Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the etiology of coronavirus disease 2019 (COVID-19), is readily transmitted person to person. Optimal control of COVID-19 depends on directing resources and health messaging to mitigation efforts that are most likely to prevent transmission, but the relative importance of such measures has been disputed.

Objective

To assess the proportion of SARS-CoV-2 transmissions in the community that likely occur from persons without symptoms.

Design, Setting, and Participants

This decision analytical model assessed the relative amount of transmission from presymptomatic, never symptomatic, and symptomatic individuals across a range of scenarios in which the proportion of transmission from people who never develop symptoms (ie, remain asymptomatic) and the infectious period were varied according to published best estimates. For all estimates, data from a meta-analysis was used to set the incubation period at a median of 5 days. The infectious period duration was maintained at 10 days, and peak infectiousness was varied between 3 and 7 days (−2 and +2 days relative to the median incubation period). The overall proportion of SARS-CoV-2 was varied between 0% and 70% to assess a wide range of possible proportions.

Main Outcomes and Measures

Level of transmission of SARS-CoV-2 from presymptomatic, never symptomatic, and symptomatic individuals.

Results

The baseline assumptions for the model were that peak infectiousness occurred at the median of symptom onset and that 30% of individuals with infection never develop symptoms and are 75% as infectious as those who do develop symptoms. Combined, these baseline assumptions imply that persons with infection who never develop symptoms may account for approximately 24% of all transmission. In this base case, 59% of all transmission came from asymptomatic transmission, comprising 35% from presymptomatic individuals and 24% from individuals who never develop symptoms. Under a broad range of values for each of these assumptions, at least 50% of new SARS-CoV-2 infections was estimated to have originated from exposure to individuals with infection but without symptoms.

Conclusions and Relevance

In this decision analytical model of multiple scenarios of proportions of asymptomatic individuals with COVID-19 and infectious periods, transmission from asymptomatic individuals was estimated to account for more than half of all transmissions. In addition to identification and isolation of persons with symptomatic COVID-19, effective control of spread will require reducing the risk of transmission from people with infection who do not have symptoms. These findings suggest that measures such as wearing masks, hand hygiene, social distancing, and strategic testing of people who are not ill will be foundational to slowing the spread of COVID-19 until safe and effective vaccines are available and widely used.

Introduction

As severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the novel coronavirus that causes coronavirus disease 2019 (COVID-19), began to spread globally, it became apparent that the virus, unlike the closely related SARS-CoV in the 2003 outbreak, could not be contained by symptom-based screening alone. Asymptomatic and clinically mild infections were uncommon during the 2003 SARS-CoV outbreak, and there were no reported instances of transmission from persons before the onset of symptoms.¹ SARS-CoV-2 spread faster than SARS-CoV, and accumulating evidence showed that SARS-CoV-2, unlike SARS-CoV, is transmitted from persons without symptoms. However, measures to reduce transmission from individuals who do not have COVID-19 symptoms have become controversial and politicized and have likely had negative effects on the economy and many societal activities. Optimal control of COVID-19 depends on directing resources and health messaging to mitigation efforts that are most likely to prevent transmission. The relative importance of mitigation measures that prevent transmission from persons without symptoms has been disputed. Determining the proportion of SARS-CoV-2 transmission that occurs from persons without symptoms is foundational to prioritizing control practices and policies.

Transmission by persons who are infected but do not have any symptoms can arise from 2 different infection states: presymptomatic individuals (who are infectious before developing symptoms) and individuals who never experience symptoms (asymptomatic infections, which we will refer to as never symptomatic). Early modeling studies of COVID-19 case data found that the generation interval of SARS-CoV-2 was shorter than the serial interval, indicating that the average time between 1 person being infected and that person infecting someone else was shorter than the average time between 1 person developing symptoms and the person they infected developing symptoms.^{2,3,4,5} This finding meant that the epidemic was growing faster than would be expected if transmission were limited to the period of illness during which individuals were symptomatic. By the time a second generation of individuals was developing

symptoms, a third generation was already being infected. Epidemiological data from early in the pandemic also suggested the possibility of presymptomatic transmission,^{6,7} and laboratory studies confirmed that levels of viral RNA in respiratory secretions were already high at the time of symptom onset.^{8,9,10}

Asymptomatic SARS-CoV-2 transmission also occurs because of individuals with infection who are never symptomatic (or who experience very mild or almost unrecognizable symptoms). The proportion of individuals with infection who never have apparent symptoms is difficult to quantify because it requires intensive prospective clinical sampling and symptom screening from a representative sample of individuals with and without infection. Nonetheless, evidence from household contact studies indicates that asymptomatic or very mild symptomatic infections occur,^{11,12,13,14} and laboratory and epidemiological evidence suggests that individuals who never develop symptoms may be as likely as individuals with symptoms to transmit SARS-CoV-2 to others.^{9,15,16}

Methods

The Centers for Disease Control and Prevention determined that this decision analytical study, which involved no enrollment of human subjects, did not require institutional review board approval. We used a simple model to assess the proportion of transmission from presymptomatic (ie, infectious before symptom onset), never symptomatic, and symptomatic individuals across a range of scenarios in which we varied the timing of the infectious period to assess different contributions of presymptomatic transmission and the proportion of transmission from individuals who never develop symptoms (ie, remain asymptomatic).

For all estimates we used data from a meta-analysis of 8 studies from China to set the incubation period at a median of 5 days with 95% of symptomatic individuals developing symptoms by day 12.¹⁷ Therefore the daily (t) probability of symptom onset (p_{so}) for individuals who develop symptoms was:

$$p_{so}(t) = F_{Log-Normal}(t, \logmean = 1.63, \logsd = 0.5).$$

To approximate a distribution of the infectious period, we made a baseline assumption that peak infectiousness occurs on average at the same time as the median incubation period, such that infectiousness begins prior to symptom onset (Table).^{9,12,14,15,16,18,20} We then assumed that infectiousness (I) over time can be approximated by a γ density function and that the average person is infectious for as long as approximately 10 days (ie, 98% of transmission happens within a 10-day period)¹¹:

$$I(t) = f_{\gamma}(t, \text{mode} = 5, \text{interval} = 10).$$

For all estimates, we maintained the infectious period duration as 10 days, but varied the mode between 3 and 7 days (−2 and +2 days relative to the median incubation period).

Uncertainty also remains about the proportion of individuals with infection who are never symptomatic (p_{ns}) and the relative contribution of these infections to transmission (r_{ns}). Estimates of p_{ns} range from single digits to more than 50%, many with potential biases related to the study population (eg, age, prevalence of comorbidities) and the extent of long-term follow-up^{12,13,14,19,20} (Table). We made a baseline assumption that 30% of individuals with infection are never symptomatic and then assessed higher or lower assumptions. We also made a baseline assumption that individuals with asymptomatic infections are on average 75% as infectious as those with symptomatic infections.^{9,15,16} Combined, these baseline assumptions imply that persons with infection who never develop symptoms may account for approximately 24% of all transmission (T):

$$T_{ns} = p_{ns} \times r_{ns} / (p_{ns} \times r_{ns} + [1 - p_{ns}]).$$

We varied this overall proportion, T_{ns} , between 0% and 70% to assess a wide range of possible proportions. The daily proportion of transmission from individuals after symptom onset (T_s) was therefore:

$$T_s(t) = (1 - T_{ns}) \times p_{so}(t) \times I(t),$$

and the daily proportion of transmission from presymptomatic (T_{ps}) individuals, ie, those who develop symptoms but become infectious prior to symptom onset, is:

$$T_{ps}(t) = 1 - T_s(t) - T_{ns}.$$

We modified baseline assumptions to consider the relative importance of different levels of never symptomatic and presymptomatic transmission. Code is available in the eAppendix in the [Supplement](#).

Statistical Analysis

All analyses were conducted in R version 4.0.1 (R Project for Statistical Computing). No statistical testing was conducted, so no prespecified level of significance was set.

Results

Under baseline assumptions, approximately 59% of all transmission came from asymptomatic transmission: 35% from presymptomatic individuals and 24% from individuals who are never symptomatic ([Figure 1](#)). Because each component is uncertain, we assessed different timings of peak infectiousness relative to illness onset and different proportions of transmission from individuals who never have symptoms. Maintaining the 24% of transmission from individuals who never have symptoms, but shifting peak infectiousness 1 day earlier (to day 4) increased presymptomatic transmission to 43% and all asymptomatic transmission to 67% ([Figure 1A](#)). A later peak (ie, day 6) decreased presymptomatic to 27% and all asymptomatic transmission to 51% ([Figure 1C](#)).

Holding the day of peak infectiousness constant at day 5 and decreasing the proportion of transmission from individuals who are never symptomatic to 10% with a relative infectiousness of 75% (baseline assumption), the proportion of all transmission from those who are never symptomatic decreased to 8%, presymptomatic transmission increased to 42%, and combined asymptomatic transmission was 50% of all transmission ([Figure 1D](#)). In contrast, if the proportion of those who ever develop symptoms was 30% and their relative infectiousness increased to 100%, they contributed 30% of all transmission, presymptomatic transmission was 32%, and combined asymptomatic transmission was 62% of all transmission ([Figure 1F](#)).

