Certain persons, known as superemitters, who release more aerosol particles during speech than do their peers, might have contributed to this and previously reported COVID-19 superspreading events (2–5). These data demonstrate the high transmissibility of SARS-CoV-2 and the possibility of superemitters contributing to broad transmission in certain unique activities and circumstances. It is recommended that persons avoid face-to-face contact with others, not gather in groups, avoid crowded places, maintain physical distancing of at least 6 feet to reduce transmission, and wear cloth face coverings in public settings where other social distancing measures are difficult to maintain.

Investigation and Findings

The choir, which included 122 members, met for a 2.5-hour practice every Tuesday evening through March 10. On March 15, the choir director e-mailed the group members to inform them that on March 11 or 12 at least six members had developed fever and that two members had been tested for SARS-CoV-2 and were awaiting results. On March 16, test results for three members were positive for SARS-CoV-2

and were reported to two respective local health jurisdictions, without indication of a common source of exposure. On March 17, the choir director sent a second e-mail stating that 24 members reported that they had developed influenza-like symptoms since March 11, and at least one had received test results positive for SARS-CoV-2. The email emphasized the importance of social distancing and awareness of symptoms suggestive of COVID-19. These two emails led many members to self-isolate or quarantine before a delegated member of the choir notified SCPH on March 17.

All 122 members were interviewed by telephone either during initial investigation of the cluster (March 18–20; 115 members) or a follow-up interview (April 7–10; 117); most persons participated in both interviews. Interviews focused on attendance at practices on March 3 and March 10, as well as attendance at any other events with members during March, other potential exposures, and symptoms of COVID-19. SCPH used Council of State and Territorial Epidemiologists case definitions to classify confirmed and probable cases of COVID-19 (6). Persons who did not have symptoms at the initial interview were instructed to quarantine for 14 days from the last practice they had attended. The odds of becoming ill after attending each practice were computed to ascertain the likelihood of a point-source exposure event.

No choir member reported having had symptoms at the March 3 practice. One person at the March 10 practice had cold-like symptoms beginning March 7. This person, who had also attended the March 3 practice, had a positive laboratory result for SARS-CoV-2 by reverse transcription–polymerase chain reaction (RT-PCR) testing.

In total, 78 members attended the March 3 practice, and 61 attended the March 10 practice (Table 1). Overall, 51 (65.4%) of the March 3 practice attendees became ill; all but one of these persons also attended the March 10 practice. Among 60 attendees at the March 10 practice (excluding the patient who became ill March 7, who also attended), 52 (86.7%) choir members subsequently became ill. Some members exclusively attended one practice; among 21 members who only attended March 3, one became ill and was not tested (4.8%), and among three members who only attended March 10, two became ill (66.7%), with one COVID-19 case being laboratory-confirmed.

Summary

What is already known about this topic?

Superspreading events involving SARS-CoV-2, the virus that causes COVID-19, have been reported.

What is added by this report?

Following a 2.5-hour choir practice attended by 61 persons, including a symptomatic index patient, 32 confirmed and 20 probable secondary COVID-19 cases occurred (attack rate = 53.3% to 86.7%); three patients were hospitalized, and two died. Transmission was likely facilitated by close proximity (within 6 feet) during practice and augmented by the act of singing.

What are the implications for public health practice?

The potential for superspreader events underscores the importance of physical distancing, including avoiding gathering in large groups, to control spread of COVID-19. Enhancing community awareness can encourage symptomatic persons and contacts of ill persons to isolate or self-quarantine to prevent ongoing transmission.

Because illness onset for 49 (92.5%) patients began during March 11–15 (Figure), a point-source exposure event seemed likely. The median interval from the March 3 practice to symptom onset was 10 days (range = 4–19 days), and from the March 10 practice to symptom onset was 3 days (range = 1–12 days). The odds of becoming ill after the March 3 practice were 17.0 times higher for practice attendees than for those who did not attend (95% confidence interval [CI] = 5.5–52.8), and after the March 10 practice, the odds were 125.7 times greater (95% CI = 31.7–498.9). The clustering of symptom onsets, odds of becoming ill according to practice attendance, and known presence of a symptomatic contagious case at the March 10 practice strongly suggest that date as the more likely point-source exposure event. Therefore, that practice was the focus of the rest of the investigation. Probable cases were defined as persons who attended the March 10 practice and developed clinically compatible COVID-19 symptoms, as defined by Council of State and Territorial Epidemiologists (6). The choir member who was ill beginning March 7 was considered the index patient.

The March 10 choir rehearsal lasted from 6:30 to 9:00 p.m. Several members arrived early to set up chairs in a large multipurpose room. Chairs were arranged in six rows of 20 chairs each, spaced 6–10 inches apart with a center aisle dividing left and right stages. Most choir members sat in their usual rehearsal seats. Sixty-one of the 122 members attended that evening, leaving some members sitting next to empty seats. Attendees practiced together for 40 minutes, then split into two smaller groups for an additional 50-minute practice, with one of the groups moving to a smaller room. At that

time, members in the larger room moved to seats next to one another, and members in the smaller room sat next to one another on benches. Attendees then had a 15-minute break, during which cookies and oranges were available at the back of the large room, although many members reported not eating the snacks. The group then reconvened for a final 45-minute session in their original seats. At the end of practice, each member returned their own chair, and in the process congregated around the chair racks. Most attendees left the practice immediately after it concluded. No one reported physical contact between attendees. SCPH assembled a seating chart of the all-choir portion of the March 10 practice (not reported here because of concerns about patient privacy).

Among the 61 choir members who attended the March 10 practice, the median age was 69 years (range = 31–83 years); 84% were women. Median age of those who became ill was 69 years, and 85% of cases occurred in women. Excluding the laboratory-confirmed index patient, 52 (86.7%) of 60 attendees became ill; 32 (61.5%) of these cases were confirmed by RT-PCR testing and 20 (38.5%) persons were considered to have probable infections. These figures correspond to secondary attack rates of 53.3% and 86.7% among confirmed and all cases, respectively. Attendees developed symptoms 1 to 12 days after the practice (median = 3 days). The first SARS-CoV-2 test was performed on March 13. The last person was tested on March 26.

Three of the 53 patients were hospitalized (5.7%), including two who died (3.8%). The mean interval from illness onset to hospitalization was 12 days. The intervals from onset to death were 14 and 15 days for the two patients who died.

SCPH collected information about patient signs and symptoms from patient interviews and hospital records (Table 2). Among persons with confirmed infections, the most common signs and symptoms reported at illness onset and at any time during the course of illness were cough (54.5% and 90.9%, respectively), fever (45.5%, 75.8%), myalgia (27.3%, 75.0%), and headache (21.2%, 60.6%). Several patients later developed gastrointestinal symptoms, including diarrhea (18.8%), nausea (9.4%), and abdominal cramps or pain (6.3%). One person experienced only loss of smell and taste. The most severe complications reported were viral pneumonia (18.2%) and severe hypoxemic respiratory failure (9.1%).

Among the recognized risk factors for severe illness, the most common was age, with 75.5% of patients aged ≥65 years. Most patients (67.9%) did not report any underlying medical conditions, 9.4% had one underlying medical condition, and 22.6% had two or more underlying medical conditions. All three hospitalized patients had two or more underlying medical conditions.

TABLE 1. Number of choir members with and without COVID-19-compatible symptoms (N = 122)* and members' choir practice attendance† — Skagit County, Washington, March 3 and 10, 2020

Attendance	No. (row %)					
	March 3 practice			March 10 practice

Public Health Response

SCPH provided March 10 practice attendees with isolation and quarantine instructions by telephone, email, and postal mail. Contacts of patients were traced and notified of isolation and quarantine guidelines. At initial contact, 15 attendees were quarantined, five of whom developed symptoms during quarantine and notified SCPH.

Before detection of this cluster on March 17, Skagit County had reported seven confirmed COVID-19 cases (5.4 cases per 100,000 population). At the time, SCPH informed residents that likely more community transmission had occurred than indicated by the low case counts.* On March 21, SCPH issued a press release to describe the outbreak and raise awareness about community transmission.† The press release emphasized

the highly contagious nature of COVID-19 and the importance of following social distancing guidelines to control the spread of the virus.

Discussion

Multiple reports have documented events involving super-spreading of COVID-19 (2–5); however, few have documented a community-based point-source exposure (5). This cluster of 52 secondary cases of COVID-19 presents a unique opportunity for understanding SARS-CoV-2 transmission following a likely point-source exposure event. Persons infected with SARS-CoV-2 are most infectious from 2 days before through 7 days after symptom onset (7). The index patient developed symptoms on March 7, which could have placed the patient within this infectious period during the March 10 practice. Choir members who developed symptoms on March 11 (three) and March 12 (seven) attended both the March 3

Abbreviation: COVID-19 = coronavirus disease 19.

* Including the index patient.

and March 10 practices and thus could have been infected earlier and might have been infectious in the 2 days preceding symptom onset (i.e., as early as March 9). The attack rate in this group (53.3% and 86.7% among confirmed cases and all cases, respectively) was higher than that seen in other clusters, and the March 10 practice could be considered a superspreading event (3,4). The median incubation period of COVID-19 is estimated to be 5.1 days (8). The median interval from exposure during the March 10 practice to onset of illness was 3 days, indicating a more rapid onset.

Choir practice attendees had multiple opportunities for droplet transmission from close contact or fomite transmission (9), and the act of singing itself might have contributed to SARS-CoV-2 transmission. Aerosol emission during speech has been correlated with loudness of vocalization, and certain persons, who release an order of magnitude more particles than their peers, have been referred to as superemitters and have been hypothesized to contribute to superspreading events (1). Members had an intense and prolonged exposure, singing while sitting 6–10 inches from one another, possibly emitting aerosols.

The findings in this report are subject to at least two limitations. First, the seating chart was not reported because of concerns about patient privacy. However, with attack rates of 53.3% and 86.7% among confirmed and all cases, respectively,

and one hour of the practice occurring outside of the seating arrangement, the seating chart does not add substantive additional information. Second, the 19 choir members classified as having probable cases did not seek testing to confirm their illness. One person classified as having probable COVID-19 did seek testing 10 days after symptom onset and received a negative test result. It is possible that persons designated as having probable cases had another illness.

This outbreak of COVID-19 with a high secondary attack rate indicates that SARS-CoV-2 might be highly transmissible in certain settings, including group singing events. This underscores the importance of physical distancing, including maintaining at least 6 feet between persons, avoiding group gatherings and crowded places, and wearing cloth face coverings in public settings where other social distancing measures are difficult to maintain during this pandemic. The choir mitigated further spread by quickly communicating to its members and notifying SCPH of a cluster of cases on March 18. When first contacted by SCPH during March 18–20, nearly all persons who attended the practice reported they were already self-isolating or quarantining. Current CDC recommendations, including maintaining physical distancing of at least 6 feet and wearing cloth face coverings if this is not feasible, washing hands often, covering coughs and sneezes, staying home when ill, and frequently cleaning and disinfecting

high-touch surfaces, remain critical to reducing transmission. Additional information is available at <https://www.cdc.gov/coronavirus/2019-ncov/prevent-getting-sick/prevention.html>.

The Middle East respiratory syndrome coronavirus (MERS-CoV) presents a novel emerging threat to public health worldwide. Several treatments for infected individuals have been suggested including IFN, ribavirin and passive immunotherapy with convalescent plasma. Administration of IFN- α 2b and ribavirin has improved outcomes of MERS-CoV infection in rhesus macaques when administered within 8 h post-challenge. However, detailed and systematic evidence on the activity of other clinically available drugs is limited. Here we compared the susceptibility of MERS-CoV with different IFN products (IFN- α 2b, IFN- γ , IFN-universal, IFN- α 2a and IFN- β), as well as with two antivirals, ribavirin and mycophenolic acid (MPA), against MERS-CoV (Hu/Jordan-N3/2012) *in vitro*. Of all the IFNs tested, IFN- β showed the strongest inhibition of MERS-CoV *in vitro*, with an IC₅₀ of 1.37 U ml⁻¹, 41 times lower than the previously reported IC₅₀ (56.08 U ml⁻¹) of IFN- α 2b. IFN- β inhibition was confirmed in the virus yield reduction assay, with an IC₉₀ of 38.8 U ml⁻¹. Ribavirin did not inhibit viral replication *in vitro* at a dose that would be applicable to current treatment protocols in humans. In contrast, MPA showed strong inhibition, with an IC₅₀ of 2.87 μ M. This drug has not been previously tested against MERS-CoV and may provide an alternative to ribavirin for treatment of MERS-CoV. In conclusion, IFN- β , MPA or a combination of the two may be beneficial in the treatment of MERS-CoV or as a post-exposure intervention in high-risk patients with known exposures to MERS-CoV.

Received 4 December 2013

Accepted 5 December 2013

INTRODUCTION

In June 2012, a novel betacoronavirus was isolated from a fatal case of pneumonia with renal failure (Zaki *et al.*, 2012). Owing to the genetic similarities as well as the development of respiratory disease, the new virus was commonly referred to as severe respiratory syndrome coronavirus (SARS)-like virus. The virus was later renamed Middle East respiratory syndrome coronavirus (MERS-CoV). MERS-CoV has been confirmed in 150 cases with 64 deaths to date (as of 4 November 2013; World Health Organization, 2013). Whilst the majority of the cases have occurred in the Kingdom of Saudi Arabia, cases have been identified across the Arabian Peninsula (Qatar, Jordan and United Arab Emirates). Imported cases have also been identified in the UK, Italy, Spain, Germany and Tunisia. Importantly, there are no approved medical countermeasures

for MERS-CoV disease, and thus case management has relied on supportive care, contact tracing, monitoring of close contacts and appropriate infection control (ISARIC, 2013).

Appreciable efforts have been made to identify novel antiviral therapeutics for MERS-CoV. It has been demonstrated that compounds targeting host effectors can be beneficial when administered alone or in combination with antivirals during the course of viral infection (Josset *et al.*, 2010; Ludwig, 2011; Tisoncik *et al.*, 2012). Falzarano *et al.* (2013a, b) recently reported that the administration of IFN- α 2b and ribavirin resulted in synergistic antiviral activities both *in vitro* and *in vivo* in rhesus macaques.

This paper expands on reported studies to evaluate the efficacy of a variety of IFNs and mycophenolic acid (MPA)

for the inhibition of MERS-CoV infection *in vitro* (Chan *et al.*, 2013a, 2013b; de Wilde *et al.*, 2013; Kindler *et al.*, 2013). Similar to ribavirin, MPA has broad antiviral activities. Whilst the mechanism of action for MPA remains under debate, data suggest that it may have both direct antiviral activity and indirect activity through modulation of IFN response activities (Henry *et al.*, 2006; Khan *et al.*, 2011; Leyssen *et al.*, 2005; Morrey *et al.*, 2002; Pan *et al.*, 2012; Smee *et al.*, 2001). Here, we applied a cell-based ELISA screen to test the activity of MPA and the IFN products and compared them with ribavirin and IFN- α 2b *in vitro*.

RESULTS

A cell-based ELISA was developed to screen candidate antivirals for MERS-CoV. To optimize this assay, Vero E6 cells were inoculated with MERS-CoV (Hu/Jordan-N3/2012) at an m.o.i. of 0.03, 0.1 or 0.3 for 48 h. Viral antigen was detected with an antibody specific to the MERS-CoV viral spike protein S and with an Alexa Fluor 594-conjugated secondary antibody. Data from over 10 experiments indicated that an m.o.i. of 0.1 consistently demonstrated a robust fluorescent signal with signal-to-noise ratios in the range of 6–16 with no visible cell death at 48 h (Fig. 1). Based on these results, an m.o.i. of 0.1 was used in all subsequent MERS-CoV ELISA drug screens.

The MERS-CoV ELISA screen was first used to evaluate four compounds, MPA, ribavirin, IFN- α 2a and IFN- β . Subsequently, a set of different IFNs (IFN- α 2b, IFN- γ , IFN-universal, IFN- α 2a and IFN- β) was compared in the MERS-CoV ELISA screen. Vero E6 cells were treated with threefold dilutions of MPA, ribavirin, IFN- α 2a or IFN- β approximately 1 h prior to infection with MERS-CoV. Following 48 h incubation, the cells were fixed and stained, and nine image fields per well were acquired with an Operetta high-content imaging platform (Fig. 2). Use of

Fig. 1. Optimization of the cell-based ELISA screen for MERS antivirals. Vero E6 cells were infected at the indicated m.o.i. to optimize the relative fluorescence signal intensity in arbitrary relative fluorescence units (RFU) at 48 h. Signal-to-noise ratios (S/N) between mock-infected cells (noise; m.o.i. 0) and infected cells (signal; m.o.i. 0.03, 0.1, or 0.3) are shown for the indicated m.o.i. Results shown are representative of one experiment (mean \pm SD, $n=4$) out of at least 10 experiments.

the Operetta provides the advantage of monitoring different fluorescence parameters within the same well. Hoechst 33342 nuclei staining was used to determine cell numbers in each well to quantify the cytotoxic effect, and Alexa Fluor 594-conjugated secondary antibody bound to a MERS-CoV S protein-specific primary antibody was used to determine the percentage of infected cells per well. In the wells containing virus alone, 46–66 % of the cells were positive for viral antigen when left untreated (Fig. 2a, left column). MPA treatment had a significant inhibitory effect on MERS-CoV replication, whilst ribavirin did not show inhibition at the tested concentrations (Figs 2b and 3). Further analysis at lower concentrations confirmed strong inhibition of MERS-CoV replication with MPA at an IC_{50} of 2.87 μ M (Fig. 4). Ribavirin exhibited activity only at concentrations of 250 μ M or higher (Fig. 4). This inhibition of MERS-CoV with MPA is in contrast to the reported inability of MPA to inhibit SARS-CoV infection with MPA (Barnard *et al.*, 2006).

Strong anti-MERS-CoV activity was observed in the lower dose range (starting at 5 U ml^{-1} , Figs 2b and 3). A detailed comparison of various IFN products demonstrated that antiviral activity of IFN- β ($IC_{50}=1.37$ U ml^{-1}) was 16-, 41-, 83- and 117-fold higher than those of IFN- α 2b, IFN- γ , IFN-universal type 1 and IFN- α 2a, respectively (Fig. 5). The ability of IFN- β to inhibit MERS-CoV growth was confirmed in a virus yield reduction assay (Fig. 6). Vero E6 cells were infected at an m.o.i. of 0.1 and incubated in the presence of IFN- β (10–1000 U ml^{-1}) for 48 or 72 h. IFN- β reduced MERS-CoV yield very effectively with an IC_{90} and IC_{99} of 39 and 426 U ml^{-1} , respectively, at 48 h, approximately ten and four times lower, respectively, than previously reported for IFN- α 2b (Falzarano *et al.*, 2013b). At 72 h, IFN- β retained the ability to reduce MERS-CoV yield up to 99.9 % at the higher concentrations (100–1000 U ml^{-1}) tested.

DISCUSSION

Since the emergence of MERS, several potential treatments for clinical patients have been reviewed and recommended by the International Severe Acute Respiratory and Emerging Infection Consortium (Brown *et al.*, 2013). Whilst neutralizing antibody-based treatments such as convalescent plasma are considered to have the most probable beneficial effect, such plasma is limited in availability. The repurposing of Food and Drug Administration (FDA)-approved drugs typically provides the most viable treatment option during emergency situations if efficacy can be demonstrated. Previous *in vitro* and *in vivo* studies have indicated that IFN- α 2b alone, or in combination with ribavirin, could have a clinical effect if given early in the disease course (de Wilde *et al.*, 2013; Falzarano *et al.*, 2013a, b). Here, we demonstrated that IFN- β showed even higher (16 times) biological activity against MERS-CoV infection *in vitro* than IFN- α 2b. In addition, we also demonstrated that another broad-spectrum antiviral,

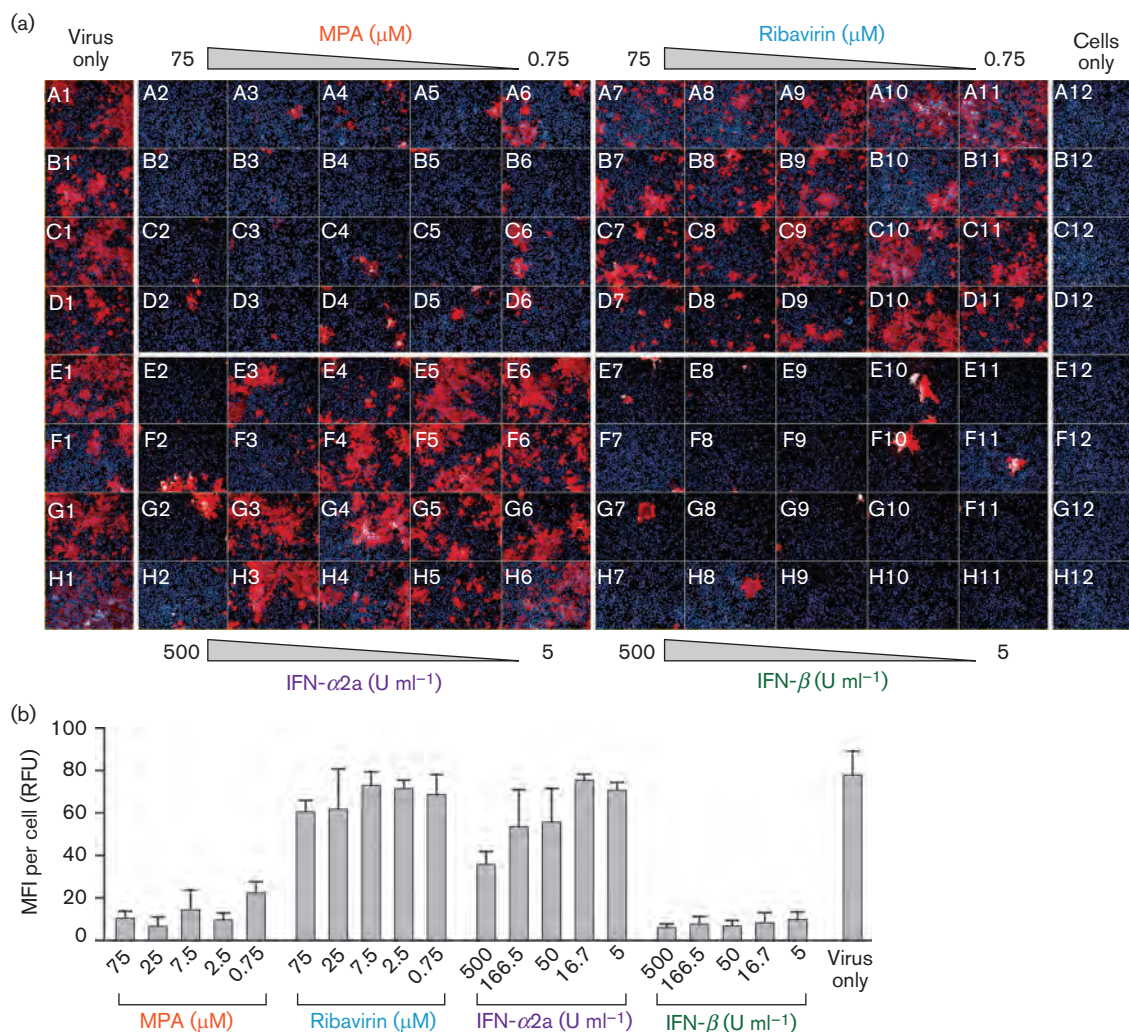

Fig. 2. High content imaging of the MPA, ribavirin, IFN- α 2a and IFN- β dose-response in MERS-CoV-infected Vero E6 cells. Vero E6 cells were treated with threefold dilutions of MPA and ribavirin (0.75–75 μ M), and threefold dilutions of IFN- α 2a and IFN- β (5–500 U ml⁻¹), and subsequently infected at an m.o.i. of 0.1 with MERS-CoV. (a) At 48 h post-inoculation, cells were fixed and stained with antibody to MERS-CoV S protein and Alexa Fluor 594-conjugated secondary antibody. High content imaging analysis (Operetta, Harmony 3.1) was performed to determine the percentage of infected cells per well, and Hoechst 33342 staining was used to determine the number of viable cells in each well. One out of nine acquired fields per well is shown. The left-hand column shows the positive control of cells infected with MERS-CoV without drug treatment. The right-hand column shows the negative control of uninfected viable cells without drug treatment. (b) Quantification of relative fluorescence intensity from fluorescence microscopic images shown in (a). Mean fluorescence intensity (MFI) was measured in relative fluorescence units (RFU) and normalized to the number of cells per well. Results are representative of one experiment (mean \pm SD, $n=4$). The experiment was repeated at least twice.

MPA, was effective against MERS-CoV infection *in vitro*. Furthermore, MERS-CoV was susceptible to MPA inhibition with an $IC_{50}=2.87 \mu$ M. Importantly, both IFN- β and MPA have been approved by the FDA for other indications and currently are in use. As a result, both of these drugs are readily available and can be used off label at the discretion of the clinician. There are also data in the literature to indicate that improved efficacy and potential synergy can be achieved when these drugs are combined.

Similar to ribavirin, there have been a number of proposed mechanisms of action for MPA. Previously, MPA treatment was shown to induce the expression of IFN-stimulated genes, including IFN regulatory factor 1, suggesting that the antiviral activity of MPA is dependent on the modulation of both inosine 5'-monophosphate dehydrogenase activity and IFN-stimulated gene expression (Pan *et al.*, 2012). These data also support the hypothesis that MPA may increase the responsiveness of cells to

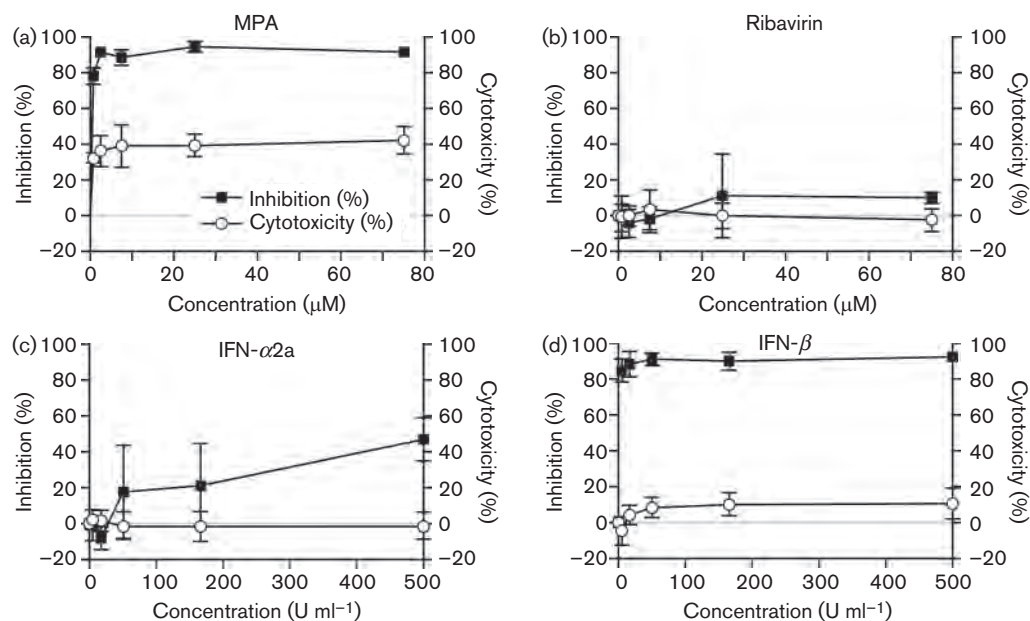

Fig. 3. Comparison of test compounds MPA (a), ribavirin (b), IFN- α 2a (c) and IFN- β (d) for inhibition of viral replication and cell cytotoxic effects. The MERS-CoV screen was performed as described in Fig. 2. The MFI of infected cells was determined using Harmony 3.1 software and the percentage inhibition of treated wells was normalized to uninfected control wells and measured relative to untreated wells. Viable cell numbers were used to determine the percentage cytotoxic effect in infected/treated wells relative to uninfected/untreated wells. Results are representative of one experiment (mean \pm SD, $n=4$). The experiment was repeated at least twice.

IFN treatment and, when combined with IFN, may act synergistically to reduce viral loads. To account for this possibility, the initial screens presented in this paper were performed in Vero cells. Vero cells, whilst responsive to IFN, cannot produce IFN. As such, the data here suggested that the observed MPA activity is not through induction or sensitization of cells to IFN. Future analysis will assess the mechanism of action for the MPA inhibitory effect on

MERS-CoV infection and possible additive or synergistic effects when combined with IFN.

In conclusion, the data presented here demonstrated that IFN- β and MPA, or a combination of the two drugs, should be considered for the treatment of MERS-CoV-infected patients. Previously published reports demonstrating IFN antagonist activity of MERS-CoV support

Fig. 4. Antiviral activity of MPA and ribavirin. Vero E6 cells were treated with threefold dilutions of MPA (0–75 μM) (a) or ribavirin (0–750 μM) (b) and subsequently infected at an m.o.i. of 0.1 with MERS-CoV. At 48 h post-inoculation, cells were fixed and stained with antibody to MERS-CoV S protein and Alexa Fluor 594-conjugated secondary antibody. Fluorescence was quantified on a plate reader and the percentage inhibition of treated wells was normalized to uninfected control wells and measured relative to untreated wells. Results are representative of one experiment (mean \pm SD, $n=4$). The experiment was repeated at least twice.

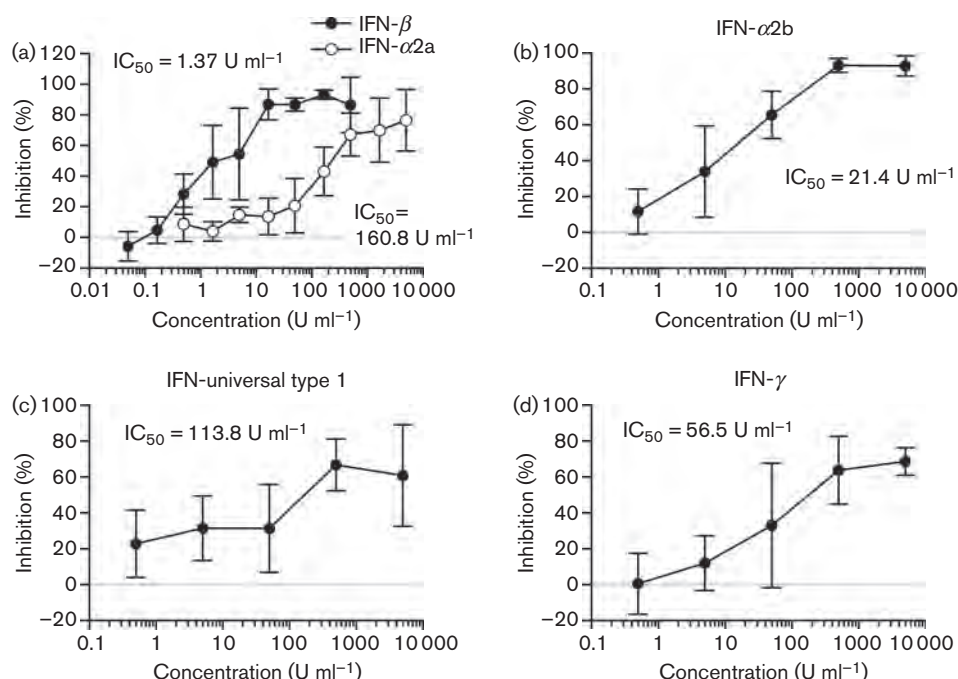

Fig. 5. Antiviral activity by various IFN types. Vero E6 cells were treated at indicated concentrations of IFN- β and IFN- α 2a (a), IFN- α 2b (b), IFN-universal (c) or IFN- γ (d) and subsequently infected at an m.o.i. of 0.1 with MERS-CoV. At 48 h post-inoculation, cells were fixed and stained with antibody to MERS-CoV S protein and Alexa Fluor 594-conjugated secondary antibody. The percentage inhibition of treated wells was normalized to uninfected control wells and measured relative to untreated wells. Results are representative of one experiment (mean \pm SD, $n=4$). The experiment was repeated at least twice.

the hypothesis that control of the host innate immune response, in particular the IFN response, is critical for survival of the virus. Early intervention with the use of exogenous IFNs alone or in combination with direct antivirals prior to complete subversion of the host's

immune response may provide a viable treatment option. In addition, the data presented here, in combination with the current state of knowledge of MERS-CoV, suggest that exogenous IFNs may also provide an option for intervention in high-risk individuals with known exposure to MERS-CoV.

Fig. 6. Reduction in virus yield by IFN- β . Vero E6 cells were infected at an m.o.i. of 0.1 with MERS-CoV. At 1 h after inoculation, inoculum was removed, and cells washed and treated with the indicated concentrations of IFN. At 48 and 72 h, supernatants were titrated in the infectivity assay. Results are representative of one experiment (mean \pm SD, $n=3$). The experiment was repeated at least twice.

METHODS

Cell lines and virus. Vero E6 cell line (ATCC 1568) was maintained in Dulbecco's modified Eagle's medium (DMEM) plus 10 % FBS. The Jordan strain of MERS-CoV (Hu/Jordan-N3/2012, GenBank accession no. KC776174.1; de Groot *et al.*, 2013), kindly provided by Drs Kanta Subbarao (National Institutes of Health, Bethesda, MD, USA) and Gabriel Defang [Naval Medical Research Unit 3 (NAMRU-3), Cairo, Egypt], was amplified in Vero E6 cells at an m.o.i. of 0.01. On day 4 after infection, when a cytopathic effect was visible, virus-containing supernatants were collected and clarified by centrifugation. MERS-CoV was titrated on Vero E6 cells by plaque assay.

Cell-based ELISA screen for MERS antiviral agents. Vero E6 cells were seeded using 40 000 cells in 100 μ l DMEM plus 10 % FBS per well in black-, opaque- or clear-bottomed 96-well plates. Test compounds MPA and ribavirin were obtained from Sigma-Aldrich, and IFN- β , IFN- α 2a, IFN- α 2b, IFN- γ and a recombinant product based on the consensus sequence of the IFN- α subtypes designated 'universal type 1 IFN' were obtained from PBL. After 24 h, five dilutions of test compounds were added to the cells in 50 μ l using

a 96-well liquidator (Rainin Instrument). The cell plates were transferred to the containment laboratory to add MERS-CoV (Hu/Jordan-N3/2012) at an m.o.i. of 0.1 in 50 µl DMEM plus 10% FBS approximately 1 h after the addition of the drugs. After 48 h, plates were fixed with 10% neutral-buffered formalin and removed from biocontainment. MERS-CoV was detected with a rabbit polyclonal antibody to the HCoV-EMC/2012 S protein (Sino Biological) followed by staining with Alexa Fluor 594-conjugated goat anti-rabbit IgG (H+L) antibody (Life Technologies). Nuclei were detected with the Hoechst 33342 dye, which stains DNA. For Alexa Fluor 594, fluorescence was quantified on a plate reader (Infinite M1000 Pro; Tecan US) with an excitation wavelength of 590 nm and an emission wavelength of 617 nm. The Operetta high content imaging system (PerkinElmer) and analysis software (Harmony 3.1) was used to quantify fluorescence of both dyes, Alexa Fluor 594 and Hoechst 33342. Wavelengths of 360–400 and 560–580 nm were used to excite Hoechst 33342 dye and Alexa Fluor 594 dye, respectively. Emission wavelengths of 410–480 and 590–640 nm were used to detect Hoechst 33342 and Alexa Fluor 594 fluorescence, respectively. Operetta software was used to set the threshold for background versus MERS-CoV-positive cells and determine the mean fluorescence intensity (MFI) of MERS-CoV-positive cells in nine fields per well at $\times 20$ magnification. MFI per cell was determined by normalizing the MFI to the total cell number in each well. The percentage inhibition of treated wells (TREAT) compared with untreated wells (UNTR) was determined using the formula: % inhibition = $[1 - (\text{TREAT} - \text{normal}) / (\text{UNTR} - \text{normal})] \times 100$. The signal from treated wells was normalized to uninfected control wells (normal) and measured (as a %) relative to untreated wells. Non-linear regression analysis was performed to calculate IC_{50} values (GraphPad Software). The MERS-CoV ELISA drug screen was carried out with four replicates for each drug concentration and the assay was repeated at least twice for confirmation. Error bars for dose-response curves represent the SD of four replicates.

Cytotoxicity assay. To evaluate the cytotoxicity of the drugs, Vero E6 cells were plated and treated with the drugs at the same concentrations used for detection of MERS-CoV replication inhibition, as described above for the cell-based MERS-CoV ELISA drug screen, but were not infected with virus. At 48 h after drug addition, the plates were analysed using a CellTiter Glo luminescent cell viability assay kit (Promega), and luminescence was read on an Infinite M1000 Pro plate reader. Alternatively, the fluorescent stain Hoechst 33342 (Life Technologies) was used to determine cell numbers in each well to quantify the cytotoxic effect.

Virus yield reduction assay. Vero E6 cells were seeded in 12-well plates at 200 000 cells per well. After overnight incubation, the cells were infected in triplicate with MERS-CoV strain Hu/Jordan-N3/2012 at an m.o.i. of 0.1 and incubated at 37 °C for 1 h with shaking every 15 min. The inoculum was removed, the cells were washed with PBS and fresh medium was added containing 10-fold dilutions of IFN- β (10–1000 U ml⁻¹) for 48 and 72 h. Supernatants were collected and titrated using the infectivity assay. The assay was carried out with three replicates for each drug concentration and was repeated at least twice for confirmation. Error bars of dose-response curves represent the SD of three replicates.

Infectivity assay. Vero E6 cells were infected in eight replicates with 10-fold dilutions of supernatants from the virus yield reduction assay. MERS-CoV was absorbed for 1 h, and then removed and replaced with DMEM plus 10% FBS. Cells were incubated at 37 °C, 5% CO₂, in a humidified environment for 6 days. The cytopathic effect in wells was scored by fixing and staining the cells with crystal violet. The TCID₅₀ was calculated with Microsoft Excel as described by Reed & Muench (1938).

ACKNOWLEDGEMENTS

We thank Calli Lear, Yingyun Cai and Cindy Allan for outstanding assistance in development of the drug screen protocol and Cindy Allan for implementation of protocols in the biocontainment suite. We thank cell culture staff in preparing the cells used in this study. In addition, we acknowledge Laura Bollinger for technical writing services in preparation of this manuscript and Jiro Wada for figure preparation. This work was supported by the Division of Intramural Research of the National Institute of Allergy and Infectious Diseases (NIAID), Integrated Research Facility (NIAID, Division of Clinical Research) and Battelle Memorial Institute's prime contract with NIAID (contract no. NERVTAG

Presented to SAGE on 21/1/21

Authors - Peter Horby, Catherine Huntley, Nick Davies, John Edmunds, Neil Ferguson, Graham Medley, Calum Semple

Summary

1. The variant of concern (VOC) B.1.1.7 appears to have substantially increased transmissibility compared to other variants and has grown quickly to become the dominant variant in much of the UK.
2. Initial assessment by PHE of disease severity through a matched case-control study reported no significant difference in the risk of hospitalisation or death in people infected with confirmed B.1.1.7 infection versus infection with other variants. [1]
3. Several new analyses are however consistent in reporting increased disease severity in people infected with VOC B.1.1.7 compared to people infected with non-VOC virus variants.
4. There have been several independent analyses of SGTF and non-SGTF cases identified through Pillar 2 testing linked to the PHE COVID-19 deaths line list:
 - a. LSHTM: reported that the relative hazard of death within 28 days of test for VOC-infected individuals compared to non-VOC was 1.35 (95%CI 1.08-1.68).
 - b. Imperial College London: mean ratio of CFR for VOC-infected individuals compared to non-VOC was 1.36 (95%CI 1.18-1.56) by a case-control weighting method, 1.29 (95%CI 1.07-1.54) by a standardised CFR method.
 - c. University of Exeter: mortality hazard ratio for VOC-infected individuals compared to non-VOC was 1.91 (1.35 - 2.71).
 - d. These analyses were all adjusted in various ways for age, location, time and other variables.
5. An updated PHE matched cohort analysis has reported a death risk ratio for VOC-infected individuals compared to non-VOC of 1.65 (95%CI 1.21-2.25).
6. There are several limitations to these datasets including representativeness of death data (<10% of all deaths are included in some datasets), power, potential biases in case ascertainment and transmission setting.
7. **Based on these analyses, there is a realistic possibility that infection with VOC B.1.1.7 is associated with an increased risk of death compared to infection with non-VOC viruses.**
8. It should be noted that the absolute risk of death per infection remains low.
9. An analysis of CO-CIN data has not identified an increased risk of death in hospitalised VOC B.1.1.7 cases. However, increased severity may not necessarily be reflected by increased in-hospital death risk.