Uncertainty remains regarding the magnitude of both presymptomatic and never symptomatic transmission. Therefore, we analyzed a wider range of each of these components, with peak infectiousness varying between 2 days before (more presymptomatic transmission) to 2 days after (less presymptomatic transmission) median symptom onset and with never symptomatic transmission ranging from 0% to 70% ([Figure 2](#)). Under this broader range of scenarios, most combined assumptions of peak infectiousness timing and transmission from individuals who never have symptoms indicated that at least 50% of new SARS-CoV-2 infections likely originated from individuals without symptoms at the time of transmission. If more than 30% of transmission was from individuals who never have symptoms, total asymptomatic transmission was higher than 50% with any value of peak infectiousness, up to 2 days after the median time of symptom onset. If peak infectiousness was at any point approximately 6 hours before median symptom onset time, more than 50% of transmission was from individuals without symptoms, regardless

of the proportion from those who never have symptoms. Even a very conservative assumption of peak infectiousness 2 days post–median onset and 0% never symptomatic transmission still resulted in more than 25% of transmission from asymptomatic individuals.

Discussion

The findings presented here complement an earlier assessment²¹ and reinforce the importance of asymptomatic transmission: across a range of plausible scenarios, at least 50% of transmission was estimated to have occurred from persons without symptoms. This overall proportion of transmission from presymptomatic and never symptomatic individuals is key to identifying mitigation measures that may be able to control SARS-CoV-2. For example, if the reproduction number (R) in a given setting is 2.0, then at least a 50% reduction in transmission is needed to drive the reproductive number below 1.0. Given that in some settings R is likely much greater than 2 and more than half of transmissions may come from individuals who are asymptomatic at the time of transmission, effective control must mitigate transmission risk from people without symptoms.

Limitations

This study has limitations. First, we used a simplistic model to represent a complex phenomenon, ie, the average infectiousness of SARS-CoV-2 infections over time. We used this model deliberately to test assumptions about the timing of peak infectiousness and transmission among asymptomatic individuals so that we could vary only these 2 critical parameters and assess their relative effects. Therefore, these results lack quantitative precision, but they demonstrate the qualitative roles of these 2 components and show that across broad ranges of possible assumptions, the finding that asymptomatic transmission is a critical component of SARS-CoV-2 transmission dynamics remains constant.

As discussed here, the exact proportions of presymptomatic and never symptomatic transmission are not known. This also applies to the incubation period estimates, which are based on individual exposure and onset windows that are difficult to observe with precision and therefore include substantial uncertainty even when leveraging estimates across multiple studies. Moreover, they likely vary substantially in different populations. For example, older individuals are more likely than younger persons to experience symptoms,²⁰ so in populations of older individuals, never asymptomatic transmission may be less important. However, specific age groups are rarely exclusively isolated from other age groups, so asymptomatic transmission risk is still important in those groups and even more so in younger age groups, in which transmission may be even more dominated by asymptomatic transmission.²⁰

Real-world transmission dynamics are also not entirely dependent on the individual-level dynamics of infectiousness over time. Now that COVID-19 is widely recognized, individuals with COVID-19 symptoms are more likely to isolate themselves and further reduce the proportion of transmission from symptomatic individuals, shifting a greater proportion of transmission to those who do not have symptoms. In this sense, the estimates here represent the lower end of the proportion of asymptomatic transmission in the presence of interventions to reduce symptomatic transmission.

Conclusions

Under a range of assumptions of presymptomatic transmission and transmission from individuals with infection who never develop symptoms, the model presented here estimated that more than half of transmission comes from asymptomatic individuals. In the absence of effective and widespread use of therapeutics or vaccines that can shorten or eliminate infectivity, successful control of SARS-CoV-2 cannot rely solely on identifying and isolating symptomatic cases; even if implemented effectively, this strategy would be insufficient. These findings suggest that effective control also requires reducing the risk of transmission from people with infection who do not have symptoms. Measures such as mask wearing

and social distancing empower individuals to protect themselves and, if infected, to reduce risk to their communities.²¹ These measures can also be supplemented by strategic testing of people who are not ill, such as those who have exposures to known cases (eg, contact tracing) or are at high risk of exposing others (eg, congregate facility staff, those with frequent contact with the public). Multiple measures that effectively address transmission risk in the absence of symptoms are imperative to control SARS-CoV-2.

Figures and Tables

Table.**Key Assumptions and Evidence Informing Those Assumptions**

Source	Evidence base	Estimate or assumption
Assumptions for presymptomatic transmission		
Peak infectiousness relative to onset, d		
Casey et al, 2020 ¹⁸	Range, 17 studies	−3 to 1.2 d
Assumed baseline	NA	0 d
Assumed range	NA	−2 to 2 d
Assumptions for never symptomatic transmission		
Proportion never symptomatic		
Oran et al, 2020 ¹²	Inferred range, 16 studies	30% to 45%
Buitrago-Garcia et al, 2020 ¹⁴	Meta-estimate, 7 studies	26% to 37%
Davies et al, 2020 ²⁰	Age-dependent estimate, 6 studies	20% to 70%
Assumed baseline	NA	30%
Relative infectiousness of individuals who never have symptoms		
Lee et al, 2020 ⁹	303 patients, assessment of viral shedding	Approximately 100%
Chaw et al, 2020 ¹⁵	1701 secondary contacts	40% to 140%
Mc Evoy et al, 2020 ¹⁶	Inferred range, 6 studies	40% to 70%
Assumed baseline		75%
Overall proportion of individuals who never have symptoms transmission		
Assumed range	NA	0% to 70%

Abbreviation: NA, not applicable.

Figure 1.**The Contribution of Asymptomatic Transmission Under Different Infection Profiles**

The top curve in each panel represents the average relative hourly infectiousness, such that while the lower curves change under different assumptions, the total hourly infectiousness equals 1 in all cases. Within each curve, the colored area indicates the proportion of transmission from each class of individuals. The portion attributed to individuals with symptoms (light blue) can also be interpreted as the maximum proportion of transmission that can be controlled by immediate isolation of all symptomatic cases. Panels A, B, and C show different levels of presymptomatic transmission. We calibrated infectiousness to peak at day 4 (A), 5 (B; median incubation period), or 6 (C) days. Panels D, E, and F show different proportions of transmission from individuals who are never symptomatic: 8% (C; eg, 10% never symptomatic and 75% relative infectivity), 24% (D; baseline, 30% never symptomatic and 75% relative infectivity), and 30% (E; eg, 30% never symptomatic and 100% relative infectivity).

Figure 2.**Combined Transmission From Individuals Who Are Presymptomatic and Those Who Never Have Symptoms**

Colors indicate the proportion of transmission due to all individuals without symptoms at the time of transmission, including presymptomatic transmission (x-axis, the timing of peak infectiousness relative to symptom onset) and transmission from individuals who are never symptomatic (y-axis). For example, peak infectiousness at the same time as median symptom onset (0 days difference) with 10% of transmission from individuals who never have symptoms would mean that approximately 51% of transmission is from asymptomatic individuals.

Epidemiologic Evidence for Airborne Transmission of SARS-CoV-2 during Church Singing, Australia, 2020

Anthea L. Katelaris, Jessica Wells, Penelope Clark, Sophie Norton, Rebecca Rockett, Alicia Arnott, Vitali Sintchenko, Stephen Corbett, Shopna K. Bag

An outbreak of severe acute respiratory syndrome coronavirus 2 infection occurred among church attendees after an infectious chorister sang at multiple services. We detected 12 secondary case-patients. Video recordings of the services showed that case-patients were seated in the same section, up to 15 m from the primary case-patient, without close physical contact, suggesting airborne transmission.

The circumstances under which airborne transmission of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) might occur are uncertain (1,2). Previous cluster reports have suggested involvement of airborne transmission (3,4), but clear epidemiologic evidence is lacking. We investigated a SARS-CoV-2 outbreak in a church in Sydney, New South Wales, Australia, and reviewed the epidemiologic and environmental findings to assess the possibility of airborne transmission of SARS-CoV-2.

The Study

On July 18, 2020, the Western Sydney Public Health Unit was notified of a positive SARS-CoV-2 test result for an 18-year-old man (PCR cycle threshold [C_t] values: envelope gene 14.5, nucleocapsid gene 16.8). He had sought testing the day before, after learning of a SARS-CoV-2 exposure at a venue he attended on July 11. He reported symptom onset of malaise and headache on July 16 and cough and fever on July 17. He

was a church chorist and, during his infectious period (from 48 hours before onset), had sung at four 1-hour services, 1 each on July 15 and 16 and 2 on July 17.

The case-patient had sung from a choir loft, elevated 3.5 m above the congregation, which he entered before and left after the service. He denied touching objects in the church or mixing with the general congregation. Video recordings of the services corroborated this history. We identified close contacts according to the national coronavirus disease (COVID-19) control guidelines at the time (5): anyone who had spent >15 min face-to-face or shared a closed space for 2 hours with a case-patient during the infectious period of the case-patient. Initially, 10 other chorists and staff were classified as close contacts and required to quarantine (5).

On July 18, the church informed the community about the case-patient, prompting testing among members. On July 20, the Western Sydney Public Health Unit was notified of 2 additional case-patients who reported attendance on July 15 and 16. Neither was known by the primary case-patient.