10. Since the time lag from infection to hospitalisation and death is relatively long, data will accrue in coming weeks, at which time the analyses will become more definitive.

Full text

11. Previously, preliminary results from a matched-cohort study conducted by PHE reported no statistically significant increased risk of hospitalisation or death in VOC-infected individuals compared to non-VOC [1].
12. On Friday 15th January NERVTAG was presented with two papers that reported an increased case fatality rate in subjects with s-gene target failure (SGTF, a proxy for variant B.1.1.7).
13. Both papers used the same core dataset of SGTF cases identified through Pillar 2 testing linked to the PHE COVID-19 deaths line list: a paper from LSHTM [2] and a paper from Imperial College London [3].
14. The LSHTM paper used a Cox proportional hazards model to estimate change in risk of death within 28 days of test for individuals infected with the VOC [2].
 - a. The study was based on 2,583 deaths among 1.2 million tested individuals. 384 deaths were among SGTF individuals.
 - b. Results were controlled for age, sex, index of multiple deprivation, and Upper Tier Local Authority (UTLA).
 - c. The relative hazard of death within 28 days of test was 1.35 (95%CI 1.08-1.68) for VOC-infected individuals, compared to non-VOC, with adjustment made for misclassification of SGTF.
 - d. Focusing only on individuals with SGTF after 1 November 2020 (no adjustment for SGTF misclassification), the relative hazard of death is 1.28 (95%CI 1.06-1.56).
 - e. Relative increases in CFR appeared to be consistent across age groups
 - f. Sensitivity analyses including further hospital pressure covariates (proportion of beds capable of mechanical ventilation occupied; proportion of beds capable of non-invasive ventilation occupied; number of staff absences per bed among medical staff; and number of staff absences per bed among nursing staff) did not substantially change the measure of effect.
15. The Imperial Paper reported the results of a non-parametric analysis of fatal outcomes associated with B1.1.7 [3].
 - a. Two methods were used to evaluate the differences in mortality between VOC and non-VOC cases: case-control-weighting, and standardised CFR. In each case, the ratio of s-gene positive to s-gene negative case fatality ratios (CFRs) is calculated.
 - b. The study considers data from all of England and includes specimen dates in the epidemiological week range 46-54 (54 being week 1 of 2021) inclusive. Estimates are adjusted for NHS STP area, epidemiological week, ethnicity

code, and age band.

- c. Across all specimens, the mean ratio of CFRs is 1.36 (95%CI 1.18-1.56) by the case-control weighting method, and 1.29 (95%CI 1.07-1.54) by the standardised CFR method. This estimate includes a correction for the probability over time that a specimen with SGTF is the VOC.
 - d. Relative increases in CFR appeared to be consistent across age groups.
 - e. Subsequent correction for possible differences in PCR cycle threshold values (ct) between VOC and non-VOC cases was included by restricting both groups only to those samples with ct <30. This adjustment made no meaningful difference.
16. A PHE retrospective matched cohort study was also reported [4]:
- a. 23 November 2020 – 4 January 2021 study period (period when >90% of sequenced SGTF samples confirmed to be VOC202012/01). Matching based on 10-year age bands, sex, week of test and lower-tier local authority.
 - b. 92,207 SGTF cases and corresponding comparators were included in the matched cohort (n = 184,414), although routine hospitalisation data is subject to reporting delays and this should be considered preliminary.
 - c. The odds of SGTF cases being admitted was not significantly different to non-SGTF cases (OR = 1.07, 95% CI 0.86 – 1.33).
 - d. Initial analysis identified 152 deaths following a first positive SARS-CoV-2 test, n = 86 (0.09%) SGTF cases and n = 66 (0.07%) comparator cases. It was noted that 0.07% to 0.09% represents a 28% relative increase in the risk of death, which is compatible with the results from LSHTM and Imperial.
 - e. Initial analysis of 14,939 SGTF cases and 15,555 comparators who had at least 28 days between specimen date and the study period end date. There were 25 deaths (0.17%) in SGTF cases and 26 deaths (0.17%) in comparators (RR 1.00, 95% CI 0.58 – 1.73).
 - f. Updated linkage of deaths data to the same matched cohort on 19/01/2021 identified there were 65 deaths among non-SGTF cases (0.1%) and 104 deaths among SGTF cases (0.2%), within 28 days of specimen date. With this increased time for follow-up and ascertainment of deaths, the risk ratio increased to 1.65 (95%CI 1.21-2.25).
17. There are potential limitations in these datasets:
- a. The dataset used in the LSHTM, Imperial, Exeter and PHE analyses is based on a limited subset of the total deaths. This includes approximately 8% of the total deaths occurring during the study period. Of all coronavirus deaths, approximately 26% occur in individuals who have had a Pillar 2 test, and only 30% of these have S-gene data. The results of all studies may therefore not be representative of the total population.
 - b. Restriction of analysis in the PHE matched cohort to people with a full 28 days follow up at the first analysis reduced statistical power and removed the

excess death signal. However, the LSHTM analysis show an increasing divergence in CFR between VOC and non-COV with time since diagnosis. A later update of the PHE analysis with additional follow-up time identified an increased risk ratio for 28-day case fatality.

- c. Some laboratories only report SGTF if the PCR cycle threshold (ct) value is <30, since target gene failure can occur with low viral loads. For the LSHTM paper, no such ct threshold was applied to non-SGTF positive samples.
 - i. A sensitivity analysis of the Imperial study produced a CFR ratio estimate where the cycle threshold was limited to <30 for both SGTF and non-SGTF samples. The estimate was 1.37 (95%CI 1.19-1.56) by the case-control weighting method, and 1.30 (95%CI 1.08-1.57) by the standardised CFR method. These results were similar to those obtained without this restriction.
 - d. The increased transmissibility of VOC B.1.1.7 compared to non-VOC variants might lead to differences in the context in which cases are occurring. For example, if institutional outbreaks are more likely with B1.1.7 compared to non-VOC, then an age matched analysis might be comparing frail elderly people in nursing home outbreaks of B.1.1.7 with healthier elderly people infected with the non-VOC virus in the community. However, both the Imperial and the LSHTM analyses showed increased CFRs across all age groups. This potential bias could therefore not explain the increased CFR in younger age groups.
 - e. If there is an increase in the severity of infection with VOC B1.1.7, we would also expect to see an increase in the risk of hospitalisation. Currently, we do not have evidence of an increased risk of hospitalisation in individuals with VOC B1.1.7 but data are limited due to lags in the availability of hospitalisation data.
18. A rapid analysis of CO-CIN data during the period in which VOC B1.1.7 emerged was reported [5]:
- a. Across the whole CO-CIN cohort, there is no observed increase in hospital case fatality in the period during which VOC emerged in England, after adjusting for period of admission, age, sex, deprivation, and ethnicity.
 - b. Compared to March 2020, hospital CFR continues to be lower and has been stable in September through December.
 - c. Data return from CO-CIN is currently reduced and unevenly distributed, which will impact on the representativeness of findings. Importantly there are a substantial number of outcomes missing from cases admitted in late December, when the impact of VOC emergence would start to be apparent in hospital data.
 - d. A sub-analysis included linked data from 21,882 cases (21,596 non-VOC and 286 VOC) from across the whole CO-CIN cohort. VOC in this sub-study was robustly determined by COG sequence lineage, rather than assumed by

SGTF. Outcome data was available for only 143 VOC cases. However; 32 VOC cases were identified at one trust with good data quality returns throughout the period of study.

- e. Restricting the analysis to a trust with high proportion of proven VOC which has maintained good quality data returns, and after adjusting for age and sex, found no statistically significant change in hospital CFR comparing proven VOC (n=32) with non-VOC (n=184) (OR 0.63, 95%CI 0.20 – 1.69).
 - f. An increase in case fatality rates would not necessarily manifest as an increase in case fatality rates amongst those hospitalised. Rather, it may increase the proportion of cases who are ill enough to meet the severity threshold for hospitalisation, but not affect the likelihood of death amongst those who are sick enough to be admitted.
19. A subsequent independent case control analysis of Pillar 2 data linked to the death line list by Exeter University, matched on age, specimen time, location, ethnicity, gender and index of multiple deprivation, reported a mortality hazard ratio for VOC-infected individuals compared to non-VOC was 1.91 (1.35 - 2.71).

Summary

- 20. There is evidence from analysis of Pillar 2 testing data linked to COVID-19 deaths that infection with VOC B.1.1.7 is associated with an increased case fatality rate compared to infection with non-VOC viruses. The relative increase in CFR appears to be apparent across age groups.
- 21. An initial retrospective matched cohort study from PHE (also based on linked testing and mortality data) found no evidence of a significant difference in risk of hospitalisation or death between individuals with VOC and individuals with non-VOC when analysis was restricted to those with completed 28 days follow up, but had insufficient statistical power to assess this accurately. A later update of the analysis with additional follow-up time, has now also identified an increased risk ratio for 28-day case fatality.
- 22. CO-CIN has not found evidence of an increase in hospital case fatality rate associated with VOC B.1.1.7, both across the whole cohort and in a single trust with a high rate of good quality data using sequence determined lineage. However, increased severity may not necessarily be reflected by increased in-hospital death risk.
- 23. There are limitations in all datasets that it may not be possible to resolve but as more data accrue the analyses will become more definitive.

Conclusion

- 24. **There is a realistic possibility that VOC B.1.1.7 is associated with an increased risk of death compared to non-VOC viruses.**

Recommendations

25. PHE to review if cases associated with care homes can be flagged in Pillar 2 data for an analysis adjusted for care home status.
26. ONS should assess if it is possible to link ONS survey participants to SUS data on hospitalisations and to deaths. This dataset would suffer from less ascertainment bias since participants are a random selection and ascertainment of cases is not dependent on symptoms or on seeking a test from the Test and Trace. This analysis will be limited in power, so analyses comparing ONS estimates of the proportion of the population infected over time, with the number of hospitalisations and deaths over time, stratified by age and region, could also provide insight as to whether case fatality rates have changed during the period of emergence of the virus.
27. Co-CIN to stratify analyses by region to assess whether in hospital mortality time trends differ in those regions affected by the VOC earliest.
28. ISARIC CCP-UK / CO-CIN to be re-prioritised as Tier 1 UPH study.

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Prospective contact-tracing study

SUMMARY

Background: The outbreak of coronavirus-disease-2019 (COVID-19) has rapidly spread to many places outside Wuhan. Previous studies on COVID-19 mostly included older hospitalized-adults. Little information on infectivity among and characteristics of youngsters with COVID-19 is available.

Methods: A cluster of 22 close-contacts of a 22-year-old male (Patient-Index) including youngsters with laboratory-confirmed COVID-19 and hospitalized close-contacts testing negative for severe-acute-respiratory-syndrome-coronavirus-2 (SARS-CoV-2) in Anhui Province, China was prospectively-traced.

Results: Since January 23, 2020, we enrolled a cluster of eight youngsters with COVID-19 (median age [range], 22 [16–23] years; six males) originating from Patient-Index returning from Wuhan to Hefei on January 19. Patient-Index visited his 16-year-old female cousin in the evening on his return, and met 15 previous classmates in a get-together on January 21. He reported being totally asymptomatic and were described by all his contacts as healthy on January 19–21. His very first symptoms were itchy eyes and fever developed at noon and in the afternoon on January 22, respectively. Seven youngsters (his cousin and six classmates) became infected with COVID-19 after a few-hour-contact with Patient-Index. None of the patients and contacts had visited Wuhan (except Patient-Index), or had any exposure to wet-markets, wild-animals, or medical-institutes within three months. For affected youngsters, the median incubation-period was 2 days (range, 1–4). The median serial-interval was 1 day (range, 0–4). Half or more of the eight COVID-19-infected youngsters had fever, cough, sputum production, nasal congestion, and fatigue on admission. All patients had mild conditions. Six patients developed pneumonia (all mild; one bilateral) on admission. As of February 20, four patients were discharged.

Conclusions: SARS-CoV-2-infection presented strong infectivity during the incubation-period with rapid transmission in this cluster of youngsters outside Wuhan. COVID-19 developed in these youngsters had fast onset and various nonspecific atypical manifestations, and were much milder than in older patients as previously reported.

Introduction

The outbreak of the 2019-novel-coronavirus-disease (COVID-19) caused by severe-acute-respiratory-syndrome-coronavirus-2 (SARS-CoV-2) emerging from Wuhan in December 2019 has been arousing great global health concern, with many unknowns regarding the transmission dynamics and spectrum of illness to be answered.^{1–3} SARS-CoV-2 has rapidly spread to many places outside Wuhan, where imported cases with ascertained COVID-19 among travelers returning from Wuhan without direct exposure to any wet-markets or wild-animals have been reported.^{2–4} Current epidemiologic data indicate that human-to-human transmission of SARS-CoV-2 has been rapidly occurring.^{2,5,6}

The great number of COVID-19 infections may be attributable to the late identification of sources-of-infection and the ability of the host to shed the infection while asymptomatic.^{1,7} While a study⁸ suggests that transmission may occur during the incubation-period, the validity was questioned by *Science* because the evidence was not directly obtained from the infectious-patient, who actually had developed symptoms, which were controlled by a fever-lowering agent, before disease transmission to others.⁹

Published reports^{2,10,11} focused on hospitalized older patients in Wuhan, many of whom had a history of exposure to the Huanan-Seafood-Wholesale-Market, and suggested that COVID-19 mainly affected older adults with frequent chronic comorbidities, and that many of them developed severe pneumonia, for whom organ dysfunction and failure and death can occur. However, the characteristics and infectivity of COVID-19 among youngsters have been rarely reported, and information on SARS-CoV-2-negative close-contacts, patients with mild infections, or those with infections outside Wuhan remains limited.

We collected and analyzed detailed data from a cluster of youngsters aged 16–23 years with laboratory-confirmed COVID-19 in Hefei, China, originating from a 22-year-old youngster (Patient-Index) returning from Wuhan who rapidly transmitted COVID-19 to seven other youngsters of similar ages without recent travel to Wuhan, where rapid transmission had occurred during the incubation-period of illness in Patient-Index. We also identified all the SARS-CoV-2-negative close-contacts of Patient-Index, and further compared them with the SARS-CoV-2-positive patients. We carefully examined the infectivity and transmission dynamics by obtaining valid information directly from the patients and contacts themselves. We are herein describing the demographic, epidemiological, clinical, radiological, and laboratory features, management, and outcomes of the cluster of youngsters with COVID-19 and also the SARS-CoV-2-negative close-contacts.

Methods

Participants

On January 23, 2020, we initially enrolled a 22-year-old male (Patient-Index/1) returning from Wuhan who initially presented to Feidong People's Hospital (Hospital-1; the eastern branch of First Affiliated Hospital of Anhui Medical University [Hospital-2]) in Hefei, with fever, productive cough, myalgia, and lung infiltrates on chest-computed-tomography (CT)-scan. He was suspected to be infected with COVID-19. We immediately formed an expert investigation-team prospectively following-up and tracing all the contacts.

Subsequently, from January 25 through 27, seven young symptomatic close-contacts of Patient-Index (his cousin and six classmates) also presented to hospital (**Table 1**; **Fig. S1**) for management of relevant manifestations and assessment of health-conditions after having learned about the COVID-19 outbreak in Wuhan and the human-to-human-transmission. All

the eight patients tested positive for SARS-CoV-2 using real-time-reverse-transcriptase-polymerase-chain-reaction (rRT-PCR), confirming COVID-19. Starting from January 27, the other contacts of Patient-Index were admitted to Hospital-1 for quarantine (nine; Contacts-1-9) if residing in Feidong, a county >400 kilometers northeast of Wuhan, or directly isolated at home and home-visited by local healthcare-authorities if living in other parts of Hefei (two), and they all tested negative for SARS-CoV-2. This study was approved by the Ethics Committee of Hospital 1. Informed consent was obtained from all patients and contacts.

We prospectively collected information on the demographic, epidemiological, clinical, radiological, and laboratory characteristics and management and outcomes for all the eight youngsters with laboratory-confirmed COVID-19 and the nine admitted SARS-CoV-2-negative contacts of Patient-Index. All data were collected into a standardized and customized data-collection form, and validated by a trained team of physician-scientists. At least two investigators independently reviewed the collected information to double-check the data and verify the accuracy. Follow-up was until February 20.

We directly communicated with and interviewed all SARS-CoV-2-positive patients and SARS-CoV-2-negative contacts themselves, and their family-members, relatives, classmates, friends, and healthcare-workers when necessary, to collect and ascertain all medical-history, epidemiological (exposure-history, timelines of events, close-contact identification, etc.), and symptom data, which were cross-checked with information from multiple sources. We determined exposure-histories during the three months before illness-onset or hospital-admission, including the dates, time, frequencies, and patterns of contacts with any person who had fever, respiratory-symptoms, or other relevant symptoms, with any wild-animals, or with any relevant environments such as any wet-markets or medical-institutes. Information on history of travel to Wuhan and direct contact with people returning from Wuhan within three months before symptom-onset or hospital-admission was also included.

The definitions and management of all suspected and ascertained COVID-19 cases enrolled were according to the World Health Organization (WHO) guidance¹² and the New Coronavirus Pneumonia Prevention and Control Program by the China National Health Commission,¹³ and pathogen examinations are detailed in *Supplementary methods*.

Statistics

The incubation-period was defined as days from infection/exposure to illness-onset was estimated. The serial-interval was defined as the time delay between illness-onset dates in successive cases in a transmission-chain.

Continuous variables were shown as median (range), and categorical variables as count (percentage). Blood laboratory-examination findings were illustrated using boxplots, assessed regarding whether the measurements were outside the reference-range, and compared between SARS-CoV-2-positive patients and SARS-CoV-2-negative contacts using the Mann-Whitney-Wilcoxon-test for unpaired samples. Considering the potential type-I-error, the findings should be interpreted as exploratory.

A two-sided *p*-value of <0.05 was considered statistically-significant. Statistical-analyses were performed using the R 3.6.2 software (<https://www.r-project.org/>).

Results

Patient-Index/1 is a 22-year-old overweight otherwise-healthy male-nonsmoker and a Wuhan company-employee. He took the high-speed-rail leaving Wuhan in the morning on January 19,

Table 1

Demographic and baseline characteristics of the eight young patients with confirmed 2019 novel coronavirus disease as of February 17, 2020

Characteristics	Patient 1	Patient 2	Patient 3	Patient 4	Patient 5	Patient 6	Patient 7	Patient 8	Summary ¹

¹ Described for continuous and categorical variables, and expressed as median (range) and count/total number of patients with available data (percentage), respectively.² For Patients 3-8.³ For Patients 2-8.⁴ For Patients 1-6; the other patients have not been transferred.⁵ For Patients 2, 3, and 8; the other patients remain in hospital. Values shown in bold indicate abnormal ones. ↑, above the upper limit of the normal range; ↓, below the lower limit of the normal range; -, not applicable; Y, Yes; N, No; rRT-PCR, real-time reverse-transcriptase polymerase-chain-reaction.

Fig. 1. Representative transverse chest computed tomography scan images. (A) Day 1 after illness onset for Patient Index. A few infiltrates (slight slice-like shadow with increased density) in the lower lobe of the right lung were seen. (B) Day 3 after illness onset for Patient Index. In the peripheral zones of both lungs, scattered ground-glass opacities with fuzzy edges were seen, suggesting bilateral pneumonia with highly likely viral nature. (C) Day 2 after illness onset for Patient 3. A few infiltrates and ground-glass opacities were detected in the lower lobe of left lung. (D) Day 3 after illness onset for Patient 4. Ground-glass opacities and infiltrates in the right lung were observed. (E) Day 2 after illness onset for Patient 7. Small patchy and mottling high-density sub-pleural shadows were seen in the upper lobe of left lung. (F) Day 5 after illness onset for Patient 7. The left upper lung lesion progressed. Antiviral therapy started. (G) Day 13 after illness onset for Patient 7. Patchy blurring infiltrates in the peripheral parts of the left lung with obscure boundary remained. (H) Day 21 after illness onset for Patient 7. The patchy ground-glass density shadows and infiltrates with fuzzy edges in the left lung had been obviously absorbed. (I) Day 3 after illness onset for Patient 8. Few strip-like shadows with uneven density were seen in both lungs. (J) Day 6 after illness onset for Patient 8. Multifocal ground-glass density shadows and opacities in the peripheral parts of both lungs were observed. Antiviral therapy started. (K) Day 14 after illness onset for Patient 8. The multiple patchy high-density shadows consistent with novel coronavirus pneumonia with unclear boundary seen in the peripheral parts of both lungs progressed. (L) Day 18 after illness onset for Patient 8. Absorption of pneumonia lesions in both lungs was observed compared to the previous scan.

2020, four days before the “lockdown” of Wuhan, and arrived at his hometown in Feidong in the afternoon for the China Spring-Festival (Fig. 1). In the evening on January 19, he went to visit (talk and have supper with) his cousin, a 16-year-old otherwise-healthy female (Patient-2) and his uncle (Contact-1; later excluded from infection), in their apartment for about 0.5 hours without air-conditioning or wearing a mask. Further exposure and contact details are shown in Supplementary results and Table S1.

At noon on January 20, he met and ate hotpot with a female (Contact-2; later excluded from infection), sitting face-to-face for about one hour, and went shopping together afterwards. The following day on January 21, he took part in a classmate-get-together in Feidong where he had dinner in a restaurant-room with air-conditioning and also windows open at about 11:30–14:00 and afterwards sang Karaoke in a confined-room at about 14:00–16:30 with air-conditioning and with some fruits shared, with 15 of his previous classmates whose hometowns are all in Hefei. Further details on the get-together are shown in Supplementary results, Table S1, and Figs. S1 and S4. Afterwards, he had supper with a 22-year-old otherwise-healthy male (Patient-4) while the others went right back home. Nobody found him unhealthy that day. He reported that he was totally asymptomatic and well before and on January 21. Among his classmates he contacted, six (Patients-3–8) were later confirmed with COVID-19, and the person who first ex-

perienced any relevant symptoms was Patients-4 and 8 (both on January 22).

Patient-Index reported that the very first symptom that he experienced was itchy eyes at noon on January 22 (Fig. S1). In the afternoon, he felt dizzy with a fever of 37.5°C developed (measured by himself), and he (starting to wear a mask) attended a local outpatient-clinic in Feidong and was prescribed amoxicillin capsules, paracetamol and amantadine compound capsules, and ambroxol dispersible-tablets, after taking which his temperature returned to normal (36.5°C). On the same day, he also developed mild nasal-congestion and rhinorrhea, both lasting 2 days. On January 23, his body temperature was normal in the morning but rose again to 37.5°C at noon, which was again temporarily controlled by the drugs; however, in the evening he had fever again. On the same day before the onset of fever, Patient-2 went to visit Patient-Index, and brought him some home-made food. They ate and chatted together in his room which was tightly confined with no doors or windows open and without air-conditioning for about 0.5 h. Patient-2 later became infected. Having learned about the COVID-19 emergence in Wuhan and the possible human-to-human-transmission from Internet at noon on January 22, he decided to go to Hospital-1 for further assessment and management in the evening on January 23. Virus-RNA detection using respiratory-samples taken on January 26 and 27 both revealed

positive results on rRT-PCR assays, confirming the SARS-CoV-2 infection (Fig. 1). Assays to detect other pathogens were all negative. Further descriptions of the disease-course and management of Patient-Index are detailed in *Supplementary results*.

Tracing of the contacts of Patient-Index started immediately after his admission to hospital. Before illness onset, he closely contacted 22 people (15 classmates and seven family-members). 16 of the contacts were admitted to hospital under isolation: seven (Patients-2–8) developed COVID-19-relevant symptoms, and were later identified to have laboratory-confirmed SARS-CoV-2-infection, and nine (Contacts-1–9) tested negative for SARS-CoV-2 and had normal CT-scan findings, and were discharged to home-isolation 4–5 days after admission. The other six contacts were quarantined and isolated at home, and closely watched by healthcare-workers; they all tested negative for SARS-CoV-2.

None of the contacts had visited any wet-markets or hospitals, contacted any wild-animals, or eaten any game-meat within three months (Tables S1). None of them had resided in, traveled to, or passed Wuhan, other cities in Hubei, or any region where SARS-CoV-2-transmission was known to be occurring within three months. They reported no contacts with any individual recently returning from such a region, with anyone having any suspicious symptoms (e.g., fever, cough, or other respiratory or relevant digestive symptoms), or with anybody later developing relevant symptoms or confirmed with COVID-19 except Patient-Index within three months (this was ascertained by an investigation by the healthcare-authority in Hefei). They did not have any infected family-members or members having visited Wuhan. None of the contacts had any symptom of illness during exposure.

Patients-2–8 were admitted to hospital under isolation 1–3 days after the admission of Patient-Index on February 25–27. The respiratory-samples of all patients tested positive for SARS-CoV-2 for at least two times. Five of the classmates Patient-Index contacted in the get-together initially tested positive for SARS-CoV-2 on January 26, and another classmate and Patient-Index's cousin initially on January 27. We did not find any evidence of co-infection with other known respiratory viral, bacterial, or fungal pathogens in any of the patients on microbiological-testing.

Of all the eight infected youngsters, the median-age was 22 years (range, 16–23; Table 1), and six were male. Three were company-employees, four university-students, and Patient-2 a senior-high-school-student. Three were overweight. Patients-4 and 8 were current-smokers. Three had mild comorbidities (Patients-5 and 7, chronic gastritis; Patient 6, fatty-liver). While Patient-3 initially reported no coexisting medical-conditions, his blood-pressure was measured to be 150/94 mm Hg on admission. They all immediately wore masks and paid special attention to hand-hygiene after illness-onset.

The median incubation-period for Patients-3–8 was two days (range, 1–4; Table 1). The median serial-interval in the young-cluster was one day (range, 0–4; Patients-4 and 8 had symptom onset on the same day as Patient-Index). Among the eight youngsters with COVID-19, the median duration from illness-onset to first-hospital-admission was two days (range, 1–3). The median interval between illness-onset and second positive-test for SARS-CoV-2 which ascertained the COVID-19 diagnosis was four days (range, 2–5).

The presentations of the eight young-patients are shown in Table 2 and Fig. S2. Because manifestations acquired after hospitalization may be influenced by the hospital-environment and drug-use, we primarily describe those developed before or on admission. We did not identify any patients asymptomatic on admission but testing positive for SARS-CoV-2. All patients had mild clinical-conditions, and developed ≥ 2 symptoms and/or signs before or on admission. Most youngsters (seven) developed fever

(except Patient-6). The median body-temperature on admission was 37.5°C (range, 37.0–38.2), and the median highest temperature during disease-course was 38.5°C (range, 37.1–38.9). None had a high fever (temperature $>39^\circ\text{C}$). The fever of Patients-Index, 2, and 5 showed an intermittent pattern, and Patients-3–5 experienced chills. Four patients had productive-cough, and Patients-6 and 7 had dry-cough. Five patients had both fever and cough. Four youngsters experienced fatigue, and three myalgia. Patients-2 and 7 reported experiencing no upper-respiratory-tract-infection symptoms (sore-throat, nasal-congestion, rhinorrhea, and/or sneezing), while five youngsters had more than two such symptoms. Patient-7 reported shortness of breath for two days on admission. None of the youngsters developed dyspnea, or chest-discomfort or pain. Three patients had headache, and Patient-Index reported dizziness. Eye-discomfort was noted in Patients-Index and 3, and backache in Patient-3. Two patients had anorexia, and three nausea, but vomiting did not develop in any of them before or on admission. Only Patient-8 developed diarrhea, and Patient-5 reported abdominal-discomfort. Nobody only presented with digestive-symptoms. Patient-2, the youngest patient (16 years), had only two presentations on admission: intermittent fever for two days and headache for one day, while the others reported 4–11 symptoms. The symptoms on illness onset are described in *Supplementary results*.

On admission, abnormalities in chest-CT-images suggesting viral-pneumonia were detected in six (all males; 22–23 years) of the eight youngsters confirmed with COVID-19 (Table 2; Fig. 1). None of the conditions were severe. Of the six pneumonia-patients, five had unilateral-involvement, and Patient-8 had bilateral-pneumonia on admission; four had involvement of the lower-lobe, and the other two of the middle-lobe. Of the five patients with unilateral-disease, pneumonia was located in the right-lung in four patients, and in the left-lung in Patient-3. The typical-findings on chest-CT-scan, multifocal-mottling, patchy-shadows, and/or ground-glass-opacities,² which were mostly around the peripheral-parts of the lungs and which were compatible with abnormalities seen in viral-pneumonia, were detected in the pneumonia-patients on admission. Patient-Index's pneumonia progressed to bilateral-pneumonia two days after the initial scan. For the youngest patient (Patient-2; 16 years), while no abnormalities were detected the next day after illness-onset, a few infiltrates were noticed in the lower-lobe of left-lung six days later.

The blood-routine tests of the seven youngsters with available information on admission showed leucopenia and substantial neutropenia in Patients-2 and 4 (Table 3). Patient-8 had increased neutrophils, but decreased lymphocytes. Patient-7 also had lymphopenia. Patients-1 and 3 had both red-blood-cell count and hemoglobin above the normal-range. Patient-2 had slightly shortened prothrombin-time, while Patient-4 showed mildly extended activated-partial-thromboplastin-time, and Patient-8 slightly increased international-normalized-ratio. Patient-3 had elevation of creatine-kinase and lactate-dehydrogenase reaching the upper-limit of reference-range. Regarding the infection-index, procalcitonin was above the normal-range in Patient-4. Patient-1 had an elevated level of C-reactive-protein. Most patients had normal serum levels of procalcitonin on admission (five of six youngsters with available information).

While testing negative for SARS-CoV-2, Contacts-1–9 also showed some changes in blood-examinations (Table 4; *Supplementary results*). When comparing the laboratory-findings between Patients-1–5 ascertained with COVID-19 with Contacts-1–9 with negative SARS-CoV-2-tests (Fig. S3), all of whom were initially admitted to Hospital-1, lymphocyte-count on admission was lower in the SARS-CoV-2-positive patients than the SARS-CoV-2-negative contacts ($p=0.042$). Initial fibrinogen-concentrations were higher in the patients ($p=0.019$). Levels of sodium were lower in the

Table 2

Symptoms, signs, radiological findings, treatment, and outcomes of the young cluster infected with the 2019 novel coronavirus disease.

patients ($p=0.016$). Plasma-concentrations of C-reactive-protein were markedly higher in SARS-CoV-2-positive patients ($p=0.016$).

Management and outcomes of the eight youngsters with laboratory-confirmed COVID-19, and description of all the other contacts are detailed in *Supplementary results*.

Discussion

Currently, our understanding of the spectrum and natural-history of SARS-CoV-2-infection remains limited. We herein provide an assessment of the infectivity, transmission dynamics, and other characteristics of a cluster of eight young-patients aged 16–23 years confirmed with SARS-CoV-2 on rRT-PCR originating from Patient-Index returning from Wuhan who rapidly transmitted COVID-19 when totally asymptomatic, and compare them to the other nine close-contacts of Patient-Index testing negative for SARS-CoV-2. The disease was transmitted outside Wuhan and all patients were diagnosed and managed in Hefei. The young patients admitted with COVID-19 had fast illness-onset and symptoms somehow resembling a common-cold, which were much milder than those of older hospitalized adults with COVID-19 as recently-reported.^{1,2,10} While patchy-shadows and ground-glass-opacity on CT-scan were common, they were much less severe than the older patients.^{2,10} Not all patients had radiological-changes indicating viral-pneumonia on admission.

Notably, our findings provide valid evidence demonstrating efficient local human-to-human-transmission with strong infectivity of SARS-CoV-2 within this cluster of youngsters during the incubation-period and asymptomatic-phase of COVID-19. SARS-CoV-2 tested positive in six of the 15 young classmates Patient-Index contacted in the get-together when he was totally asymptomatic, with the minimal exposure-duration of only two hours. The attack-rate is high (40%). The symptoms of Patients-4 and 8 developed on the same day as that of Patient-Index. We carefully had interviews directly with both Patient-Index himself and all the other contacts to confirm the absence of any symptoms of Patient-Index before and during the contacts, thus ascertaining the transmission during asymptomatic-phase. We may need to pay special attention to preventing COVID-19 transmission from people looking asymptomatic but with exposure-history. The incubation-period and serial-interval in this young cluster were much shorter than previously-reported for majorly older patients at the earlier stage of the epidemic.¹

Infected-youngsters may act as important sources-of-infection. Notably, Patient-6 remained afebrile throughout the disease-course. These cryptic cases of walking-SARS-CoV-2-infection might act as potential sources to propagate the epidemic. Since it is difficult to differentiate and screen patients during the incubation-period, further studies on the popularity of this transmission-pattern and the epidemiological-significance of cases with null or mild symptoms are warranted, which would help make relevant control-measures to prevent the future spread of infection. It may be needed to commit sufficient resources to examination in outpatient-clinics and emergency-departments for proactive case-identification, both as part of the containment-strategy in locations without local-spread yet and to permit earlier clinical-management of infected-individuals.

The most likely transmission-scenario is that Patient-Index acquired the SARS-CoV-2-infection in Wuhan, and then transmitted the virus to Patient-2 after two contacts and Patients-3–8 during get-together on January 21 after returning to Feidong on January 19. Patient-2 more likely acquired the infection during the second contact on January 23 with an incubation-period of three days rather than on January 19, since Contacts-1 and 2, with whom Patient-Index had close-contacts in the evening on January 19 and on January 20, respectively, did not develop the infection. These

indicate the relatively weak infectivity up till January 20, and the possibility of dynamic changes in infectivity, which possibly became strong enough to enable the disease to affect others sometime on January 20 or 21, still during the incubation-period of Patient-Index. Further studies on the diverse infectivity during different stages of disease and the corresponding time-points are warranted.

Almost half of the previously-reported cases were in adults aged ≥ 60 years.¹ Younger patients were thought to be less likely infected.¹ Few reports exist on younger patients aged 15–25 years. Delays from illness-onset to admission were generally short in these eight youngsters with COVID-19 in our study, with five hospitalized within two days of illness-onset. The symptoms of these youngsters were all mild and largely-nonspecific, which may be hardly clinically-distinguishable from many other common infectious-diseases, particularly in winter.

The first three most common symptoms on illness-onset were fever, cough, and sore-throat. None initially presented with a digestive-symptom. On admission, half or more of the youngsters with COVID-19 presented with fever, cough, sputum-production, nasal-congestion, and fatigue, which are much milder than previous reports including majorly older hospitalized-patients with frequent comorbidities, who may have lower immune-function than younger people.^{2,10} Fever developed in seven of the eight youngsters, with six having fever on illness-onset. Three youngsters developed one or more digestive-manifestations before or on admission, which are more frequent than the previous report on older hospitalized-patients.^{2,10} Patient-8 developed diarrhea before admission. About 11% of SARS-CoV¹⁴ and 30% of MERS-CoV patients¹⁵ also had diarrhea. None of the abovementioned symptoms was present in all youngsters. Notably, two youngsters presented with eye-discomfort on admission (one had itchy-eyes as the very initial symptom) and one with backache at illness-onset, which appears to not have been observed in older patients.^{2,10}

For the six youngsters showing pneumonia on admission, multifocal ground-glass opacities typical of viral-pneumonia on chest-CT-scans were frequently seen, while their lung-involvement was much milder and more local and limited than older patients.^{2,10} Unlike older patients typically having bilateral-pneumonia,^{2,10} the pneumonia youngsters mostly had showed unilateral lung-involvement on admission.

Regarding laboratory-examinations, two patients had leucopenia. The absolute neutrophil-counts were reduced in the same two patients, while they were elevated in another patient. Furthermore, lymphopenia occurred in two patients, and two youngsters had both elevated red-blood-cell-count and hemoglobin level. These changes were not consistent with the previous report on older patients with more severe conditions.¹⁰ These may suggest diverse immune-status against the virus. Neutrophilia may be related to cytokine-storm induced by SARS-CoV-2 invasion. Compared with SARS-CoV-2-negative contacts, SARS-CoV-2-positive patients had fewer lymphocytes and higher fibrinogen and C-reactive-protein levels. These suggest that SARS-CoV-2-infection may be associated with deficiency in immune-function and activation of coagulation, which could have been related to inflammatory-response.

As of February 20, 2020, none of the eight young patients had dyspnea, developed any severe clinical-conditions, complications, or adverse-outcomes, were admitted to an intensive-care-unit, required machine-ventilation, or died, which is largely different from the findings in older patients.^{2,3,10} They mostly remained stable during hospitalization. These suggest that age, comorbidity, and symptoms on illness-onset or admission may be important prognostic factors.

Our study has some limitations. First, the case number is limited, which necessitates the cautious interpretation of the generalizability of our findings. Collection of data for a larger

cohort would help to enable a more comprehensive understanding of COVID-19 among youngsters. Second, the route of transmission was not totally clear. While the most likely one was via droplets or aerosol or airborne, we did not collect urine or fecal samples, which prevented us from analyzing whether COVID-19 could be transmitted through the fecal-oral pathway. Third, the relative-risk of infection among youngsters compared to older individuals and the association of timing or mode of manifestations and CT and laboratory findings with disease-course, outcomes, and spread need to be further evaluated. Fourth, the serum of patients and contacts was not obtained to evaluate possible viremia. Respiratory-tract samples were used to diagnose COVID-19 through rRT-PCR according to the guidelines,^{1,16–19} and they have a higher positive rate than blood and other samples and are more clinically and epidemiologically relevant.²⁰ There could have been transient viremia in the SARS-CoV-2-negative contacts, which was not captured on admission. The corresponding epidemiological and clinical significances need to be further clarified.

Conclusion

We provide valid evidence supporting efficient asymptomatic human-to-human transmission of SARS-CoV-2 showing strong infectivity based on a cluster of youngsters aged 16–23 years in a local community setting outside Wuhan. COVID-19 was rapidly transmitted by the index patient during the (late) incubation-period to other seven youngsters, demonstrating strong infectivity. The symptoms of the youngsters with COVID-19 had fast-onset, and were generally mild, nonspecific, atypical, and diverse.

Declaration of Competing Interest

None reported.

Author contributions

Drs Lei Huang, Xiuwen Zhang, Xinyue Zhang, and Zhijian Wei contributed equally to this article. LH, XWZ, CYZ, and AMX had the idea for the study and full access to all data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. LH is an epidemiologist and physician scientist with clinical epidemiology as the major subject and public health and statistics as subjects during his PhD, XWZ is an infectious disease specialist with rich work experience in isolation ward, XYZ is a statistician, ZJW is a physician scientist, LLX and JJX have rich experience in clinical communication and data collection, PPL is an emergency medicine specialist, YHX is a professor of laboratory medicine, CYZ is a respiratory medicine and critical care medicine specialist, and AMX is a physician scientist with interest in clinical epidemiology and public health. LH, XWZ, ZYZ, ZJW, CYZ, and AMX played roles in the literature search, study conception and design, patient recruitment, clinical management, sample collection, data collection, analysis, and interpretation, and writing of the report. LLZ, JJX, and YHX played roles in the laboratory assays, data collection, analysis, interpretation, and confirmation and critical revision of the report. PPL played roles in recruitment, clinical management, data collection, and critical revision of the report. All authors reviewed and approved the final version of the manuscript. AMX is the guarantor. The corresponding authors attest that all listed authors meet authorship criteria and that no others meeting the criteria have been omitted.