Because transmission was deemed likely to have occurred at these services, we classified all attendees of the 4 services as close contacts, required to quarantine, and requested to seek baseline SARS-CoV-2 testing regardless of symptoms (in addition to if symptoms developed). Public health staff telephoned attendees (identified by mandatory service sign-in records), released alerts through the church and media, and established a testing clinic on-site. Close contacts were contacted every 2–3 days to inquire about symptoms and advised to retest if symptoms developed.

We identified 508 close contacts across the 4 services (Table), of which 434 (85%) were recorded as having a test within 17 days after exposure. Most contacts were tested 2–7 days after exposure (Appendix Figure 1,

Total	508	434	85	12	2.4

*SARS-CoV-2, severe acute respiratory syndrome coronavirus 2; NC, not calculated.

†Contacts identified through church service sign-in records and staff lists. This procedure might slightly underestimate the number of contacts because some persons might not have signed in and some telephone numbers were illegible or invalid.

‡Contacts were tested within 17 d (14-d incubation period plus 3 d) of the last exposure date. Pathology providers in New South Wales, Australia, routinely report SARS-CoV-2 test results (positive or negative) to public health authorities. This number would not include tests performed under a different name or spelling to that on the sign-in records.

§One case-patient attended 2 services on July 16 and 17. Because of the absence of additional case-patients on July 17, we have attributed exposure of this case-patient to have been on July 16.

<https://wwwnc.cdc.gov/EID/article/27/6/21-0465-App1.pdf>.

We detected 12 secondary case-patients among 508 service attendees, yielding an overall secondary attack rate (SAR) of 2.4% across the 4 services (Table). Five case-patients attended only the service on July 15 (SAR 5/215, 2.3%), and 7 attended only on July 16 (SAR 7/120, 5.8%). One case-patient who attended on July 16 also attended on July 17; however, no case-patients were identified who attended only a service on July 17. Secondary case-patients showed development of symptoms 2–12 days after exposure (Figure 1). Five of the secondary case-patients were from the same households as earlier cluster case-patients. Thus, these case-patients might have been infected within the household rather than the church. No secondary case-patients reported other SARS-CoV-2 exposures outside these services. There were no deaths, although 3 case-patients were hospitalized, including 2 who required intensive care.

SARS-CoV-2 genome sequencing was performed for the primary case-patient and 10 secondary case-patients (6). These case-patients formed a single genomic cluster with a maximum of 2 nt changes from the SARS-CoV-2 genome of the primary case-patient (Appendix Figure 2). High C_t values for the remaining 2 case-patients prohibited sequencing.

To further characterize exposures, we determined the seating positions of secondary case-patients within the church. We asked case-patients to describe where they sat, and the video recordings of the services were reviewed, jointly with the case-patients where possible, to confirm locations.

The church was round, and pews were located circumferentially. We were able to locate the exact location of 10 of the 12 secondary case-patients by using the recordings. The remaining 2 case-patients (case-patients 3 and 4) were unable to review the recordings but described the section and row in which they sat. All secondary case-patients sat within a 70° section, below and 1–15 m from the primary case-patient (Figure 2). The primary case-patient faced away from this area, and used a microphone. Cases were not detected in attendees seated in other sections, and the spatial clustering remains if the 5 potentially household-acquired case-patients are excluded (case-patients 7, 8, 10, 12, and 13). None of the other choristers showed symptoms or tested positive for SARS-CoV-2. Use of masks was not in place.

To understand the ventilation, we conducted 2 site visits with the building manager. The church had a high conical roof, and the ventilation system at the apex was not in operating during the services. The doors and windows were largely closed, except

Figure 1. Epidemiologic curve of an outbreak of infection with severe acute respiratory syndrome coronavirus 2 in a church, Australia, 2020. Red indicates symptom onset date for the index case-patient, who sang at 4 services on July 15–17; secondary case-patient symptom onset dates are color coded by date of service attendance as indicated along baseline (1 secondary case-patient attended services on July 16 and 17). The 5 case-patients with onsets of July 22–26 also had exposures to earlier outbreak case-patients in their households.

Figure 2. Schematic diagram of church layout showing seating locations of primary and secondary case-patients during an outbreak of infection with severe acute respiratory syndrome coronavirus 2, Australia, 2020. Case numbers are based on order of notification received by the Public Health Unit. Location of case-patients indicated in green and dark blue were confirmed on video recordings; the 2 case-patients indicated in light blue described their locations. The primary case-patient was located in an elevated loft ≈ 3 m above ground level. He was singing and playing the piano throughout the services and faced toward the piano. Other members of the congregation were seated throughout all sections of the church during the 4 services. Relatively more persons were seated in the front area of the church than in the sides or back.

as persons entered and exited, and the wall fans were off, meaning there was minimal ventilation.

Conclusions

We detected 12 secondary case-patients linked to an infectious case-patient at church services on 2 days. Secondary case-patients were seated in the same area of the church, up to 15 m from the primary case-patient, with whom there was no evidence of close physical contact. We believe that transmission during this outbreak is best explained by airborne spread, potentially the result of 3 factors. First, singing has been demonstrated to generate more respiratory aerosol particles and droplets than talking (7). Second, minimal ventilation might have enabled respiratory particles to accumulate in the air, and convection currents might have carried particles toward the pews where secondary case-patients were seated. Third, the primary case-patient was likely near the peak of infectiousness on the basis of low C_t values (8) and symptom onset occurring around the exposure dates (9). Although we cannot completely exclude fomite transmission, this transmission would not explain the spatial clustering of case-patients within the church over 2 days.

Strengths of our investigation include detailed case and contact follow-up, availability of video recordings of the services to confirm movements and

locations of case-patients, high uptake of testing by contacts, and that SARS-CoV-2 genome sequencing provided supportive evidence that case-patients were closely related genomically. In addition, the New South Wales context of low community transmission (10) and high estimated case ascertainment (11) makes it unlikely that case-patients acquired infection outside this cluster.

A limitation was that most contacts were tested within a week of exposure, which could have been too early to detect some asymptomatic infections. Second, this investigation only provides circumstantial evidence of airborne transmission, and does not help elucidate the exact mechanism of spread. Finally, we are unsure why transmission did not occur at the services on July 17 (except in 1 possible instance); reasons might be related to altered air flow, the primary case-patient being past peak infectiousness, or that cases that did occur went undetected.

This cluster occurred despite adherence to guidelines requiring microphone use and a 3-m cordon around singers. Guidelines for places of worship were tightened after this cluster was detected, including increasing the distance required around a singer to 5 m. However additional mitigation measures might be necessary to prevent airborne infection during church services and singing, including increased natural or artificial ventilation (12) or moving activities outdoors.

Acknowledgments

We thank the case-patients, church management, and wider church community for their participation and support during the outbreak management and investigations; Jennifer Paterson, Jennifer Lampard, Stephen Crone, and the Public Health Unit surge team for assistance with case and contact tracing; Kate Ward, Duleepa Jayasundara, and the Institute of Clinical Pathology and Medical Research, New South Wales Health Pathology for their contributions to the study; Aneliese Goodwin, Clement Lee, Carl Banting, Connie Lam, Karen-Ann Gray, Eby Sim, Elena Martinez, Mailie Gall, Jenny Draper, Rosemarie Sadsad, Andrew Ginn, and Qinning Wang for performing genome sequencing and bioinformatic analysis; and the New South Wales Ministry of Health Public Health Response Branch for its participation in the study.

About the Author

Dr. Katelaris is a public health physician and field epidemiologist in the Western Sydney Local Health District Public Health Unit, Sydney, New South Wales, Australia. Her primary research interests include communicable disease control, infectious disease epidemiology, and outbreak investigation.

Summary

SARS-CoV-2 Spike protein is critical for virus infection via engagement of ACE2¹, and is a major antibody target. Here we report chronic SARS-CoV-2 with reduced sensitivity to neutralising antibodies in an immune suppressed individual treated with convalescent plasma, generating whole genome ultradeep sequences over 23 time points spanning 101 days. Little change was observed in the overall viral population structure following two courses of remdesivir over the first 57 days. However, following convalescent plasma therapy we observed large, dynamic virus population shifts, with the emergence of a dominant viral strain bearing D796H in S2 and H69/V70 in the S1 N-terminal domain NTD of the Spike protein. As passively transferred serum antibodies diminished, viruses with the escape genotype diminished in frequency, before returning during a final, unsuccessful course of convalescent plasma. *In vitro*, the Spike escape double mutant bearing H69/V70 and D796H conferred modestly decreased sensitivity to convalescent plasma, whilst maintaining infectivity similar to wild type. D796H appeared to be the main contributor to decreased susceptibility but incurred an infectivity defect. The H69/V70 single mutant had two-fold higher infectivity compared to wild type, possibly compensating for the reduced infectivity of D796H. These data reveal strong selection on SARS-CoV-2 during convalescent plasma therapy associated with emergence of viral variants with evidence of reduced susceptibility to neutralising antibodies.

Clinical case history of SARS-CoV-2 infection in setting of immune-compromised host

A septuagenarian male was admitted to a tertiary hospital in summer of 2020 and had tested positive for SARS-CoV-2 RT-PCR 35 days previously on a nasopharyngeal swab (Day 1) at a local hospital (Extended data 1 and 2). His past medical history was significant for marginal B cell lymphoma diagnosed in 2012, with previous chemotherapy including vincristine, prednisolone, cyclophosphamide and anti-CD20 B cell depletion with rituximab. It is likely that both chemotherapy and underlying lymphoma contributed to B and T cell combined immunodeficiency (Extended data 2 and 3, Supplementary Table 1). Computed tomography (CT) of the chest showed widespread abnormalities consistent with COVID-19 pneumonia (Supplementary Figure 1). Treatment included two 10-day courses of remdesivir with a five day gap in between (Extended data 1). Two units of convalescent plasma were administered on days 63 and 65 (Extended data 3). Following clinical deterioration, remdesivir and a unit of convalescent plasma were administered on day 95, but the individual unfortunately died on day 102 (Supplementary text).

Virus genomic comparative analysis of 23 sequential respiratory samples over 101 days

The majority of samples were respiratory samples from nose and throat or endotracheal aspirates during the period of intubation (Supplementary Table 3). Ct values ranged from 16-34 and all 23 respiratory samples were successfully sequenced by standard single molecule sequencing approach as per the ARTIC protocol implemented by COG-UK; of these 20 additionally underwent short-read deep sequencing using the Illumina platform (Supplementary table 4). There was general agreement between the two methods (Extended data 4). However due to the higher reliability of Illumina for low frequency variants, this was used for formal analysis^{2,3}. Additionally, single genome amplification and sequencing of Spike using extracted RNA from respiratory samples was used as an independent method to detect mutations observed (Extended data 4). Finally, we detected no evidence of recombination, based on two independent methods.

Maximum likelihood analysis of patient-derived whole genome consensus sequences demonstrated clustering with other local sequences from the same region (Figure 1). The infecting strain was assigned to lineage 20B bearing the D614G Spike variant. Environmental sampling showed evidence of virus on surfaces such as telephone and call bell. Sequencing of these surface viruses showed clustering with those derived from the respiratory tract (Extended data 2). All samples were consistent with having arisen from a single underlying viral population. In our phylogenetic analysis, we included sequential sequences from three other local patients identified with persistent viral RNA shedding over

a period of 4 weeks or more as well as two long term immunosuppressed SARS-CoV-2 ‘shedders’ recently reported^{4,5}, (Extended data 2, Supplementary Table 2). While the sequences from the three local patients as well as from Avanzato et al⁵ showed little divergence with no amino acid changes in Spike over time, the case patient showed significant diversification. The Choi et al report⁴ showed similar degree of diversification as the case patient. Further investigation of the sequence data suggested the existence of an underlying structure to the viral population in our patient, with samples collected at days 93 and 95 being rooted within, but significantly divergent from the original population (Extended data 5 and 6). The relationship of the divergent samples to those at earlier time points argues against superinfection.

SARS-CoV-2 viral diversity

All samples tested positive by RT-PCR and there was no sustained change in Ct values throughout the 101 days following the first two courses of remdesivir (days 41 and 54), or the first two units of convalescent plasma with polyclonal antibodies (days 63 and 65, Extended data 3). Of note we were not able to culture virus from stored swab samples. Consensus sequences from short read deep sequence Illumina data revealed dynamic population changes after day 65, as shown by a highlighter plot (Extended data 6). In addition, we were also able to follow the dynamics of virus populations down to low frequencies during the entire period (Figure 2, Supplementary Table 4). Following remdesivir at day 41 the low frequency variant analysis allowed us to observe transient amino acid changes in populations at below 50% abundance in Orf 1b, 3a and Spike, with a T39I (C27509T) mutation in ORF7a reaching 79% on day 45 (Figure 2, pink, supplementary information). At day 66 we noted I513T in NSP2 (T2343C) and V157L (G13936T) in RdRp had emerged from undetectable at day 54 to almost 100% frequency (Figure 2, red and green dashed lines), with the polymerase being the more plausible candidate for driving this sweep. Notably, spike variant N501Y, which can increase the ACE2 receptor affinity⁶, and which is present in the new UK B.1.1.7 lineage⁷, was observed on day 55 at 33% frequency, but was eliminated by the sweep of the NSP2/RdRp variant.

In contrast to the early period of infection, between days 66 and 82, following the first two administrations of convalescent sera, a shift in the virus population was observed, with a variant bearing D796H in S2 and H69/ V70 in the S1 N-terminal domain (NTD) becoming the dominant population at day 82. This was identified in a nose and throat swab sample with high viral load as indicated by Ct of 23 (Figure 3A). The deletion was detected transiently at baseline according to short read deep sequencing. H69/ V70 was due to an out of frame six nucleotide deletion resulting in the sequence of codon 68 changing from ATA to ATC.

On Days 86 and 89, viruses obtained from upper respiratory tract samples were characterised by the Spike mutations Y200H and T240I, with the deletion/mutation pair observed on day 82 having fallen to frequencies of 10% or less (Figure 2 and 3). The Spike mutations Y200H and T240I were accompanied at high frequency by two other non-synonymous variants with similar allele frequencies, coding for I513T in NSP2, V157L in RdRp and N177S in NSP15 (Figure 2A). Both of these were also previously observed at

>98% frequency in the sample on day 66 (Figure 2A, red and green lines), arguing that this new lineage emerged out of a previously existing population.

Sequencing of a nose and throat swab sample at day 93 identified viruses characterised by Spike mutations P330S at the edge of the RBD and W64G in S1 NTD at close to 100% abundance, with D796H along with H69/ V70 at <1% abundance and the variants Y200H and T240I at frequencies of <2%. Viruses with the P330S variant were detected in two independent samples from different sampling sites, arguing against the possibility of contamination. The divergence of these samples from the remainder of the population (Figure 2, 3B and Extended data 5 and 6) suggests the possibility that they represent a compartmentalised subpopulation.

Patterns in the variant frequencies suggest competition between virus populations carrying different mutations, viruses with the D796H/ H69/ V70 deletion/mutation pair rising to high frequency during CP therapy, then being outcompeted by another population in the absence of therapy. Specifically, these data are consistent with a lineage of viruses with the NSP2 I513T and RdRp V157L variant, dominant on day 66, being outcompeted during therapy by the mutation/deletion variant. With the lapse in therapy, the original strain, having acquired NSP15 N1773S and the Spike mutations Y200H and T240I, regained dominance, followed by the emergence of a separate population with the W64G and P330S mutations.

In a final attempt to reduce the viral load, a third course of remdesivir (day 93) and third dose of CP (day 95) were administered. We observed a re-emergence of the D796H + H69/ V70 viral population (Figure 2, 3). The inferred linkage of D796H and H69/ V70 was maintained as evidenced by the highly similar frequencies of the two variants, suggesting that the third unit of CP led to the re-emergence of this population under renewed positive selection. In further support of our proposed idea of competition, noted above, frequencies of these two variants appeared to mirror changes in the NSP2 I513T mutation (Figure 2), suggesting these as markers of opposing clades in the viral population. Ct values remained low throughout this period with hyperinflammation, eventually leading to multi-organ failure and death at day 102. The repeated increase in frequency of the viral population with CP therapy strongly supports the hypothesis that the deletion/mutation combination conferred selective advantage.

Spike mutants emerging post convalescent plasma impair neutralising antibody potency

Using lentiviral pseudotyping we generated wild type, H69/ V70 + D796H and single mutant Spike proteins in enveloped virions in order to measure neutralisation activity of CP against these viruses (Figure 4). This system has been shown to give generally similar results to replication competent virus^{8,9}. Spike protein from each mutant was detected in pelleted virions (Figure 4A). We also probed with an HIV-1 p24 antibody to monitor levels of lentiviral particle production (Figure 4A, Supplementary Figure 2). We then measured infectivity of the pseudoviruses, correcting for virus input using reverse transcriptase activity measurement, and found that H69/ V70 appeared to have two-fold higher infectivity over

a single round of infection compared to wild type (Figure 4B, Extended data 7). By contrast, the D796H single mutant had significantly lower infectivity as compared to wild type and double mutant had similar infectivity to wild type (Figure 4B, Extended data 7).

We found that D796H alone and the D796H + H69/ V70 double mutant were less sensitive to neutralisation by convalescent plasma samples (Figure 4C-E, Extended data 7). By contrast the H69/ V70 single mutant did not reduce neutralisation sensitivity. In addition, patient derived serum from days 64 and 66 (one day either side of CP2 infusion) similarly showed lower potency against the D796H + H69/ V70 mutants (Figure 4F, G).