Funding/support

This work was supported by the Emergency Scientific Research Projects of Anhui Medical University (YJGG202002), National Natural Science Foundation of China (81572350), Hefei Key Medical

Specialty Construction Project, Fifth Round (2016256), and Feidong People's Hospital Key Specialty Project, First Round (201911).

Role of the funders/sponsors

None of the funders had any role in the study design and the collection, analysis, and interpretation of data or in the writing of the article and the decision to submit it for publication. The researchers confirm their independence from funders.

Data sharing

The data that support the findings of this study are all included in the manuscript, with no additional data available.

Acknowledgments

We would like to thank the patients and contacts; all healthcare workers and hospitals who provide care for patients with COVID-19 and are involved in the diagnosis and treatment of COVID-19 patients and those who trace and quarantine the contacts; staff at the local, city, and province healthcare departments; members of the COVID-19 response teams at the local, city, province, and national levels; Feidong Center for Disease Control and Prevention (CDC) and medical institutions in Hefei for assistance with field investigation administration and data collection; the Feidong CDC for coordinating data collection for patients with COVID-19; and the Anhui Province CDC and Hefei City CDC for assistance with laboratory testing.

RESPIRATORY INFECTION

Impact of severe acute respiratory syndrome (SARS) on pulmonary function, functional capacity and quality of life in a cohort of survivors

Objective: To examine the impact of severe acute respiratory syndrome (SARS) on pulmonary function, exercise capacity, and health-related quality of life (HRQoL) among survivors.

Methods: 110 survivors with confirmed SARS were evaluated at the Prince of Wales Hospital, HK at the end of 3 and 6 months after symptom onset. The assessment included lung volumes (TLC, VC, RV, FRC), spirometry (FVC, FEV₁), carbon monoxide transfer factor (TlCO adjusted for haemoglobin), inspiratory and expiratory respiratory muscle strength (Pimax and Pemax), 6 minute walk distance (6MWD), chest radiographs, and HRQoL by SF-36 questionnaire.

Results: There were 44 men and 66 women with a mean (SD) age of 35.6 (9.8) years and body mass index of 23.1 (4.8) kg/m². Seventy (64%) were healthcare workers. At 6 months 33 subjects (30%) had abnormal chest radiographs; four (3.6%), eight (7.4%), and 17 (15.5%) patients had FVC, TLC, and TlCO below 80% of predicted values; and 15 (13.9%) and 24 (22.2%) had Pimax and Pemax values below 80 cm H₂O, respectively. The 6MWD increased from a mean (SD) of 464 (83) m at 3 months to 502 (95) m (95% CI 22 to 54 m, $p < 0.001$), but the results were lower than normal controls in the same age groups. There was impairment of HRQoL at 6 months. Patients who required ICU admission ($n = 31$) had significantly lower FVC, TLC, and TlCO than those who did not.

Conclusion: The exercise capacity and health status of SARS survivors was considerably lower than that of a normal population at 6 months. Significant impairment in surface area for gas exchange was noted in 15.5% of survivors. The functional disability appears out of proportion to the degree of lung function impairment and may be related to additional factors such as muscle deconditioning and steroid myopathy.

Severe acute respiratory syndrome (SARS) is a recently emerged infectious disease caused by a SARS coronavirus (CoV).^{1–3} From 1 November 2002 to 31 July 2003, 8098 probable cases were reported worldwide with a death toll of 774.⁴ The clinical course of SARS is characterised by fever, myalgia, and other systemic symptoms that generally improve after a few days, followed by a second phase with recurrence of fever, oxygen desaturation, and radiological progression of pneumonia.⁵ The majority of patients improve with treatment, but 20–36% require intensive care unit (ICU) admission and 13–26% progress into acute respiratory distress syndrome (ARDS) necessitating invasive ventilatory support.^{5–8} The lung pathology of fatal SARS cases was dominated by diffuse alveolar damage, epithelial cell proliferation, an increase in macrophages in the lung, and extensive consolidation,^{9–11} but features of bronchiolitis obliterans organising pneumonia were also noted.¹² Previous studies on survivors of acute lung injury (ALI)¹³ and ARDS^{14–17} unrelated to SARS have shown variable degrees of residual abnormalities in pulmonary function, exercise capacity, and impairment in health-related quality of life (HRQoL).

During the global outbreak of SARS in 2003, healthcare workers were particularly vulnerable as the viral load increased to peak levels around day 10 from symptom onset.^{5–8 18 19} In a major outbreak of SARS at our hospital, over half of those infected were previously healthy healthcare workers.⁶ High resolution computed tomography (HRCT) performed at 5 weeks after discharge selectively on 24 outpatients with residual opacities revealed multiple patchy

ground glass appearance and interstitial thickening ($n = 9$, 38%) whereas CT evidence of fibrotic changes was noted in 15 patients (62%).²⁰ It is possible that ongoing active alveolitis—probably as a result of an uncontrolled host immune response triggered by the viral antigen—may lead to pulmonary fibrosis in some patients. It is thus important to follow these patients to detect and manage pulmonary sequelae and functional impairment.

We report the short to medium term outcome of a prospective follow up study of our cohort which was epidemiologically linked to a single index case during a major hospital outbreak in 2003.^{6 21} Serial lung function, exercise capacity, chest radiographs, and HRQoL were examined at 3 and 6 months after illness onset. In addition, SARS survivors who had required ICU admissions were compared with those who were treated on the medical wards with reference to the same outcome parameters.

METHODS

Subjects

This is a prospective longitudinal follow up study of patients with SARS who were discharged from our hospital after

Abbreviations: BMI, body mass index; CRP, C-reactive protein; FEV₁, forced expiratory volume in 1 second; FRC, functional residual capacity; FVC, forced vital capacity; HRQoL, health-related quality of life; LDH, lactate dehydrogenase; LOS, length of stay; 6MWD, 6 minute walk distance; 6MWT, 6 minute walk test; Pimax, Pemax, maximum static inspiratory and expiratory pressures; RV, residual volume; SARS, severe acute respiratory syndrome; TLC, total lung capacity; TlCO, carbon monoxide transfer factor

surviving the major outbreak in 2003. The patients came from our previously reported cohort⁶ recruited over a period of 2 weeks from 11 March to 25 March 2003. The diagnosis of SARS was based on the CDC criteria at the time,²² and all patients had subsequent laboratory confirmation of SARS.²³ The treatment and outcome of these patients during hospitalisation has been reported in detail elsewhere.²³ This prospective outcome study of SARS survivors was approved by the ethics committee of the Chinese University of Hong Kong.

Assessment

Following discharge from hospital, patients were evaluated in the lung function laboratory at the end of 3 and 6 months after disease onset. During the visit, subjects were interviewed and underwent a physical examination, pulmonary function testing, respiratory muscle strength measurement, postero-anterior chest radiography, resting oximetry, and a standardised 6 minute walk test (6MWT).^{24–25} In addition, they completed the Medical Outcomes Study 36-item Short-Form General Health Survey (SF-36) to measure HRQoL.²⁶

6 minute walk test (6MWT)

This provides a standardised, objective, integrated assessment of cardiopulmonary and musculoskeletal function that is relevant to daily activities.^{24–25} The self-paced 6MWT assesses the sub-maximal level of functional capacity²⁵ and has been applied in a long term follow up study of survivors of ARDS.¹⁴ The 6 minute walk distances (6MWD) were compared with the normative reference data collected from a population survey of 538 normal healthy subjects in 2004 by the Coordinating Committee in Physiotherapy, HK Hospital Authority, on two separate days. The mean (SD) 6MWD of the controls ($n = 538$) on days 1 and 2 of assessment were 598.4 (98.7) m and 609.2 (100.4) m, respectively, with an intra-class correlation coefficient of 0.87 (95% CI 0.84 to 0.89), standard error of measurement 35.3 m, minimum detectable change 97.8 m, and limits of agreement 10.8 (95% CI –87.1 to 108.6) m. The 6MWD data stratified into different age groups are available for comparison with the SARS patients, although we have no access to individual data of this population survey.

SF-36

This includes eight multiple item domains that assess physical functioning (PF), social functioning (SF), role limitation due to physical problems (RP), role limitation due to emotional problems (RE), mental health (MH), bodily pain (BP), vitality (VT), and general health (GH).²⁶ Scores for each aspect can range from 0 (worst) to 100 (best) with higher scores indicating better HRQoL. The validated Chinese (HK) version of the SF-36²⁷ was used for this study and the results were compared with the HK normative data collected from a random telephone survey of 2410 Chinese adults aged 18 years or above.²⁸ Based on this survey, SF-36 domain scores stratified into two age groups (18–40 years and 41–64 years) are available²⁸ for comparison with those of our SARS survivors.

Lung function testing

Lung volumes (total lung capacity (TLC), vital capacity (VC), residual volume (RV), functional residual capacity (FRC) using the nitrogen washout method), spirometric parameters (pre and post bronchodilator forced vital capacity (FVC), forced expiratory volume in 1 second (FEV₁), FEV₁/FVC ratio), and surface area for gas exchange (carbon monoxide transfer factor adjusted for haemoglobin (Tlco) and carbon monoxide transfer coefficient (Kco)) were measured using the SensorMedic Vmax System, USA. Tlco was determined

by the single breath carbon monoxide technique using an infrared analyser. Spirometric tests (FEV₁ and FVC pre and post bronchodilator) were performed according to the standards of the American Thoracic Society.²⁹ After the pre-bronchodilator measurement, salbutamol 400 µg was given via a metered dose inhaler with a spacer. Spirometric testing was repeated 10 minutes later. An increase in FEV₁ of more than 12% and more than 0.2 l was regarded as a positive bronchodilator response.³⁰ The results were compared with the normative data³¹ which have been widely adopted as the reference data in HK.

Measurement of the maximum static inspiratory pressure that a subject can generate at the mouth (Pimax) or the maximum static expiratory pressure (Pemax) is a simple way to gauge inspiratory and expiratory muscle strength.^{32–33} Since respiratory muscle weakness may lead to a restrictive pattern on lung function testing, Pimax and Pemax were assessed with a mouth pressure meter via a flanged mouthpiece³⁴ after full lung function testing. In a study of 24 normal subjects (23 Chinese and one Indian of mean age 29.2 years) in Singapore, the mean (SD) maximal static inspiratory effort from residual volume (Pdi Pimax) for the group was 83.5 (35.5) cm H₂O.³⁵ A Pimax of –80 cm H₂O or a Pemax of +80 cm H₂O generally excludes clinically significant weakness of the inspiratory or expiratory muscles.³⁶

To protect lung function laboratory staff, extra exhaust fans were installed in the lung function room and staff wore personal protective equipment including N95 respirators, protective goggles, gloves, and gowns. In addition, a disposable viral and bacterial filter (Spiroguard 2800/01, USA) was used for each patient during each visit.

Radiographic assessment

Frontal chest radiographs were performed at 3 and 6 months using standardised techniques with computed radiography equipment as reported during the major hospital outbreak.⁶ The images were assessed using a PACs system (Siemens Magicview Version VA22E, Germany) viewer (Siemens 2K monitor). Each lung was divided into three zones (upper, middle and lower) on the frontal radiograph. The observers assessed the presence, appearances (airspace opacities or reticular opacities), distribution, and size of lung parenchymal abnormalities on each chest radiograph of all patients. The size of the lesion was assessed by visually estimating the percentage area occupied in each zone on each side. The overall percentage of involvement was obtained by averaging the percentage involvement of the six lung zones. The frontal chest radiograph closest to the date of the lung function test was assessed by two radiologists, both blinded to the clinical information. Agreement was reached by consensus. The assessment method was as described in our previous study.³⁷

Analysis of data

Statistical analysis was performed using Statistical Package for Social Science (SPSS) Version 11.0. Cumulative steroid dosage during inpatient treatment and outpatient follow up was converted into hydrocortisone (mg) to facilitate analysis of the study. Continuous variables were compared using an independent sample *t* test and the Mann-Whitney U test was used for non-parametric data. Categorical variables were compared using the χ^2 test. All statistical tests were two tailed. Statistical significance was taken as $p < 0.05$. Univariate analyses were performed to evaluate the potential determinants of exercise capacity expressed as the 6MWD. Variables significant in the univariate analyses ($p < 0.1$) were included in the multivariate analysis. Age and sex were included in the final multivariable models because they are independent determinants of the 6MWD.³⁸

Table 1 Results of serial pulmonary function tests and respiratory muscle strength among SARS survivors (n = 110)

Parameter	3 months	6 months
FVC (% of predicted)	104.5 (95.0–114.0)	104.5 (95.0–113.0)
FEV ₁ (% of predicted)	108.0 (99.0–118.5)	106.0 (97.8–116.0)
TLC (% of predicted)	104.0 (93.3–115.8)	108.0 (98.0–117.0)
VC (% of predicted)	105.0 (95.0–115.5)	105.5 (95.0–113.5)

TLC, total lung capacity; VC, vital capacity; FVC, forced vital capacity; FEV₁, forced expiratory volume in 1 second; RV, residual volume; TlCO, carbon monoxide transfer factor adjusted for haemoglobin; Kco, transfer coefficient (transfer factor per alveolar volume); Pimax, Pemax, maximum static inspiratory and expiratory pressures.

Values are expressed as median (interquartile range).

*p < 0.01, Kco at 3 months v 6 months. No statistically significant differences were noted between other lung function parameters at 3 and 6 months.

RESULTS

Of the first 138 patients infected with SARS in March 2003, 15 (10.9%) died.²³ Among the 123 survivors, 13 (10.6%) did not attend for follow up (three returned overseas and 10 refused to participate in the study). A total of 110 were therefore available for analysis, 70 (64%) of whom were healthcare workers (doctors, nurses, ward assistants, and medical students). Sixty six (60%) patients were women. The mean (SD) age was 35.6 (9.8) years and the body mass index (BMI) was 23.1 (4.8) kg/m² during the visit at 3 months from illness onset. The mean (SD) length of stay (LOS) in hospital for the group was 22.0 (13.9) days. There were only three smokers (2.7%) among the whole group.

Seventeen patients had medical co-morbidities which included chronic obstructive pulmonary disease (COPD; n = 1 (0.9%)), ischaemic heart disease (IHD; n = 1 (0.9%)), ischaemic stroke (n = 1 (0.9%)), breast cancer stable on tamoxifen (n = 1 (0.9%)), diabetes mellitus (n = 3 (2.7%)), cirrhosis (n = 1 (0.9%)), hypertension (n = 4 (3.6%)), and five asymptomatic hepatitis B carriers (4.5%).

Among the 110 patients, 31 (28.2%; 17 men and 14 women) had required admission to the ICU with a mean (SD) LOS of 13.5 (15.6) days (median 7, range 2–64); six (5.5%) required invasive mechanical ventilation. Based on our ICU admission criteria,²³ all the 31 patients would have a Pao₂/Fio₂ ratio <300 mm Hg while the six patients who were intubated had a Pao₂/Fio₂ ratio <200 mm Hg. Among these 31 patients, six had medical co-morbidities (one IHD, one diabetes mellitus, two hypertension, and two asymptomatic hepatitis B carriers), but none had any history of smoking or pulmonary disease.

Lung function tests and respiratory muscle strength

An overview of the serial lung function test and respiratory muscle strength results for the group is shown in table 1. At 3 months 89 patients (80.9%) had an FEV₁/FVC ratio of >80% while one patient with COPD (0.9%) had an FEV₁/FVC ratio of <70%. Overall, the lung volume parameters and surface area for exchange were well preserved at 3 and 6 months. A significant proportion of patients appeared to have increased RV at 3 and 6 months (median (interquartile range, IQR) 108 (71–141)% and 115 (84–140)%, respectively. Although none complained of symptoms of asthma, seven (6.4%) had a significant bronchodilator response with increments of FEV₁ >200 ml after inhalation of salbutamol at 3 months. 22 (20.6%) and eight (7.5%) patients, respectively, had Pimax and Pemax values below 80 cm H₂O.

At 6 months 79 (71.8%) had an FEV₁/FVC ratio of >80% while the same patient with COPD had an FEV₁/FVC ratio of <70%. None had a significant bronchodilator response after inhalation of salbutamol. 15 (13.9%) and 24 (22.2%) subjects, respectively, had Pimax and Pemax values below 80 cm H₂O. There was a slight increase in Kco but no change in other lung function parameters at 6 months compared with 3 months (table 1).

The frequency of lung function parameters below 80% of predicted values in SARS survivors is shown in table 2. Seventeen patients (15.5%) had impaired TlCO while up to 7.3% of patients had reduced lung volume measurements at 6 months.

6MWD

The 6MWD of the SARS survivors at 3 and 6 months, compared with normative data, is shown in table 3. The mean 6MWD increased significantly from 464 m at 3 months to 502 m at 6 months (95% CI of difference 22 to 54, p < 0.01). When the subjects were stratified into different age groups and compared with the corresponding normative values, their exercise capacity was significantly lower than the normal subjects (table 3). There was no difference in oxygen saturation after exercise at 3 and 6 months (97.8 (2.6)% v 97.4 (8.8)%, p = 0.61). Two patients and one patient, respectively, had Sao₂ <88% after 6MWT at 3 and 6 months.

Univariate analysis was performed to look for factors associated with 6MWD. At 3 months, age (β coefficient −2.48 (SE 0.79), p = 0.002), female sex (β coefficient −43.33 (15.82), p = 0.007), and hospital LOS (β coefficient −1.72 (0.55), p = 0.002) were significant negative predictors of 6MWD whereas total dose of steroid (β coefficient 0.00 (0.00), p = 0.86), ICU admission (β coefficient −8.27 (17.81), p = 0.64), baseline lactate dehydrogenase (LDH) (β coefficient −0.02 (0.05), p = 0.69), peak LDH (β coefficient −0.01 (−0.02), p = 0.848), BMI (β coefficient −2.16 (1.66), p = 0.20), and peak CRP (β coefficient 0.25 (0.17), p = 0.143) were not. Following multivariate analysis (adjusted R² = 0.17), the independent negative predictors

*Including one woman aged 61 years with 6MWD 492 m and 465 m at 3 and 6 months, respectively.

**p < 0.01.

†6 months v 3 months.

for 6MWD were female sex (β coefficient -38.02 (15.18), $p = 0.014$) and hospital LOS (β coefficient -1.28 (0.57), $p = 0.028$), with a trend for age being a negative predictor (β coefficient -1.54 (0.82), $p = 0.063$). Based on this model, the mean (SE) difference in 6MWD between women and men after adjusting for hospital LOS was -34.0 (14.8) m (95% CI -63.5 to -4.6), $p = 0.024$.

At 6 months, age (β coefficient -3.31 (SE 0.88), $p < 0.001$), female sex (β coefficient -67.62 (17.41), $p < 0.001$), and hospital LOS (β coefficient -1.39 (0.65), $p = 0.036$) were significant negative predictors of 6MWD whereas total dose of steroid (β coefficient 0.00 (0.00), $p = 0.66$), ICU admission (β coefficient 28.17 (20.37), $p = 0.17$), baseline LDH (β coefficient 0.06 (0.06), $p = 0.31$), peak LDH (β coefficient 0.07 (0.13), $p = 0.19$), BMI (β coefficient -2.59 (2.04), $p = 0.21$), and peak CRP (β coefficient 0.26 (0.21), $p = 0.20$) were not. Following multivariate analysis (adjusted $R^2 = 0.20$), the independent negative predictors for 6MWD

were age (β coefficient -2.53 (0.91), $p = 0.006$) and female sex (β coefficient -60.11 (16.74), $p < 0.001$) whereas hospital LOS was no longer a factor (β coefficient -0.71 (0.63), $p = 0.264$). Based on this model, the adjusted mean (SE) difference in 6MWD between women and men was -55.3 (16.3) m, (95% CI -87.6 to -30.0), $p = 0.001$.

Chest radiographs and correlations with lung function and 6MWD

Thirty eight patients (35.8%) had abnormal total chest radiographic scores at 3 months involving a mean (SD) of 3.9 (3.5)% (range 0.5–15) of the total lung fields. These included eight patients with abnormal scores in both airspace opacity and reticular shadows, 16 with an abnormal airspace score, and 14 with an abnormal reticular score. At 6 months 33 subjects (30%) still had abnormal chest radiographic scores involving 3.1 (3.3)% (range 0.8–15) of the lung fields. These included three patients with abnormalities in both

airspace and reticular shadows, 16 with abnormal airspace shadows, and 14 with abnormal reticular shadows.

Correlations between the extent of radiographic abnormality and cumulative steroid dosage, lung function parameters, and 6MWD at 6 months were examined. There was a significant positive correlation between the extent of radiographic abnormalities (% of lung fields) and the cumulative hydrocortisone dosage ($r = 0.38$, $p < 0.01$), and a significant

negative correlation between the extent (%) of radiographic abnormalities and FVC ($r = -0.23$, $p = 0.02$), TLC ($r = -0.22$, $p = 0.02$), TlCO ($r = -0.29$, $p < 0.01$), and Kco ($r = -0.22$, $p = 0.02$) with a trend towards a negative correlation with VC ($r = -0.17$, $p = 0.07$). However, no significant correlations were noted between the extent of radiographic abnormalities and 6MWD ($r = -0.14$, $p = 0.15$), FEV₁ ($r = -0.12$, $p = 0.20$), RV ($r = -0.11$, $p = 0.25$), Pimax ($r = 0.10$, $p = 0.29$), and

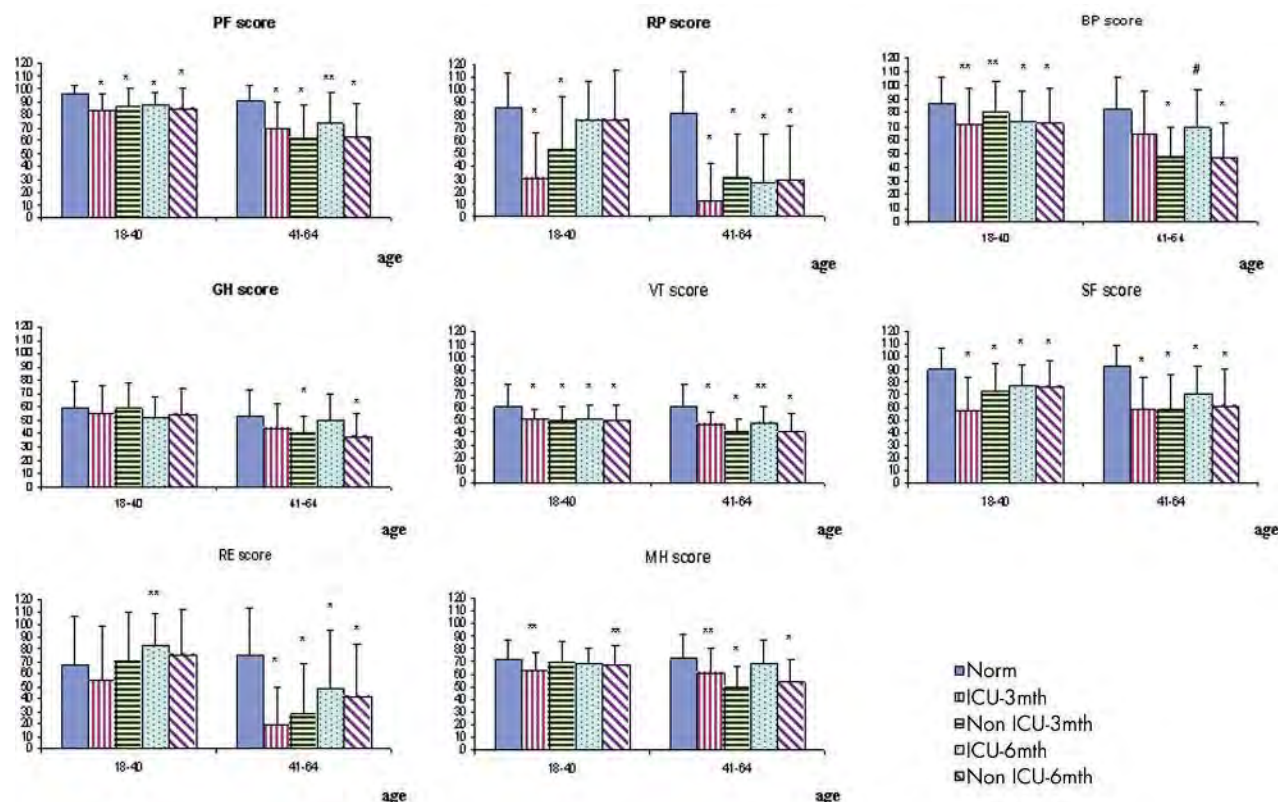

Figure 1 Health-related quality of life (SF-36) among SARS survivors at 3 and 6 months after illness onset compared with Hong Kong normative data stratified into different age groups.²⁸ The vertical axis represents mean (SD) SF-36 domain scores from 0 (minimum) to 100 (maximum) and the horizontal axis defines age groups in years. Based on the study by Lam *et al*²⁸ there were 1244 and 695 normal subjects in the age groups 18–40 years and 41–64 years, respectively. There were 19 and 12 SARS survivors who had required ICU support in the age groups 18–40 years and 41–64 years, and 60 and 19 SARS survivors, respectively, who did not require ICU support in the two age groups. PF, physical functioning; SF, social functioning; RP, role limitation due to physical problems; RE, role limitation due to emotional problems; MH, mental health; BP, bodily pain; VT, vitality; GH, general health. * $p < 0.01$; ** $p < 0.03$; # $p < 0.05$.

Pemax ($r = 0.12$, $p = 0.21$). These data are shown in a supplementary file available on the *Thorax* website at <http://www.thoraxjnl.com/supplemental>.

Comparison of patients requiring ICU support with those treated on the wards

Patients who had required ICU admission ($n = 31$, 17 men and 14 women) were older with a higher peak LDH, a longer hospital LOS, and received a significantly higher total steroid dosage than those who did not require ICU care (table 4). The lung function tests at 6 months showed significantly lower FVC, TLC, and Tlco in survivors who had required ICU support than those who were treated on medical wards, although no significant differences were noted in 6MWD and respiratory muscle strength between the two groups (table 5).

HRQoL among SARS survivors and its correlation with lung function parameters

Correlations between lung function parameters and SF-36 domains at 6 months are shown in table 6. In general there were significant positive correlations between lung function parameters (FVC, VC, FEV₁, and Tlco) and several SF-36 domains (PF, RP, GH, and SF).

SF-36 domain scores at 3 and 6 months after illness onset of patients who did and did not require ICU support during the acute illness compared with normative data are shown in fig 1 (more data are available in supplemental tables 2a and b on the *Thorax* website <http://www.thoraxjnl.com/>

supplemental). There was significant impairment of HRQoL among the SARS survivors at 6 months.

When those who had required ICU admissions were directly compared with those treated on the medical wards there was a significantly lower score in RP ($p = 0.026$) and SF ($p = 0.02$) for those aged 18–40 years who had required ICU support ($n = 19$) but no significant difference in any domain for those aged 41–64 years ($n = 12$) at 3 months. There was no significant difference in SF-36 domains between the two groups at 6 months apart from a lower score in BP ($p = 0.021$) for those aged 41–64 years who had required ICU support ($n = 12$).

In comparing the 25 patients who did not require intubation in the ICU with those who had required intubation ($n = 6$), the latter had more severe lung injury as reflected by a higher peak LDH level (median 466.0 (IR 259.0) v 652.0 (124.5) U/L, $p = 0.02$). There was, however, no statistically significant difference with regard to age (36.0 (15.5) v 36.5 (17.5) years, $p = 0.87$) and 6MWD (507.7 (163.9) v 449.0 (129.3) m, $p = 0.18$) at 6 months. In addition, there were no significant differences between the two groups with regard to lung function indices and SF-36 domain scores at 6 months (data available in supplemental table 3 on the *Thorax* website <http://www.thoraxjnl.com/supplemental>).

DISCUSSION

During the global outbreak of SARS in 2003 there was an enormous demand on ICU support for patients who developed severe respiratory failure.^{5–8 18 19} Although the use of

pulse methylprednisolone during clinical progression was associated with favourable clinical improvement in most of our patients with resolution of fever and improvement of lung opacities within 2 weeks.^{6, 23, 39, 40} Our preliminary follow up study with HRCT scanning has revealed multiple patchy ground glass appearance and interstitial thickening in nine patients and CT evidence of fibrotic changes in 15 out of 24 patients with residual radiographic opacities.²⁰ This has raised concern that some patients with SARS may have ongoing immune mediated alveolitis which has the potential to lead to significant parenchymal fibrosis and lung function impairment. A recent report by Ng *et al*⁴¹ has indicated that residual abnormalities of pulmonary function were still observed in three quarters of their cohort ($n = 57$), mostly consisting of isolated reductions in Tlco, while an abnormal HRCT score was detected in 75.4% of SARS patients at 6 months after admission to hospital.

This prospective cohort study has shown that most of the SARS survivors had relatively well preserved lung function at 6 months after symptom onset. Up to 15.5% of patients had significant impairment of lung function, as reflected by reduced Tlco with well preserved Kco. These results suggest an increase in the intra-alveolar diffusion pathway which may be the result of diffuse alveolar damage and/or bronchiolitis obliterans organising pneumonia in the acute stage,⁹⁻¹² followed by post-inflammatory changes such as atelectasis, ongoing alveolitis, and parenchymal fibrosis later in the course of the disease. Several studies on ARDS survivors have shown that their pulmonary function generally returns to normal or near normal by 6-12 months,⁴²⁻⁴⁴ but Tlco may remain abnormal in up to 80% of patients at 1 year after recovery.¹⁶

The self-paced 6MWT was performed to evaluate the global and integrated responses to exercise, and these would include cardiorespiratory systems, systemic and peripheral circulation, blood, neuromuscular units, and muscle metabolism. However, the 6MWT does not provide specific information on the function of individual organs and systems.²⁵ The 6MWD was substantially reduced for all age groups at 3 and 6 months compared with controls. Two previous studies have shown that 6MWD was substantially lower among ARDS survivors than controls 1-2 years after mechanical ventilation^{14, 45} while the absence of systemic steroid treatment, the absence of illness acquired and rapid resolution of lung injury, and rapid resolution of lung injury during ICU stay were important factors associated with a longer 6MWD at 3, 6, and 12 months, respectively.¹⁴ In contrast, our analysis has shown that a longer hospital stay and female sex were independent factors associated with lower 6MWD at 3 months whereas age and female sex were negative predictors for 6MWD at 6 months. During hospitalisation for an average of 3 weeks, most of our patients were on bed rest because of respiratory failure. Given the relatively well preserved lung function in the majority of our SARS survivors, the poor performance in 6MWT in all age groups could be due to additional factors such as muscle wasting, steroid myopathy, and possibly cardiac diastolic dysfunction.⁴⁶ In a study of the physical profile of SARS survivors ($n = 171$ and including the current cohort) at 3 months after illness onset, Lau *et al*⁴⁷ noted that muscle strength and endurance were more impaired in proximal than in distal muscles. This was reflected by "average" handgrip measured by a hand-held dynamometer and "below average" to "poor" performance for curl-up and push-up testing compared with the normative Hong Kong data. Ong *et al*⁴⁸ have recently reported that 18 of 44 SARS survivors in Singapore had reduced exercise capacity at 3 months after hospital discharge that could not be accounted for by impairment of pulmonary function. Their results suggest that the inability to

exercise in recovered SARS patients is primarily due to extrapulmonary disease and is probably caused by myopathy or physical deconditioning.⁴⁸

In addition, at 6 months there was significant impairment in HRQoL as measured by the Chinese version of the SF-36 questionnaire^{27, 28} in most domains. There were significant and positive correlations between lung function parameters (VC, FVC, FEV₁, and Tlco) and SF-36 domains such as PF, RP, GH, and SF. The results are not surprising as, in addition to the physical impairment, the long period of isolation and extreme uncertainty during the SARS illness had created tremendous psychological and mood disturbances. Other contributing factors included intense media attention, bereavement, phobia, and rejection of SARS survivors by some members of the general public (particularly in the initial phase of the outbreak), and fear of transmission of SARS to others.⁴⁰ Other studies on ALI or ARDS survivors unrelated to SARS have reported impaired HRQoL at 1-5 years after recovery,¹³⁻¹⁶ whereas pulmonary function abnormalities, especially Tlco, were correlated with SF-36 domains.^{15, 16}

Herridge *et al*¹⁴ reported that 20% of their ARDS survivors had minor abnormalities on the chest radiograph at 1 year. Our study has shown that 33 subjects (30%) still had abnormal radiographic scores at 6 months. The positive correlation between the extent of residual radiographic abnormalities and the cumulative steroid dosage used for SARS was not surprising as the former was an indication on the treatment protocol for more systemic steroid during the outbreak.^{5, 6, 23} The negative correlation between residual radiographic abnormalities and lung volume parameters (FVC, TLC) and parameters of surface area for gas exchange (Tlco and Kco) reflected the physiological effects of parenchymal inflammation and fibrosis. Patients with more severe disease (as reflected by higher peak LDH)^{6, 23, 39} who had required ICU support during the acute illness tended to have more residual opacities on the chest radiograph at 6 months. In addition, they had more extensive pulmonary injury and fibrosis as reflected by significantly lower lung volume parameters (FVC and TLC) and transfer factor (Tlco) at 6 months than those treated on the general wards. There were, however, no significant differences in 6MWD and HRQoL between the two groups at 6 months. In addition, there were no differences in any functional parameters between mechanically ventilated and non-ventilated ICU patients. It is interesting that, in those patients surviving to the chronic phase of SARS related ARDS, HRCT scanning showed no visible differences between the patients who had been mechanically ventilated and those who had not.³⁹

A significant proportion of SARS patients had evidence of respiratory muscle weakness, as reflected by decreased Pimax and Pemax values below 80 cm H₂O in 15 (13.9%) and 24 (22.2%), respectively, at 6 months. Weakness of the expiratory muscles (abdominal and intercostal muscles) could lead to air trapping (as reflected by increased RV above 120% of predicted in some patients), whereas inspiratory muscle weakness may lead to atelectasis. There are many possible causes for respiratory muscle weakness among SARS survivors. Many patients complained of myalgia with elevation of creatinine kinase suggestive of viral induced myositis at initial presentation.⁶ At least 40% of patients suffered from acute respiratory failure requiring supplemental oxygen and bed rest during the second phase of the disease.^{5-8, 23} The long period of bed rest could lead to muscle wasting and deconditioning, while the use of systemic corticosteroids to suppress immune mediated lung injury⁵⁻⁸ could contribute to myopathy. In 13 patients given high dose steroids for acute lung transplant rejection over 5 days, about 45% developed acute generalised muscle weakness which

took about 2 months to recover.⁵⁰ Similarly, myopathy has been observed in patients with status asthmaticus treated with high dose corticosteroid.^{51–52} Corticosteroids are thought to produce adverse effects on muscles through several mechanisms: altered electrical excitability of muscle fibres, loss of thick filaments, and/or inhibition of protein synthesis.^{53–56}

Interestingly, seven patients (6.4%) without any past history of airway disease had a significant bronchodilator response to salbutamol³⁰ with increments of FEV₁ of at least 12% and over 200 ml from baseline at 3 months, but the positive response was no longer present at 6 months. Although these patients had neither wheeze nor persistent cough at follow up, the bronchodilator response suggested that transient bronchial hyperresponsiveness might develop after SARS. Although we did not perform bronchial challenge in our patients, bronchial reactivity has been observed in some survivors of ARDS.⁴² Viral respiratory infections may cause increased airway responsiveness which can be observed in response to inhalation of histamine, methacholine, citric acid, or allergen.^{57–60}

There are several limitations to this study. Firstly, we assessed inspiratory and expiratory muscle strength with mouth pressure, but low P_{max} values do not always indicate expiratory muscle weakness and might result from technical difficulties such as mouth leakage. However, it is a well established simple test^{32–33} and none of our patients suffered from facial muscle or bulbar weakness. Cough gastric pressure provides a useful complementary test for the assessment of expiratory muscle strength but it involves insertion of a gastric balloon catheter and cough.⁶¹ At the time of planning this study there was still some concern among our lung function staff about potential infectivity via respiratory secretion of SARS survivors even though published data suggested this to be unlikely.⁵ It was therefore decided not to involve any invasive procedure. Lastly, although full lung function tests and 6 MWT were conducted in our patients, we did not perform cardiopulmonary exercise testing as most of our patients were complaining of generalised muscle weakness on follow up. In addition, cardiopulmonary exercise testing would be too labour intensive for the large cohort of SARS survivors. Nevertheless, reduced pulmonary gas exchange can be detected with cardiopulmonary exercise testing in many survivors of SARS at 3 months⁴⁸ and other causes of ARDS¹⁷ with normal Tl_{CO}.

In summary, this study has shown significant impairment of surface area for gas exchange in 15.5% of SARS survivors, while their functional ability and health status were significantly lower than the general population at 6 months after illness onset. The functional disability appears out of proportion to the degree of lung function impairment and may be due to additional factors such as muscle deconditioning and steroid myopathy. Long term follow up is needed to determine whether these deficits persist.

ACKNOWLEDGEMENTS

The authors would like to thank the following colleagues who have offered tremendous help in this ongoing study: PY Chan RN, MS Cheng RN, TY Cheong RN, MY Leung EN, Erica Lee (clerk) and Catherine Ho (research assistant). They would also like to acknowledge the Coordinating Committee in Physiotherapy, HK Hospital Authority, for collecting the updated normative data on 6 minute walk distances. They also thank Dr CC Szeto for his statistical advice on the data analysis.

Further data are given in a supplementary file available on the *Thorax* website at <http://www.thoraxjnl.com/supplemental>.

LUNG ALERT

Molecular techniques improve organism identification from pleural fluid in empyema

▲ Saglani S, Harris KA, Wallis C, Hartley JC. Empyema: the use of broad range 16S rDNA PCR for pathogen detection. *Arch Dis Child* 2005;**90**:70–3

This study compares a broad range molecular technique with bacterial culture for the detection of organisms from pleural fluid in 32 children with empyema. The concordance of organisms identified and influence of prior antibiotic treatment was also investigated. There was a median duration of 8 (1–42) days antibiotic therapy before pleural fluid aspiration.

The molecular assay is an established and validated broad range 16S rDNA PCR technique. This is based on bacterial ribosomal (r)DNA with sequencing of the PCR product to reveal the source organism. Significant organisms were detected in 19% of cases by culture, whilst 69% of cases were PCR positive. Of the six culture positive samples, five were PCR positive and the organism identified was identical using both techniques. The organism not detected by PCR was grown only after enrichment culture and was present at levels below the PCR detection limit. The presence of organisms detected by PCR but not culture was probably because of prior antibiotic treatment. The PCR negative cases had also all received antibiotic therapy, causing organism death and DNA degradation.

Molecular (non-culture) techniques improve organism identification from pleural fluid in children with empyema, even after commencement of antibiotics, but should be considered complementary to culture. This assay produces a result in 48 hours, allowing appropriate alterations in management soon within the inpatient stay.

High COVID-19 Attack Rate Among Attendees at Events at a Church — Arkansas, March 2020

Allison James, DVM, PhD^{1,2}; Lesli Eagle¹; Cassandra Phillips¹; D. Stephen Hedges, MPH¹; Cathie Bodenhamer¹; Robin Brown, MPAS, MPH¹; J. Gary Wheeler, MD¹; Hannah Kirking, MD³

On May 19, 2020, this report was posted as an MMWR Early Release on the MMWR website (<https://www.cdc.gov/mmwr>).