A panel of nineteen monoclonal antibodies (mAbs) isolated from three donors was previously identified to neutralize SARS-CoV-2. To establish if the mutations incurring *in vivo* (D796H and H69/ V70) resulted in a global change in neutralization sensitivity we tested neutralising mAbs targeting the seven major epitope clusters previously described (excluding non-neutralising clusters II, V and small [$n \leq 2$] neutralising clusters IV, X). The eight RBD-specific mAbs (Extended data 8) exhibited no major change in neutralisation potency and non-RBD specific COVA1-21 showing 3-5 fold reduction in potency against H69/ V70+D796H and H69/ V70, but not D796H alone⁹ (Extended data 8). We observed no differences in neutralisation between single/double mutants and wild type, suggesting that the mechanism of escape was likely outside these epitopes in the RBD. These data confirm the specificity of the findings from convalescent plasma and suggest that mutations observed are related to antibodies targeting regions outside the RBD. Interestingly, H69/ V70 containing viruses showed reduced neutralisation sensitivity to the mAb COVA1-21, targeting an as yet undefined epitope outside the RBD.¹⁰

To understand how the H69/ V70 and D796H might confer antibody resistance, we assessed how they might affect the Spike structure (Extended data 9). We based this analysis primarily on a structure lacking stabilising modifications (PDB 6xr8)¹¹, but also referred to stabilised structures determined at different pH values¹². H69/ V70 is located in a disordered, glycosylated loop at the distal surface of the NTD, near the binding site of polyclonal antibodies derived from COV57 plasma^{13,14} (Extended data 9). As this loop is flexible and highly accessible, H69/V70 could in principle affect antibody binding in this region. D796 is located near the base of Spike, in a surface loop that is structurally somewhat disordered in the prefusion conformation and becomes part of a large disordered region in the post fusion S2 trimer¹¹ (Extended data 9). The loop containing residue 796 is proposed to be targeted by antibodies¹⁵, despite mutations at position 796 being relatively uncommon (Extended data 9). In the RBD-down Spike structures^{11,12}, D796 forms contacts with residues in the neighbouring protomer, including the glycosylated residue N709 (Extended data 9).

Discussion

Here we have documented a repeated evolutionary response by SARS-CoV-2 in the presence of antibody therapy during the course of a persistent infection in an immunocompromised host. The observation of potential selection for specific variants coinciding with the presence of antibodies from convalescent plasma is supported by the experimental finding of two-fold

reduced susceptibility of these viruses to convalescent plasma containing polyclonal antibodies. In this case the emergence of the variant was not the primary reason for treatment failure. We have noted in our analysis signs of compartmentalised viral replication based on the sequences recovered in upper respiratory tract samples. Both population genetic and small animal studies have shown a lack of reassortment between influenza viruses within a single host during an infection, suggesting that acute respiratory viral infection may be characterised by spatially distinct viral populations^{16,17}. In the analysis of data, it is important to distinguish genetic changes which occur in the primary viral population from apparent changes that arise from the stochastic observation of spatially distinct subpopulations in the host. While the samples we observe on days 93 and 95 of infection are genetically distinct from the others, the remaining samples are consistent with arising from a consistent viral population. We note that Choi et al reported the detection in post-mortem tissue of viral RNA not only in lung tissue, but also in the spleen, liver, and heart⁴. Mixing of virus from different compartments, for example via blood, or movement of secretions from lower to upper respiratory tract, could lead to fluctuations in viral populations at particular sampling sites.

This is a single case report and therefore limited conclusions can be drawn about generalisability.

An important limitation is that the data were derived from sampling from the upper respiratory tract and not the lower tract, thus limiting the inferences that can be drawn regarding viral populations in this single case.

In addition to documenting the emergence of SARS-CoV-2 Spike H69/ V70 *in vivo*, we show that this mutation modestly increases infectivity of the Spike protein in a pseudotyping assay. The deletion was observed contemporaneously with the rare S2 mutation D796H after two separate courses of CP, with other viral populations emerging. D796H, but not H69/ V70, conferred reduction in susceptibility to polyclonal antibodies in the units of CP administered, though we cannot speculate as to their individual impacts on sera from other individuals. It is intriguing that the H69/ V70 + D796H double mutant diminished in between CP courses, suggesting that there were other selective forces at play in the intervening period, possibly driven by the inflammation observed in the individual. This includes the possibility that the haplotype with H69/ V70 + D796H may have carried mutations in other regions deleterious during that intervening period. Although H69/V70 is expanding at a high rate¹⁸, D796 mutations are also increasing. D796H has been documented in 0.02% of global sequences and D796Y appears in 0.05% of global sequences (Extended data 9).

The effects of CP on virus evolution seen here are unlikely to apply in immune competent hosts where viral diversity is likely to be lower due to better immune control. Our data highlight that infection control measures may need to be tailored to the needs of immunocompromised patients and also caution in interpretation of CDC guidelines that recommend 20 days as the upper limit of infection prevention precautions in immune compromised patients who are afebrile¹⁹. Due to the difficulty with culturing clinical isolates, use of surrogates are warranted²⁰. However, where detection of ongoing viral

evolution is possible, this serves as a clear proxy for the existence of infectious virus. In our case we detected environmental contamination whilst in a single occupancy room and the patient was moved to a negative-pressure high air-change infectious disease isolation room.

Clinical efficacy of convalescent plasma in severe COVID-19 has not been demonstrated²¹, and its use in different stages of infection and disease remains experimental; as such, we suggest that it should be reserved for use within clinical trials, with rigorous monitoring of clinical and virological parameters. The data from this single case report might warrant caution in use of convalescent plasma in patients with immune suppression of both T cell and B cell arms; in such cases, the antibodies administered have little support from cytotoxic T cells, thereby reducing chances of clearance and theoretically raising the potential for escape mutations. Whilst we await further data, where clinical trial enrolment is not possible, convalescent plasma administered for clinical need in immune suppression should ideally only be considered as part of observational studies, undertaken preferably in single occupancy rooms with enhanced infection control precautions, including SARS-CoV-2 environmental sampling and real-time sequencing. Understanding of viral dynamics and characterisation of viral evolution in response to different selection pressures in the immunocompromised host is necessary not only for improved patient management but also for public health benefit.

Methods

Clinical Sample Collection and Next generation sequencing

Serial samples were collected from the patient periodically from the lower respiratory tract (sputum or endotracheal aspirate), upper respiratory tract (throat and nasal swab), and from stool. Nucleic acid extraction was done from 500µl of sample with a dilution of MS2 bacteriophage to act as an internal control, using the easyMAG platform (Biomerieux, Marcy-l'Étoile) according to the manufacturers' instructions. All samples were tested for presence of SARS-CoV-2 with a validated one-step RT q-PCR assay developed in conjunction with the Public Health England Clinical Microbiology²². Amplification reaction were all performed on a Rotorgene™ PCR instrument. Samples which generated a CT of 36 were considered to be positive.

Sera from recovered patients in the COVIDx study²³ were used for testing of neutralisation activity by SARS-CoV-2 mutants.

SARS-CoV-2 serology by multiplex particle-based flow cytometry (Luminex)

Recombinant SARS-CoV-2 N, S and RBD were covalently coupled to distinct carboxylated bead sets (Luminex; Netherlands) to form a 3-plex and analyzed as previously described (Xiong et al. 2020). Specific binding was reported as mean fluorescence intensities (MFI).

Whole blood T cell and innate stimulation assay

Whole blood was diluted 1:5 in RPMI into 96-well F plates (Corning) and activated by single stimulation with phytohemagglutinin (PHA; 10 µg/ml; Sigma-Aldrich), or LPS (1 µg/ml, List Biochemicals) or by co-stimulating with anti-CD3 (MEM57, Abcam, 200 ng/ml,

1:1000) and IL-2 (Immunotools, 1430U/ml, 1:1000). Supernatants were taken after 24 hours. Levels (pg/ml) are shown for IFN γ , IL17, IL2, TNF α , IL6, IL1 β and IL10. Cytokines were measured by multiplexed particle based Flow cytometry on a Luminex analyzer (Bio-Plex, Bio-Rad, UK) using an R&D Systems custom kit (R&D Systems, UK).

For viral genomic sequencing, total RNA was extracted from samples as described. Samples were sequenced using MinION flow cells version 9.4.1 (Oxford Nanopore Technologies) following the ARTICnetwork V3 protocol (<https://dx.doi.org/10.17504/protocols.io.bbmuik6w>) and BAM files assembled using the ARTICnetwork assembly pipeline (<https://artic.network/ncov-2019/ncov2019-bioinformatics-sop.html>). A representative set of 10 sequences were selected and also sequenced using the Illumina MiSeq platform. Amplicons were diluted to 2 ng/ μ l and 25 μ l (50 ng) were used as input for each library preparation reaction. The library preparation used KAPA Hyper Prep kit (Roche) according to manufacturer's instructions. Briefly, amplicons were end-repaired and had A-overhang added; these were then ligated with 15mM of NEXTflex DNA Barcodes (Bio Scientific, Texas, USA). Post-ligation products were cleaned using AMPure beads and eluted in 25 μ l. Then, 20 μ l were used for library amplification by 5 cycles of PCR. For the negative controls, 1ng was used for ligation-based library preparation. All libraries were assayed using TapeStation (Agilent Technologies, California, USA) to assess fragment size and quantified by QPCR. All libraries were then pooled in equimolar accordingly. Libraries were loaded at 15nM and spiked in 5% PhiX (Illumina, California, USA) and sequenced on one MiSeq 500 cycle using a Miseq Nano v2 with 2x 250 paired-end sequencing. A minimum of ten reads were required for a variant call.