On March 16, 2020, the day that national social distancing guidelines were released (1), the Arkansas Department of Health (ADH) was notified of two cases of coronavirus disease 2019 (COVID-19) from a rural county of approximately 25,000 persons; these cases were the first identified in this county. The two cases occurred in a husband and wife; the husband is the pastor at a local church (church A). The couple (the index cases) attended church-related events during March 6–8, and developed nonspecific respiratory symptoms and fever on March 10 (wife) and 11 (husband). Before his symptoms had developed, the husband attended a Bible study group on March 11. Including the index cases, 35 confirmed COVID-19 cases occurred among 92 (38%) persons who attended events held at church A during March 6–11; three patients died. The age-specific attack rates among persons aged ≤18 years, 19–64 years, and ≥65 years were 6.3%, 59.4%, and 50.0%, respectively. During contact tracing, at least 26 additional persons with confirmed COVID-19 cases were identified among community members who reported contact with church A attendees and likely were infected by them; one of the additional persons was hospitalized and subsequently died. This outbreak highlights the potential for widespread transmission of SARS-CoV-2, the virus that causes COVID-19, both at group gatherings during church events and within the broader community. These findings underscore the opportunity for faith-based organizations to prevent COVID-19 by following local authorities' guidance and the U.S. Government's Guidelines: Opening Up America Again (2) regarding modification of activities to prevent virus transmission during the COVID-19 pandemic.

On March 10 and 11, the wife of the church pastor, aged 56 years, and the pastor, aged 57 years, developed fever and cough. On March 12, the pastor, after becoming aware of similar nonspecific respiratory symptoms among members of their congregation, closed church A indefinitely. Because of fever, cough, and increasing shortness of breath, the couple sought testing for SARS-CoV-2 on March 13; both were notified of positive results by reverse transcription–polymerase chain reaction testing on March 16. The same day, ADH staff members began an investigation to identify how the couple had been exposed and to trace persons with whom they had been in contact. Based on their activities and onset dates, they likely were infected at

church A events during March 6–8, and the husband might have then exposed others while presymptomatic during a Bible study event held on March 11.

During March and April 2020, all persons in Arkansas who received testing for SARS-CoV-2 at any laboratory were entered into a database (Research Electronic Data Capture [REDCap]; version 8.8.0; Vanderbilt University) managed by ADH. Using a standardized questionnaire, ADH staff members interviewed persons who had positive test results to ascertain symptoms, onset date, and potential exposure information, including epidemiologic linkages to other COVID-19 patients; this information was stored in the database. Close contacts of patients with laboratory-confirmed cases of COVID-19 were interviewed and enrolled in active symptom monitoring; those who developed symptoms were tested and their information was also entered into the database. Church A–associated cases were defined as those in 1) persons who had laboratory results positive for SARS-CoV-2 who identified contact with church A attendees as a source of exposure and 2) actively monitored contacts of church attendees who had a test result positive for SARS-CoV-2 after becoming symptomatic.

The public health investigation focused on the transmission of SARS-CoV-2 among persons who attended church A events during March 6–11. To facilitate the investigation, the pastor and his wife generated a list of 94 church members and guests who had registered for, or who, based on the couple's recollection, might have attended these events.

During March 6–8, church A hosted a 3-day children's event which consisted of two separate 1.5-hour indoor sessions (one on March 6 and one on March 7) and two, 1-hour indoor sessions during normal church services on March 8. This event was led by two guests from another state. During each session, children participated in competitions to collect offerings by hand from adults, resulting in brief close contact among nearly all children and attending adults. On March 7, food prepared by church members was served buffet-style. A separate Bible study event was held March 11; the pastor reported most attendees sat apart from one another in a large room at this event. Most children and some adults participated in singing during the children's event; no singing occurred during the March 11 Bible study. Among all 94 persons who might have attended any of the events, 19 (20%) attended both the children's event and Bible study.

Summary**What is already known about this topic?**

Large gatherings pose a risk for SARS-CoV-2 transmission.

What is added by this report?

Among 92 attendees at a rural Arkansas church during March 6–11, 35 (38%) developed laboratory-confirmed COVID-19, and three persons died. Highest attack rates were in persons aged 19–64 years (59%) and ≥65 years (50%). An additional 26 cases linked to the church occurred in the community, including one death.

What are the implications for public health practice?

Faith-based organizations should work with local health officials to determine how to implement the U.S. Government guidelines for modifying activities during the COVID-19 pandemic to prevent transmission of the virus to their members and their communities.

The husband and wife were the first to be recognized by ADH among the 35 patients with laboratory-confirmed COVID-19 associated with church A attendance identified through April 22; their illnesses represent the index cases. During the investigation, two persons who were symptomatic (not the husband and wife) during March 6–8 were identified; these are considered the primary cases because they likely initiated the chain of transmission among church attendees. Additional cases included those in persons who attended any church A events during March 6–11, but whose symptom onset occurred on or after March 8, which was 2 days after the earliest possible church A exposure. One asymptomatic attendee who sought testing after household members became ill was included among these additional cases.

Consistent with CDC recommendations for laboratory testing at that time (3), clinical criteria for testing included cough, fever, or shortness of breath; asymptomatic persons were not routinely tested. To account for this limitation when calculating attack rates, upper and lower boundaries for the attack rates were estimated by dividing the total number of persons with laboratory-confirmed COVID-19 by the number of persons tested for SARS-CoV-2 and by the number of persons who attended church A during March 6–11, respectively. All analyses were performed using R statistical software (version 4.0.0; The R Foundation). Risk ratios were calculated to compare attack rates by age, sex, and attendance dates. Fisher's exact test was used to calculate two-sided p-values; p-values <0.05 were considered statistically significant.

Overall, 94 persons attended church A events during March 6–11 and might have been exposed to the index patients or to another infectious patient at the same event; among these persons, 92 were successfully contacted and are included in the analysis. Similar proportions of church A attendees were

aged ≤18 years (35%), 19–64 years (35%), and ≥65 years (30%) (Table 1). However, a higher proportion of adults aged 19–64 years and ≥65 years were tested (72% and 50%, respectively), and received positive test results (59% and 50%), than did younger persons. Forty-five persons were tested for SARS-CoV-2, among whom 35 (77.8%) received positive test results (Table 2).

During the investigation, two church A participants who attended the March 6–8 children's event were found to have had onset of symptoms on March 6 and 7; these represent the primary cases and likely were the source of infection of other church A attendees (Figure). The two out-of-state guests developed respiratory symptoms during March 9–10 and later received diagnoses of laboratory-confirmed COVID-19, suggesting that exposure to the primary cases resulted in their infections. The two primary cases were not linked except through the church; the persons lived locally and reported no travel and had no known contact with a traveler or anyone with confirmed COVID-19. Patient interviews revealed no additional common exposures among church attendees.

The estimated attack rate ranged from 38% (35 cases among all 92 church A event attendees) to 78% (35 cases among 45 church A event attendees who were tested for SARS-CoV-2). When stratified by age, attack rates were significantly lower among persons aged ≤18 years (6.3%–25.0%) than among adults aged 19–64 years (59.4%–82.6%) ($p<0.01$). The risk ratios for persons aged ≤18 years compared with those for persons aged 19–64 years were 0.1–0.3. No severe illnesses occurred in children. Among the 35 persons with laboratory-confirmed COVID-19, seven (20%) were hospitalized; three (9%) patients died.

At least 26 additional confirmed COVID-19 cases were identified among community members who, during contact tracing, reported contact with one or more of the 35 church A members with COVID-19 as an exposure. These persons likely were infected by church A attendees. Among these 26 persons, one was hospitalized and subsequently died. Thus, as of April 22, 61 confirmed cases (including eight [13%] hospitalizations and four [7%] deaths) had been identified in persons directly and indirectly associated with church A events.

Discussion

This investigation identified 35 confirmed COVID-19 cases among 92 attendees at church A events during March 6–11; estimated attack rates ranged from 38% to 78%. Despite canceling in-person church activities and closing the church as soon as it was recognized that several members of the congregation had become ill, widespread transmission within church A and within the surrounding community occurred. The primary patients had no known COVID-19 exposures in

the 14 days preceding their symptom onset dates, suggesting that local transmission was occurring before case detection.

Children represented 35% of all church A attendees but accounted for only 18% of persons who received testing and 6% of confirmed cases. These findings are consistent with those from other reports suggesting that many children with COVID-19 experience more asymptomatic infections or milder symptoms and have lower hospitalization rates than do adults (4,5). The role of asymptomatic or mildly symptomatic children in SARS-CoV-2 transmission remains unknown and represents a critical knowledge gap as officials consider reopening public places.

The risk for symptomatic infection among adults aged ≥65 years was not higher than that among adults aged 19–64 years. However, six of the seven hospitalized persons and all three deaths occurred in persons aged ≥65 years, consistent with other U.S. data indicating a higher risk for

COVID-19–associated hospitalization and death among persons aged ≥65 years (6).

The findings in this report are subject to at least four limitations. First, some infected persons might have been missed because they did not seek testing, were ineligible for testing based on criteria at the time, or were unable to access testing. Second, although no previous cases had been reported from this county, undetected low-level community transmission was likely, and some patients in this cluster might have had exposures outside the church. Third, risk of exposure likely varied among attendees but could not be characterized because data regarding individual behaviors (e.g., shaking hands or hugging) were not collected. Finally, the number of cases beyond the cohort of church attendees likely is undercounted because tracking out-of-state transmission was not possible, and patients might not have identified church members as their source of exposure.

FIGURE. Date of symptom onset* among persons with laboratory-confirmed cases of COVID-19 (N = 35) who attended March 6–11 church A events — Arkansas, March 6–23, 2020

Abbreviation: COVID-19 = coronavirus disease 2019.

* One asymptomatic person who had a positive test result is included on the date of specimen collection (March 18).

High transmission rates of SARS-CoV-2 have been reported from hospitals (7), long-term care facilities (8), family gatherings (9), a choir practice (10), and, in this report, church events. Faith-based organizations that are operating or planning to resume in-person operations, including regular services, funerals, or other events, should be aware of the potential for high rates of transmission of SARS-CoV-2. These organizations should work with local health officials to determine how to implement the U.S. Government's guidelines for modifying activities during the COVID-19 pandemic to prevent transmission of the virus to their members and their communities (2).

Cluster of Coronavirus Disease Associated with Fitness Dance Classes, South Korea

Sukbin Jang, Si Hyun Han, Ji-Young Rhee

Author affiliation: Dankook University Hospital, Dankook University College of Medicine, Cheonan, South Korea

DOI: <https://doi.org/10.3201/eid2608.200633>

During 24 days in Cheonan, South Korea, 112 persons were infected with severe acute respiratory syndrome coronavirus 2 associated with fitness dance classes at 12 sports facilities. Intense physical exercise in densely populated sports facilities could increase risk for infection. Vigorous exercise in confined spaces should be minimized during outbreaks.

By April 30, 2020, South Korea had reported 10,765 cases of coronavirus disease (COVID-19) (1); ≈76.2% of cases were from Daegu and North Gyeongsang provinces. On February 25, a COVID-19 case was detected in Cheonan, a city ≈200 km from Daegu. In response, public health and government officials from Cheonan and South Chungcheong Province activated the emergency response system. We began active surveillance and focused on identifying possible COVID-19 cases and contacts. We interviewed consecutive confirmed cases and found all had participated in a fitness dance class. We traced contacts back to a nationwide fitness dance instructor workshop that was held on February 15 in Cheonan.

Fitness dance classes set to Latin rhythms have gained popularity in South Korea because of the high aerobic intensity (2). At the February 15 workshop, instructors trained intensely for 4 hours. Among 27 instructors who participated in the workshop, 8 had positive real-time reverse transcription PCR (RT-PCR) results for severe acute respiratory syndrome coronavirus 2, which causes COVID-19; 6 were from Cheonan and 1 was from Daegu, which had the most reported COVID-19 cases in South Korea. All were asymptomatic on the day of the workshop.

By March 9, we identified 112 COVID-19 cases associated with fitness dance classes in 12 different sports facilities in Cheonan (Figure). All cases were confirmed by RT-PCR; 82 (73.2%) were symptomatic and 30 (26.8%) were asymptomatic at the time of laboratory confirmation. Instructors with very mild symptoms, such as coughs, taught classes for ≈1 week after attending the workshop

RESEARCH LETTERS

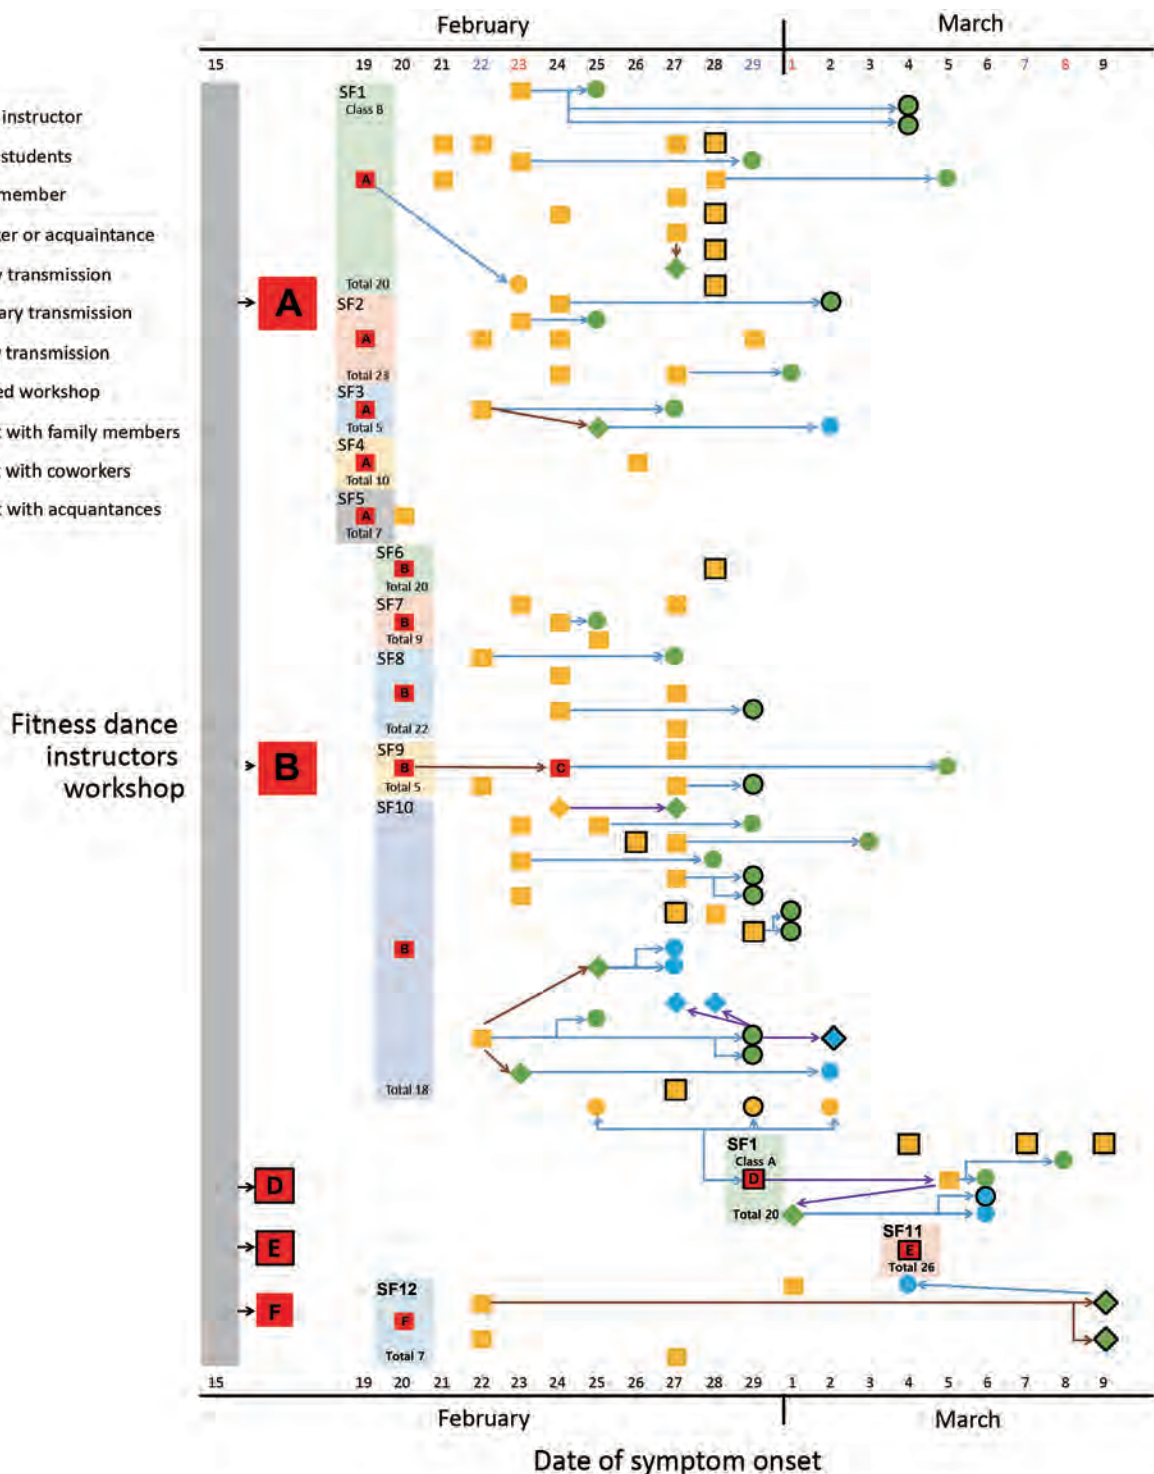

Figure. Case map of confirmed coronavirus disease (COVID-19) cases associated with fitness dance classes in Cheonan, South Korea, by date of symptom onset and relationship. Instructors outside of Cheonan are excluded. In 7 cases, transmission was suspected in the presymptomatic phase and the longest period before symptom onset was 5 days. None of the instructors had COVID-19 symptoms on the day of the workshop, but instructors from Daegu, which recently had a large outbreak, developed symptoms 3 days after the workshop. Sports facilities are represented by bars on the left with the number of students per class included. Bold outlines indicate a positive test for COVID-19 in a person in the presymptomatic phase.

(Appendix Figure 1, <https://wwwnc.cdc.gov/EID/article/26/8/20-0633.App1.pdf>). The instructors and students met only during classes, which lasted for 50 minutes 2 times per week, and did not have contact outside of class. On average, students developed symptoms 3.5 days after participating in a fitness dance class (3). Most (50.9%) cases were the result of transmission from instructors to fitness class participants; 38 cases (33.9%) were in-family transmission from instructors and students; and 17 cases (15.2%) were from transmission during meetings with co-workers or acquaintances.

Among 54 fitness class students with confirmed COVID-19, the median age was 42, all were women, and 10 (18.5%) had preexisting medical conditions (Appendix Table 1). The most common symptom at the time of admission for isolation was cough in 44.4% (24/54) of cases; 17 (31.5%) case-patients had pneumonia. The median time to discharge or end of isolation was 27.6 (range 13–66) days after symptom onset.

Before sports facilities were closed, a total of 217 students were exposed in 12 facilities, an attack rate of 26.3% (95% CI 20.9%–32.5%) (Appendix Table 2). Including family and coworkers, transmissions from the instructors accounted for 63 cases (Appendix Figure 2). We followed up on 830 close contacts of fitness instructors and students and identified 34 cases of COVID-19, translating to a secondary attack rate of 4.10% (95% CI 2.95%–5.67%). We identified 418 close contacts of 34 tertiary transmissions before the quarantine and confirmed 10 quaternary cases from the tertiary cases, translating to a tertiary attack rate of 2.39% (95% CI 1.30%–4.35%).

The instructor from Daegu who attended the February 15 workshop had symptoms develop on February 18 and might have been presymptomatic during the workshop. Evidence of transmission from presymptomatic persons has been shown in epidemiologic investigations of COVID-19 (4,5).

Characteristics that might have led to transmission from the instructors in Cheonan include large class sizes, small spaces, and intensity of the workouts. The moist, warm atmosphere in a sports facility coupled with turbulent air flow generated by intense physical exercise can cause more dense transmission of isolated droplets (6,7). Classes from which secondary COVID-19 cases were identified included 5–22 students in a room ≈ 60 m² during 50 minutes of intense exercise. We did not identify cases among classes with <5 participants in the same space. Of note, instructor C taught Pilates and yoga for classes of 7–8 students in the same facility

at the same time as instructor B (Figure; Appendix Table 2), but none of her students tested positive for the virus. We hypothesize that the lower intensity of Pilates and yoga did not cause the same transmission effects as those of the more intense fitness dance classes.

A limitation of our study is the unavailability of a complete roster of visitors to the sports facilities, which might have meant we missed infections among students during surveillance and investigation efforts. Discovery of outbreak cases centered on exercise facilities led to a survey of instructors who participated in a fitness dance workshop and provided clues to identifying additional cases among students. Early identification of asymptomatic persons with RT-PCR-confirmed infections helped block further transmissions. Because of the increased possibility of infection through droplets, vigorous exercise in closely confined spaces should be avoided (8) during the current outbreak, as should public gatherings, even in small groups (9,10).

Acknowledgments

We thank the state, local, and territorial health department personnel for providing the reported coronavirus disease data; patients in Dankook University Hospital participating in interviews and providing data; and the Dankook University College of Medicine for their support. We also thank Editage (<http://www.editage.co.kr>) for English language editing.

Infectious SARS-CoV-2 in Feces of Patient with Severe COVID-19

Fei Xiao,¹ Jing Sun,¹ Yonghao Xu,¹ Fang Li,¹ Xiaofang Huang,¹ Heying Li, Jingxian Zhao, Jicheng Huang, Jincun Zhao

Author affiliations: Sun Yat-sen University, Zhuhai, China (F. Xiao); Guangzhou Medical University, Guangzhou, China (J. Sun, Y. Xu, F. Li, X. Huang, Jingxian Zhao, Jincun Zhao); Chinese Academy of Sciences, Guangzhou (H. Li); Guangzhou Customs District Technology Center, Guangzhou (J. Huang)

DOI: <https://doi.org/10.3201/eid2608.200681>

¹These authors contributed equally to this article.

Severe acute respiratory syndrome coronavirus 2 was isolated from feces of a patient in China with coronavirus disease who died. Confirmation of infectious virus in feces affirms the potential for fecal-oral or fecal-respiratory transmission and warrants further study.

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) recently emerged in China, causing a major outbreak of severe pneumonia and spreading to >200 other countries (1). As of May 5, 2020, a total of 3,517,345 cases of coronavirus disease (COVID-2019) and 243,401 deaths had been reported to the World Health Organization (https://www.who.int/docs/default-source/coronaviruse/situation-reports/20200505covid-19-sitrep-106.pdf?sfvrsn=47090f63_2). The virus is believed to be spread by direct contact, fomites, respiratory droplets, and possibly aerosols (2). Viral RNA has been detected in feces and urine of some patients (3-7). Infectious virus was also isolated from urine of a patient with severe COVID-19 (8). However, it is unclear whether the virus in feces is infectious and might be an additional source for transmission.

This study was approved by the Health Commission of Guangdong Province and the Ethics Committees of Guangzhou Medical University to use patient and healthy donor sample specimens. On January 17, 2020, a 78-year-old man who had a history of recent travel to Wuhan, China, was admitted to the Fifth Affiliated Hospital of Sun Yat-Sen University because of a cough for 7 days and intermittent fever (Appendix Figure 1, panel A, <https://wwwnc.cdc.gov/EID/article/26/8/20-0681-App1.pdf>). Computed tomography of his chest showed multiple, ground-glass opacities (Appendix Figure 2). Nasopharyngeal and oropharyngeal swab specimens were positive for SARS-CoV-2 RNA by quantitative reverse transcription PCR (qRT-PCR).

On January 22, the patient's condition deteriorated and he was intubated. Ventilator-assisted breathing was instituted. The first feces specimen was collected on January 27 and was positive for viral RNA by qRT-PCR. Serial feces samples were collected on January 29, February 1, and February 7. All samples were positive for viral RNA (Appendix Figure 1, panel A). Viral antigen was also detected in gastrointestinal epithelial cells of a biopsy sample, as reported (9). The patient died on February 20.

We collected fecal specimens on January 29 to inoculate Vero E6 cells. Cycle threshold values for the fecal sample were 23.34 for the open reading frame 1lab gene and 20.82 for the nucleoprotein gene. A

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

SARS-CoV-2

ABSTRACT

Objectives: Studies are needed to better understand the genomic evolution of the recently emerged severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). This study aimed to describe genomic diversity of SARS-CoV-2 by next-generation sequencing (NGS) in a patient with longitudinal follow-up for SARS-CoV-2 infection.

Methods: Sequential samples collected between January 29th and February 4th, 2020, from a patient infected by SARS-CoV-2 were used to perform amplification of two genome fragments—including genes encoding spike, envelope, membrane and nucleocapsid proteins—and NGS was carried out with Illumina® technology. Phylogenetic analysis was performed with PhyML and viral variant identification with VarScan.

Results: Majority consensus sequences were identical in most of the samples (5/7) and differed in one synonymous mutation from the Wuhan reference sequence. We identified 233 variants; each sample harboured in median 38 different minority variants, and only four were shared by different samples. The frequency of mutation was similar between genes and correlated with the length of the gene ($r = 0.93$, $p = 0.0002$). Most of mutations were substitution variations ($n = 217$, 93.1%) and about 50% had moderate or high impact on gene expression. Viral variants also differed between lower and upper respiratory tract samples collected on the same day, suggesting independent sites of replication of SARS-CoV-2.

Conclusions: We report for the first time minority viral populations representing up to 1% during the course of SARS-CoV-2 infection. Quasispecies were different from one day to the next, as well as between anatomical sites, suggesting that *in vivo* this new coronavirus appears as a complex and dynamic distributions of variants. **Aude Jary, Clin Microbiol Infect 2020;26:1560.e1–1560.e4**

Introduction

The genome organization in severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is similar to that in the other beta-coronaviruses, with the open reading frame (ORF) 1a/b encoding non-structural proteins at the 5'-end, and structural proteins as follows: spike (S)—envelope (E)—membrane (M)—nucleocapsid

(NC)—3'-end [1]. Since the spike surface glycoprotein plays a major role in infection of the host cell, genomic variations may impact the interaction with the host receptor but also viral pathogenesis, transmissibility and infectivity [2].

As intra-host variants in a transversal study or from the same patient by nanopore sequencing have already been reported [3,4], this study aimed to describe genomic diversity of SARS-CoV-2 by

next-generation sequencing (NGS) in a patient with longitudinal follow-up for SARS-CoV-2 infection.

Methods

The first patient diagnosed with SARS-CoV-2 infection in Pitié-Salpêtrière Hospital, Paris, France, was followed daily for SARS-CoV-2 by RT-PCR of respiratory samples; viral genome could be detected between January 29th and February 10th, 2020 [5]. This patient, hospitalized on day 2 of a mild form of coronavirus disease 2019 (Covid-19), did not receive any antiviral or immunomodulation treatment during the entire study period.

Two fragments of about 4000 nucleotides (nt) were amplified by nested PCR (Supplementary Material Table S1), and NGS was performed with paired-end reads (MiSeq v3, 2 x 300 bp) on the MiSeq Illumina® system. Reads were trimmed using Trimmomatic, then mapped on SARS-CoV-2 reference sequence (NC_045512.2) with Geneious Prime software and finally assembled *de novo* with SPAdes 3.12.0 [6] to generate majority consensus sequences.

Multiple alignment was performed with Mafft7 [7] and phylogenetic analysis of S, E, M and NC genes with PhyML3.0 [8] and GTR substitution model with 1000 bootstraps resampling.

Intra-host variants were called using VarScan [9] with the following requirements: sequencing depth ≥ 1000 , minor allele frequency $\geq 1\%$ and found at least 100 times. Intra-sample viral variants were studied by comparing each consensus sequence with

all cleaned reads generated from the same sample and viral variants during follow-up by comparing consensus sequence of the first nasopharyngeal sample (01292020_NP) with all reads generated from the different samples. Synonymous mutations were identified as having a low impact, missense mutations and insertions with conservative inframe as having a moderate impact, and acquisition or loss of stop codon as well as frameshift as having a high impact on gene expression.

The Spearman rank correlation test was performed on GraphPad.

Results

The sequencing was effective for the first seven samples (one induced sputum and six nasopharyngeal swabs) from January 29th to February 4th, 2020, with a Ct value of SARS-CoV-2 RT-PCR < 30 . A full-length fragment of 8257 nt was generated with a median (IQR) of 45 523 (41 014–46 023) depth sequencing per sample (Supplementary Material Table S2).

Phylogenetic analysis

Compared to the NC_045512.2 reference sequence, our majority consensus sequences differed in the S gene by only four variations. They all harboured the synonymous mutation 3591T > C, whereas a non-synonymous mutation (859G > A) was found only in sample

Fig. 1. The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) genome diversity during infection. (A) Genome coverage (y axis) according to nucleotide position (x axis). (B) Distribution (x axis) and frequency (y axis) of the 233 intra-sample viral variants identified. Each sample is represented by the same colour in (A) and (B), and the impact of mutations on gene expression is represented by a different symbol (low: a rhombus, moderate: a square, high: a circle).

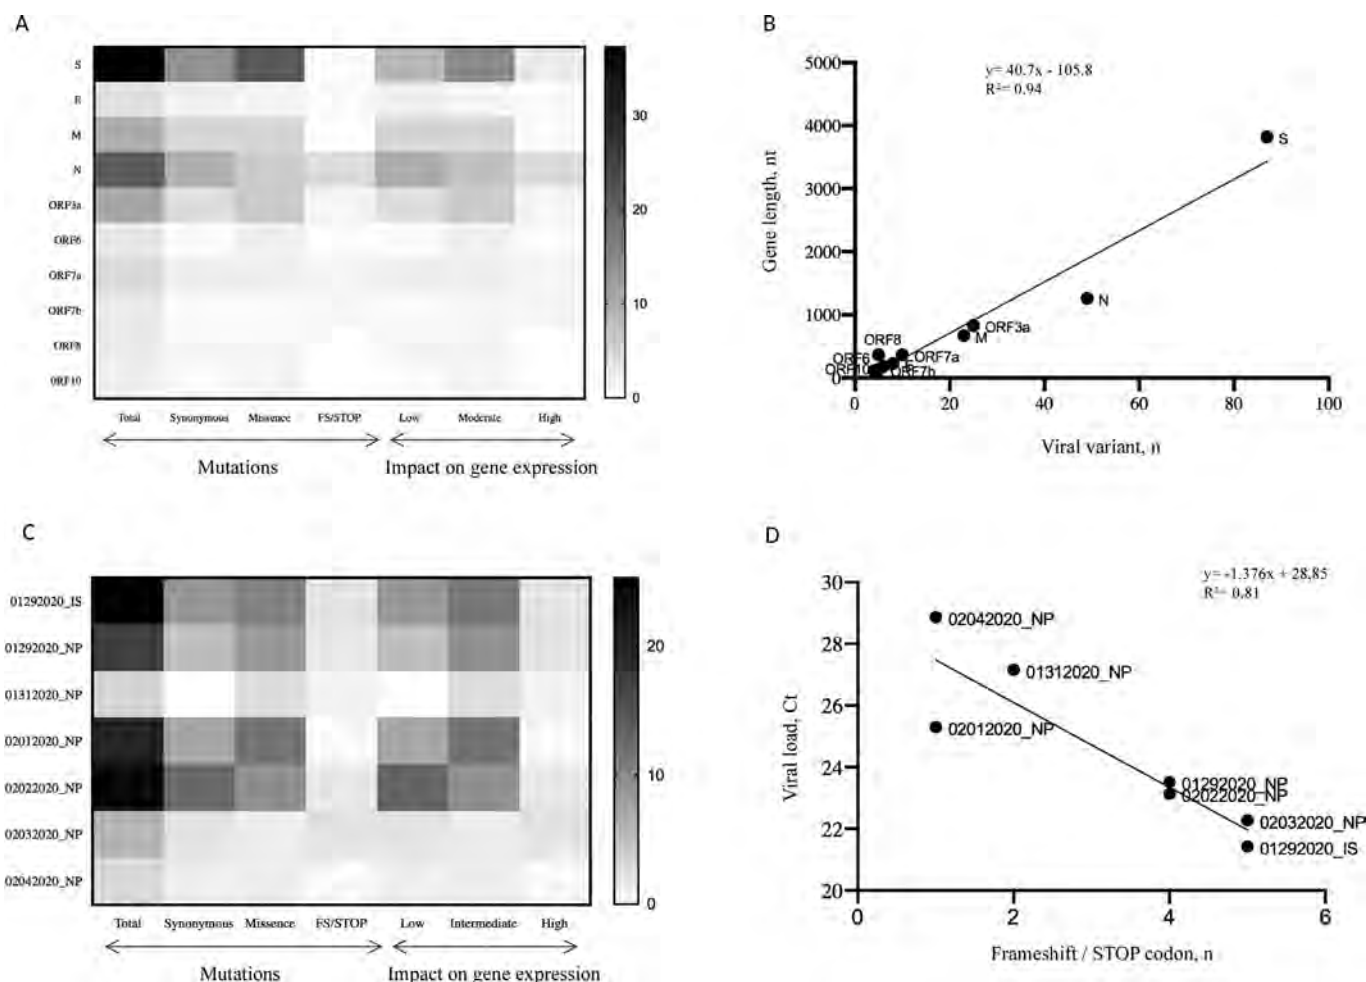

Fig. 2. Distribution of mutation frequency and correlation with gene length or viral load. (A) HeatMap representing the frequency and distribution of the mutations and their impact on gene expression between the different genes. (B) Linear regression line between the number of viral variant (x axis) and the gene length (y axis). (C) HeatMap representing the frequency and distribution of the mutations and their impact on gene expression between the different samples. (D) Linear regression line between the number of frameshift and stop codons (x axis) and the viral load expressed in cycle threshold (Ct) value (y axis). Viral variants by gene: S, $n = 87$; N, $n = 49$; ORF3a, $n = 25$; M, $n = 23$; ORF7a, $n = 10$; E, $n = 8$; ORF6, $n = 6$; ORF7b, $n = 5$; ORF8, $n = 5$; ORF10, $n = 4$. Scale on the right of (A) and (C) represents the frequency in percentages, with the largest value in dark and the lowest value in light.

02012020_NP. In sample 01312020_NP, a deletion of one nucleotide led to the appearance of a premature stop codon and a non-synonymous substitution at position 3554.

By phylogenetic analysis of the four structural genes, our sequences clustered with all the SARS-CoV-2 reference sequences issued from the NCBI database, and were distinct from the other human coronaviruses (Supplementary Material Fig. S1).

Intra-sample viral variant diversity

We identified 233 viral variants, and the number of variants per sample was not correlated with the depth sequencing ($r = 0.23$, $p = 0.28$).

Each sample harboured in median 38 (11–51.5) minority variants (<20%). Only 4/233 identical minority variants were common between two specimens, and 6/233 other mutations were identified at the same position in two samples but induced different variants (Supplementary Material Table S3). Although majority consensus sequences of the two specimens collected on January 29th were strictly identical, each one harboured their specific viral population with 59 variants identified in the induced sputum and 40 in the nasopharyngeal specimens (Fig. 1).

Nucleotide variations occurred in decreasing order in the S gene, N gene, ORF3a, M gene, ORF7a, E gene, ORF6, ORF7b and ORF8, and finally ORF10 (Fig. 2A). However, according to gene length, the frequency of mutation was similar and correlated with the length of the gene ($r = 0.93$, $p = 0.0002$) (Fig. 2B).

Most of the mutations were substitution variations (217/233), including 87/233 synonymous mutations and 107/233 missense mutations. According to gene expression, 88/233 variants had a low impact, 111/233 an intermediate impact, and 23/233 a high impact (Fig. 1). Between samples, only the frequencies of frameshift and stop codons were significantly and strongly correlated with the viral load ($r = 0.92$, $p = 0.0095$) (Fig. 2D).

Follow-up of viral variant diversity

By comparing with the consensus sequence collected on January 29th from the nasopharyngeal site, we found the same viral quasi-species in each sample as reported above. However, three majority variants emerged in the S gene obtained from the nasopharyngeal samples collected on January 31st and February 1st, corresponding to the three mutations described previously in the consensus sequences. None of them were found in the previous

and following samples as majority or minority variants (Supplementary Material Table S4).

Discussion

The virus identified in this patient was almost identical to the reference sequence from Wuhan [1]. This result was expected, as the patient was a general practitioner presumably infected by tourists from Wuhan and their guide who was later diagnosed SARS-CoV-2-positive [5].

Quasispecies in RNA viruses have previously been reported for SARS-CoV and MERS-CoV [10,11], as well as within individuals during SARS-CoV-2 infection [3,12]. The present study, allowing the analysis of SARS-CoV-2 minority variants at 1%, supports the previous finding. Indeed, we found a median of 38 different viral variants per sample during the follow-up of a single patient, with almost no common variant from one day to the next. More than half of the variants had an intermediate or high impact on gene expression and may explain the lack of persistence over time. Among the different types of mutations, the number of mutations inducing frameshift and stop codons were highly correlated with the viral load, reflecting the loss of fitness in variants harbouring deleterious mutations during intensive viral replication [13]. Otherwise, the viral variant population was also different between samples from the lower (induced sputum) and upper (nasopharyngeal swab) respiratory tract collected on the same day, suggesting independent replication of SARS-CoV-2, as previously reported [14].

Contrary to a previous study which identified a hotspot in ORF8 [15], the mutations identified in this study appeared to be spread fairly evenly throughout the sequenced fragment. Indeed, a limited number of viral variants was shared by two samples, the remainder (97%) being specific to each sample and occurring in different genomic sites, and a strong correlation was found between the number of variants and the length of each gene.

The main limitation of this study is that a fragment of only about 8000 nt was studied, in only one patient, and during a short period of follow-up because of low viral load in samples collected after February 5th. However, our results highlighted that during the first week of infection the major viral population remained identical (5/7), with several specific minority variants which did not seem to persist over time. Larger studies are needed to explore the entire intra-patient variability during the course of the infection, and in different clinical situations, to better understand the impact of the minority viral population on SARS-CoV-2 evolution, physiopathology and transmission.

Author contributions

DB, AGM, SB, VC planned the research; EKF, VP and EC collected the clinical data; VL, IM, ET and CS performed the experiments; AJ, VL, BA and MW analysed the data; AJ, SM, SB and DB wrote the paper. All the authors read and corrected the manuscript and approved the final version.

Transparency declaration

All the authors declare no competing interests. This study was funded by the Agence Nationale de Recherche sur le SIDA et les Hépatites Virales (ANRS, AC43), the Agence National de la Recherche (ANR) and Sorbonne Université.

Ethics

The study was carried out in accordance with the Declaration of Helsinki. It was a retrospective non-interventional study with no addition to standard care procedures. Reclassification of biological remnants into research material after completion of the ordered virological tests was approved by the local interventional review board of Pitié-Salpêtrière Hospital. According to the French Public Health Code (CSP Article L.1121-1.1) such protocols are exempted from individual informed consent.

Key Points

Question

What proportion of coronavirus disease 2019 (COVID-19) spread is associated with transmission of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) from persons with no symptoms?

Findings

In this decision analytical model assessing multiple scenarios for the infectious period and the proportion of transmission from individuals who never have COVID-19 symptoms, transmission from asymptomatic individuals was estimated to account for more than half of all transmission.

Meaning

The findings of this study suggest that the identification and isolation of persons with symptomatic COVID-19 alone will not control the ongoing spread of SARS-CoV-2.

Abstract

Importance