Bioinformatics Processes

For long-read sequencing, genomes were assembled with reference-based assembly and a curated bioinformatics pipeline with 20x minimum coverage across the whole-genome²⁴. For short-read sequencing, FASTQs were downloaded, poor-quality reads were identified and removed, and both Illumina and PHiX adapters were removed using TrimGalore v0.6.6²⁵. Trimmed paired-end reads were mapped to the National Center for Biotechnology Information SARS-CoV-2 reference sequence MN908947.3 using MiniMap2-2.17 with arguments -ax and sr²⁶. BAM files were then sorted and indexed with samtools v1.11 and PCR optical duplicates removed using Picard (<http://broadinstitute.github.io/picard>). A consensus sequences of nucleic acids with a minimum whole-genome coverage of at least 20 \times were generated with BCFtools using a 0% majority threshold.

Variant calling

Variant frequencies were validated using custom code as part of the *AnCovMulti* package (github.com/PollockLaboratory/AnCovMulti). The main idea behind this validation was to identify and remove consistent potential amplification errors and mutability near the end of Illumina reads. Furthermore, stringent filtering was applied to remove biased amplification of early laboratory-induced mutations or very low copy variations.

Filtering consisted of requiring exact initiation at a primer within two bp of the start of a read, a minimum of 247 bp length read, fewer than four well-separated sites divergent from

the reference sequence, a maximum insertion size of three nucleotides, a maximum deletion size of 11 bp, and resolution of conflicting signal from different primers.

Single Genome Amplification and sequencing

Viral RNA extracts were reverse transcribed from each sample to sufficiently capture the diversity of the viral population without introducing resampling bias. SuperScript IV (ThermoFisher Scientific) and the gene specific primers were used for reverse transcription. Template RNA was degraded with RNase H (ThermoFisher Scientific). All primers used were 'in-house' primers designed using the multiple sequence alignment of the patient's consensus NGS sequences. Partial Spike (amino acids 21-800) was amplified as 1 continuous length of DNA (Spike ~ 1.8 kb) by nested PCR. Terminally diluted cDNA was PCR-amplified using Platinum® Taq DNA Polymerase High Fidelity (Invitrogen, Carlsbad, CA) so that 30% of reactions were positive²⁷. By Poisson statistics, sequences were deemed 80% likely to be derived from HIV-1 single genomes. We obtained between 20–60 single genomes at each sample time point to achieve 90% confidence of detecting variants present at 8% of the viral population in vivo^{28,29}. Partial spike amplicons obtained from terminal dilution PCR amplification were Sanger sequenced to form a contiguous sequence using another set of 8 in-house primers. Sanger sequencing was provided by Genewiz UK and manual sequence editing was performed using DNA Dynamo software (Blue Tractor Software Ltd, UK).

Phylogenetic Analysis

All available full-genome SARS-CoV-2 sequences were downloaded from the GISAID database (<http://gisaid.org/>)³⁰ on 16th December. Duplicate and low-quality sequences (>5% N regions) were removed, leaving a dataset of 212,297 sequences with a length of >29,000bp. All sequences were sorted by name and only sequences sequenced with United Kingdom / England identifiers were retained. From this dataset, sequences were de-duplicated and where background sequences were required in figures, randomly subsampled using seqtk (<https://github.com/lh3/seqtk>). All sequences were aligned to the SARS-CoV-2 reference strain MN908947.3, using MAFFT v7.475 with automatic flavour selection³¹. Major SARS-CoV-2 clade memberships were assigned to all sequences using both the Nextclade server v0.9 (<https://clades.nextstrain.org/>) and Phylogenetic Assignment Of Named Global Outbreak Lineages (pangolin)³².

Maximum likelihood phylogenetic trees were produced using the above curated dataset using IQ-TREE v2.1.2³³. Evolutionary model selection for trees were inferred using ModelFinder³⁴ and trees were estimated using the GTR+F+I model with 1000 ultrafast bootstrap replicates³⁵. All trees were visualised with Figtree v.1.4.4 (<http://tree.bio.ed.ac.uk/software/figtree/>), rooted on the SARS-CoV-2 reference sequence and nodes arranged in descending order. Nodes with bootstraps values of <50 were collapsed using an in-house script.

In-depth allele frequency variant calling

The SAMFIRE package version 1.06³⁶ was used to call allele frequency trajectories from BAM file data. Reads were included in this analysis if they had a median PHRED score of at

least 30, trimming the ends of reads to achieve this if necessary. Nucleotides were then filtered to have a PHRED score of at least 30; reads with fewer than 30 such reads were discarded. Distances between sequences, accounting for low-frequency variant information, was also conducted using SAMFIRE. The sequence distance metric, described in an earlier paper³⁷, combines allele frequencies across the whole genome. Where L is the length of the genome, we define $q(t)$ as a $4 \times L$ element vector describing the frequencies of each of the nucleotides A, C, G, and T at each locus in the viral genome sampled at time t . For any given locus i in the genome we calculate the change in allele frequencies between the times t_1 and t_2 via a generalisation of the Hamming distance

$$d(q_i(t_1), q_i(t_2)) = \frac{1}{2} \sum_{a \in \{A, C, G, T\}} |q_i^a(t_1) - q_i^a(t_2)|$$

where the vertical lines indicate the absolute value of the difference. These statistics were then combined across the genome to generate the pairwise sequence distance metric

$$D(q(t_1), q(t_2)) = \sum_i d(q_i(t_1), q_i(t_2))$$

The Mathematica software package was used to conduct a regression analysis of pairwise sequence distances against time, leading to an estimate of a mean rate of within-host sequence evolution. In contrast to the phylogenetic analysis, this approach assumed the samples collected on days 93 and 95 to arise via stochastic emission from a spatially separated subpopulation within the host, leading to a lower inferred rate of viral evolution for the bulk of the viral population.

All variants were independently validated using custom code as part of the AnCovMulti package, found at <https://github.com/PollockLaboratory/AnCovMulti>.

Western blot analysis

Forty-eight hours after transfection of cells with plasmid preparations, the culture supernatant was harvested and passed through a 0.45- μ m-pore-size filter to remove cellular debris. The filtrate was centrifuged at 15,000 rpm for 120 min to pellet virions. The pelleted virions were lysed in Laemmli reducing buffer (1 M Tris-HCl [pH 6.8], SDS, 100% glycerol, β -mercaptoethanol, and bromophenol blue). Pelleted virions were subjected to electrophoresis on SDS–4 to 12% bis-Tris protein gels (Thermo Fisher Scientific) under reducing conditions. This was followed by electroblotting onto polyvinylidene difluoride (PVDF) membranes. The SARS-CoV-2 Spike proteins were visualized by a ChemiDoc^{MP} imaging system (Biorad) using anti-Spike S2 (Invitrogen at 1:1000 dilution) and anti-p24 Gag antibodies (NIH AIDS Reagents 1:1000 dilution).

Recombination Detection

All sequences were tested for potential recombination, as this would impact on evolutionary estimates. Potential recombination events were explored with nine algorithms (RDP, MaxChi, SisScan, GeneConv, Bootscan, PhylPro, Chimera, LARD and 3SEQ), implemented

in RDP5 with default settings³⁸. To corroborate any findings, ClonalFrameML v1.12³⁹ was also used to infer recombination breakpoints. Neither programs indicated evidence of recombination in our data.

Structural Viewing

The Pymol Molecular Graphics System v2.4.0 (<https://github.com/schrodinger/pymol-open-source/releases>) was used to map the location of the four spike mutations of interest onto a SARS-CoV-2 spike structure visualised by Wrobel et al (PDB: 6ZGE)⁴⁰.

Testing of convalescent plasma for antibody titres

The Anti-SARS-CoV-2 ELISA (IgG) assay used to test CP for *antibody titres* was Euroimmun Medizinische Labordiagnostika AG. This indirect ELISA based assay uses a recombinant structural spike 1 (S1) protein of SARS-CoV-2 expressed in the human cell line HEK 293 for the detection of SARS-CoV2 IgG.

Generation of Spike mutants

Amino acid substitutions were introduced into the D614G pCDNA_SARS-CoV-2_Spike plasmid as previously described⁴¹ using the QuikChange Lightning Site-Directed Mutagenesis kit, following the manufacturer's instructions (Agilent Technologies, Inc., Santa Clara, CA).

Pseudotype virus preparation

Viral vectors were prepared by transfection of 293T cells by using Fugene HD transfection reagent (Promega). 293T cells were transfected with a mixture of 11ul of Fugene HD, 1µg of pCDNAp19Spike-HA, 1ug of p8.91 HIV-1 gag-pol expression vector^{42,43}, and 1.5µg of pCSFLW (expressing the firefly luciferase reporter gene with the HIV-1 packaging signal). Viral supernatant was collected at 48 and 72h after transfection, filtered through 0.45um filter and stored at -8°C. The 50% tissue culture infectious dose (TCID50) of SARS-CoV-2 pseudovirus was determined using Steady-Glo Luciferase assay system (Promega).

Standardisation of virus input by SYBR Green-based product-enhanced PCR assay (SG-PERT)

The reverse transcriptase activity of virus preparations was determined by qPCR using a SYBR Green-based product-enhanced PCR assay (SG-PERT) as previously described⁴⁴. Briefly, 10-fold dilutions of virus supernatant were lysed in a 1:1 ratio in a 2x lysis solution (made up of 40% glycerol v/v 0.25% Triton X-100 v/v 100mM KCl, RNase inhibitor 0.8 U/ml, TrisHCL 100mM, buffered to pH7.4) for 10 minutes at room temperature.

12µl of each sample lysate was added to thirteen 13µl of a SYBR Green master mix (containing 0.5µM of MS2-RNA Fwd and Rev primers, 3.5pmol/ml of MS2-RNA, and 0.125U/µl of Ribolock RNase inhibitor and cycled in a QuantStudio. Relative amounts of reverse transcriptase activity were determined as the rate of transcription of bacteriophage MS2 RNA, with absolute RT activity calculated by comparing the relative amounts of RT to an RT standard of known activity.

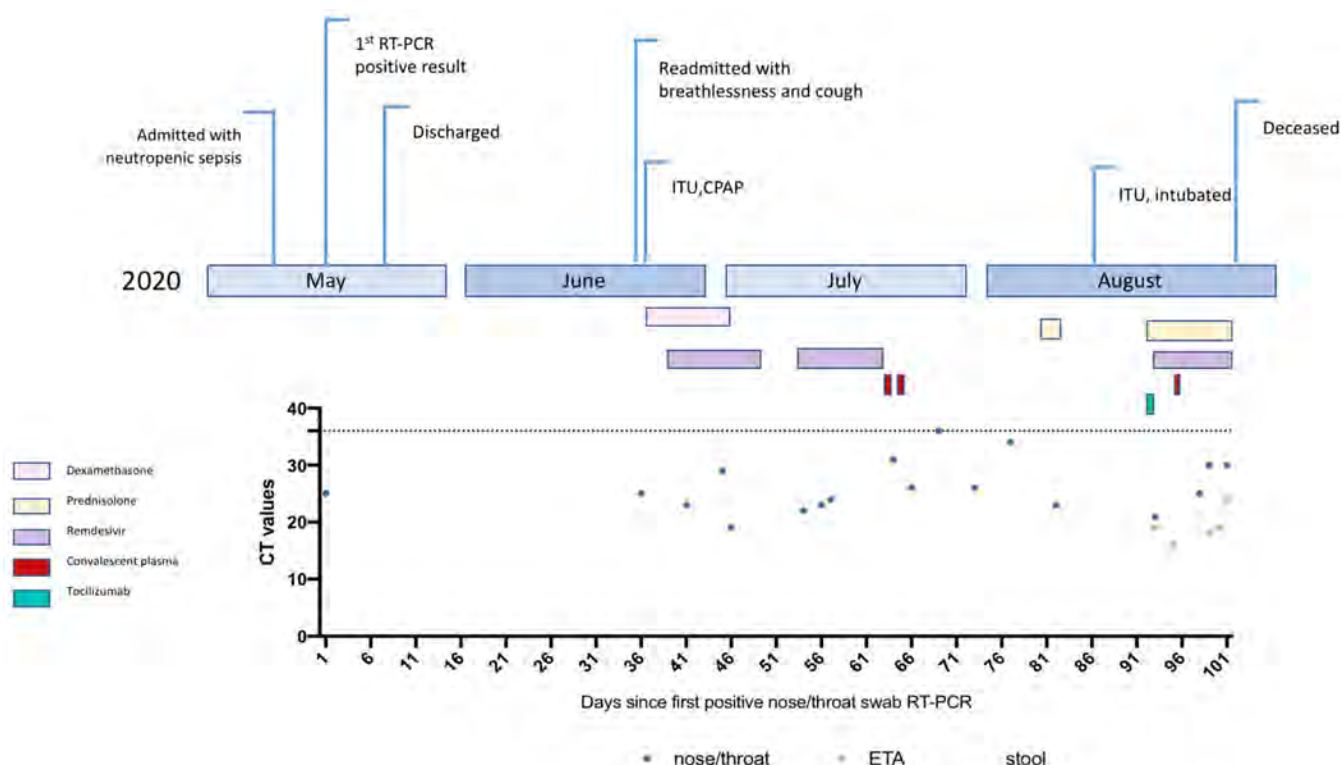

Serum/plasma pseudotype neutralization assay

Spike pseudotype assays have been shown to have similar characteristics as neutralisation testing using fully infectious wild type SARS-CoV-2⁸. Virus neutralisation assays were performed on 293T cell transiently transfected with ACE2 and TMPRSS2 using SARS-CoV-2 Spike pseudotyped virus expressing luciferase⁴⁵. Pseudotyped virus was incubated with serial dilution of heat inactivated human serum samples or convalescent plasma in duplicate for 1h at 37°C. Virus and cell only controls were also included. Then, freshly trypsinized 293T ACE2/TMPRSS2 expressing cells were added to each well. Following 48h incubation in a 5% CO₂ environment at 37°C, the luminescence was measured using Steady-Glo Luciferase assay system (Promega).

mAb pseudotype neutralisation assay

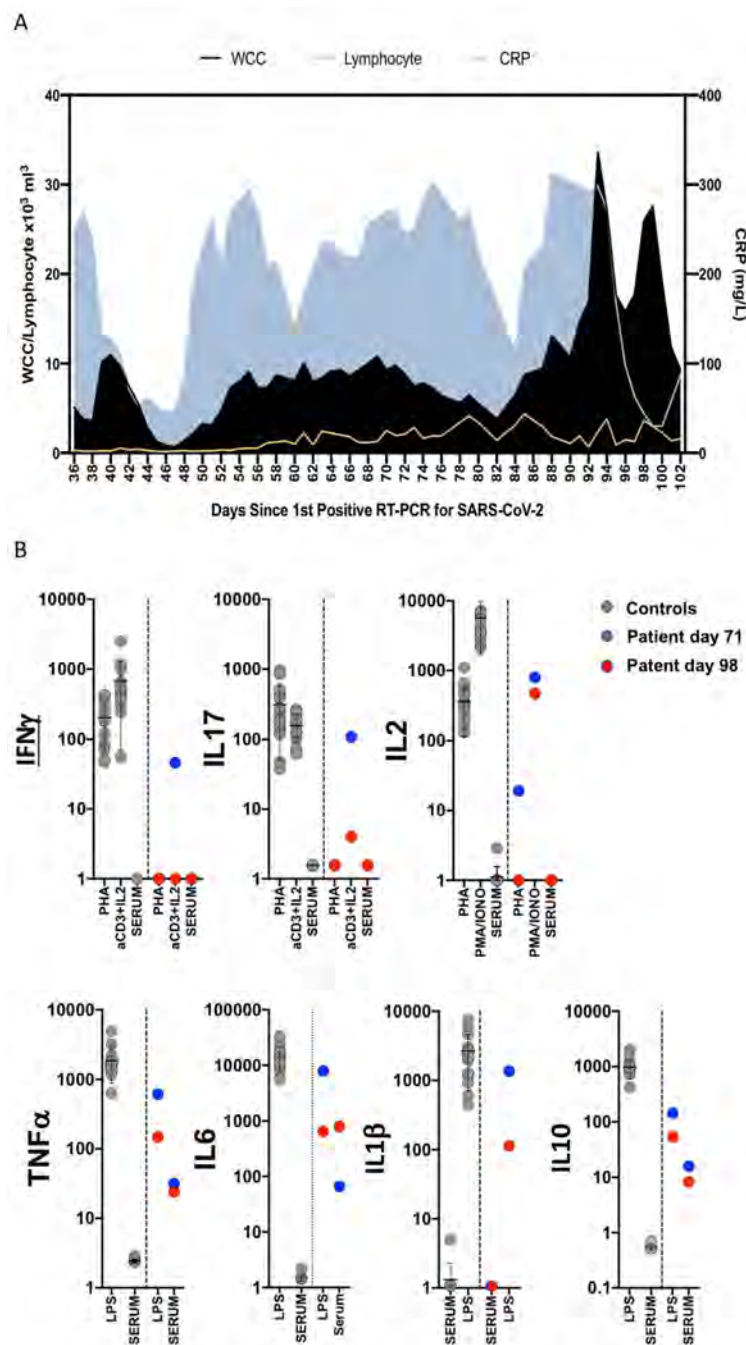

Virus neutralisation assays were performed on HeLa cells stably expressing ACE2 and using SARS-CoV-2 Spike pseudotyped virus expressing luciferase as previously described⁴⁶. Pseudotyped virus was incubated with serial dilution of purified mAbs⁹ in duplicate for 1h at 37°C. Then, freshly trypsinized HeLa ACE2-expressing cells were added to each well. Following 48h incubation in a 5% CO₂ environment at 37°C, the luminescence was measured using Bright-Glo Luciferase assay system (Promega) and neutralization calculated relative to virus only controls. IC₅₀ values were calculated in GraphPad Prism.

Extended Data

Extended Data Figure 1.

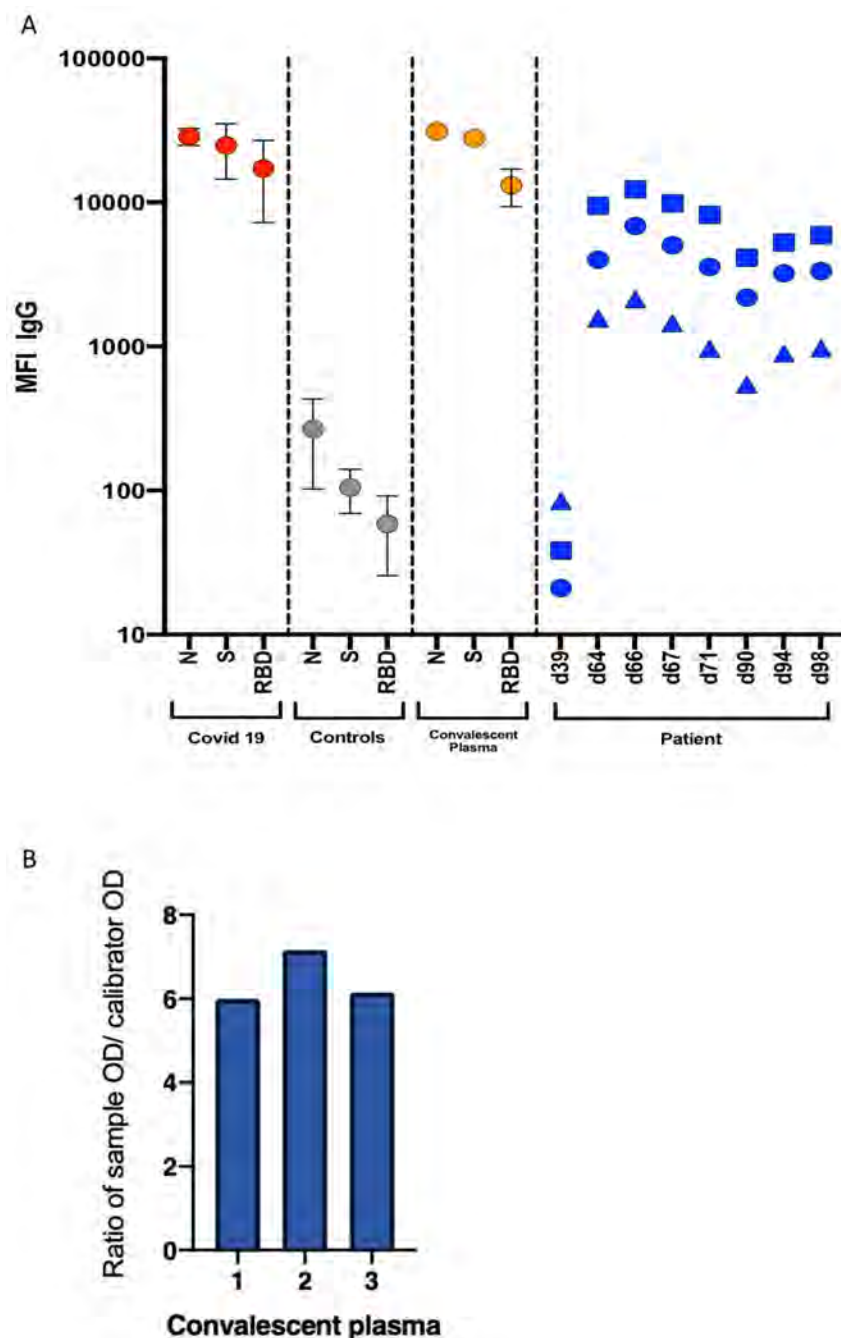

Clinical time line of events with longitudinal respiratory sample CT values. CT – cycle threshold.

Extended data 2.

A. Blood parameters over time in patient case: White cell count (WCC) and lymphocyte counts are expressed as $\times 10^3 \text{ Cells/mm}^3$. CRP: C reactive protein. **B. Assessment of T cell and innate function.** Whole blood cytokines were measured in whole blood after 24 hours stimulation either after T-cell stimulation with PHA or anti CD3/IL2 or innate stimulation

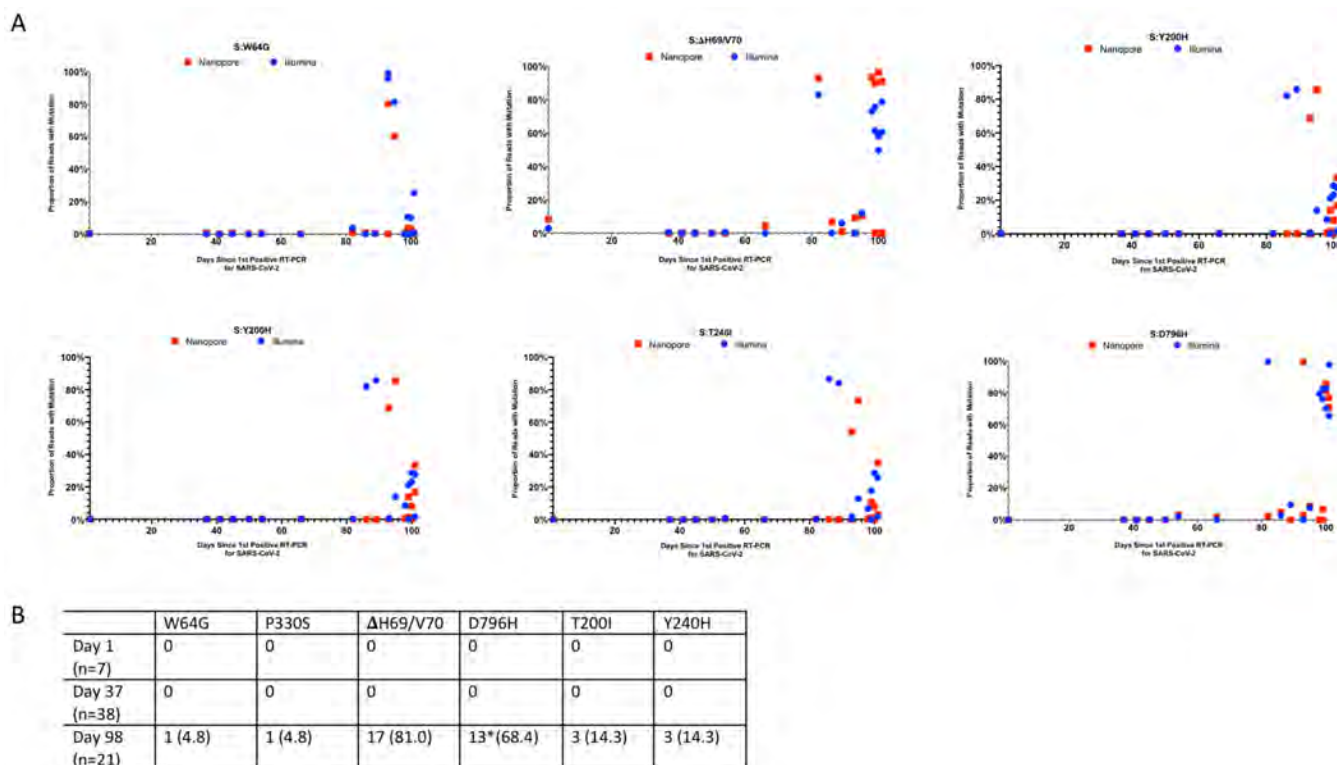

with LPS. Healthy controls are shown as grey circles (N=15), Patient at d71 and d98 is shown as blue circles or red circles respectively. Cytokine levels are shown as pg/ml stimulation. Mean is shown by line and whiskers representing standard deviation.

Extended Data Figure 3.

A. Serum SARS-CoV-2 antibody levels and virus population changes in chronic SARS-CoV-2 infection. Anti SARS-CoV2 IgG antibodies in patient and pre/post convalescent plasma compared to RNA+ Covid19 patients and pre-pandemic healthy controls: Red,

grey and gold: IgG antibodies to SARS-CoV2 nucleocapsid protein (N), trimeric S protein (S) and the receptor binding domain (RBD) were measured by multiplexed particle based flow cytometry (Luminex) in RNA+ COVID-19 patients (N=20, red dots), Pre-pandemic healthy controls (N=20, grey dots) and in the convalescent donor plasma (orange dots); Results are shown as mean fluorescent intensity (MFI) +/- SD. **Patient sera over time in blue:** Anti SARS-CoV2 IgG to N (blue squares), S (blue circles) and RBD (blue triangles). Timing of CP units is also shown. **B. SARS-CoV-2 antibody titres in patient and in convalescent plasma.** Measurement of SARS-CoV-2 specific IgG antibody titres in three units of convalescent plasma (CP) by Euroimmun assay.

Extended data 4. Comparison between short-read (Illumina) and long-read single molecule (Oxford Nanopore) sequencing methods for the six observed Spike mutations.

Concordance was generally good between the majority of timepoints, however due to large discrepancies in a number of timepoints, we suggest that due to the high base calling error rate, Nanopore is not yet suitable for calling minority variants. As such, all figures in the main paper were produced using Illumina data only. **B. Single genome sequencing (SGS) data from respiratory samples at indicated days.** Indicated are the number of single genomes obtained at each time point with the mutations of interest (identified by deep sequencing). *denominator is 19 as for 2 samples the primer reads were poor quality at amino acid 796 at day 98. Amino acid variant and corresponding nucleotide position: S:W64G = 21752, S: 69 = 21765-21770, S:Y200H = 22160, S:T240I = 22281, S:P330S = 22550, S:D795H = 23948

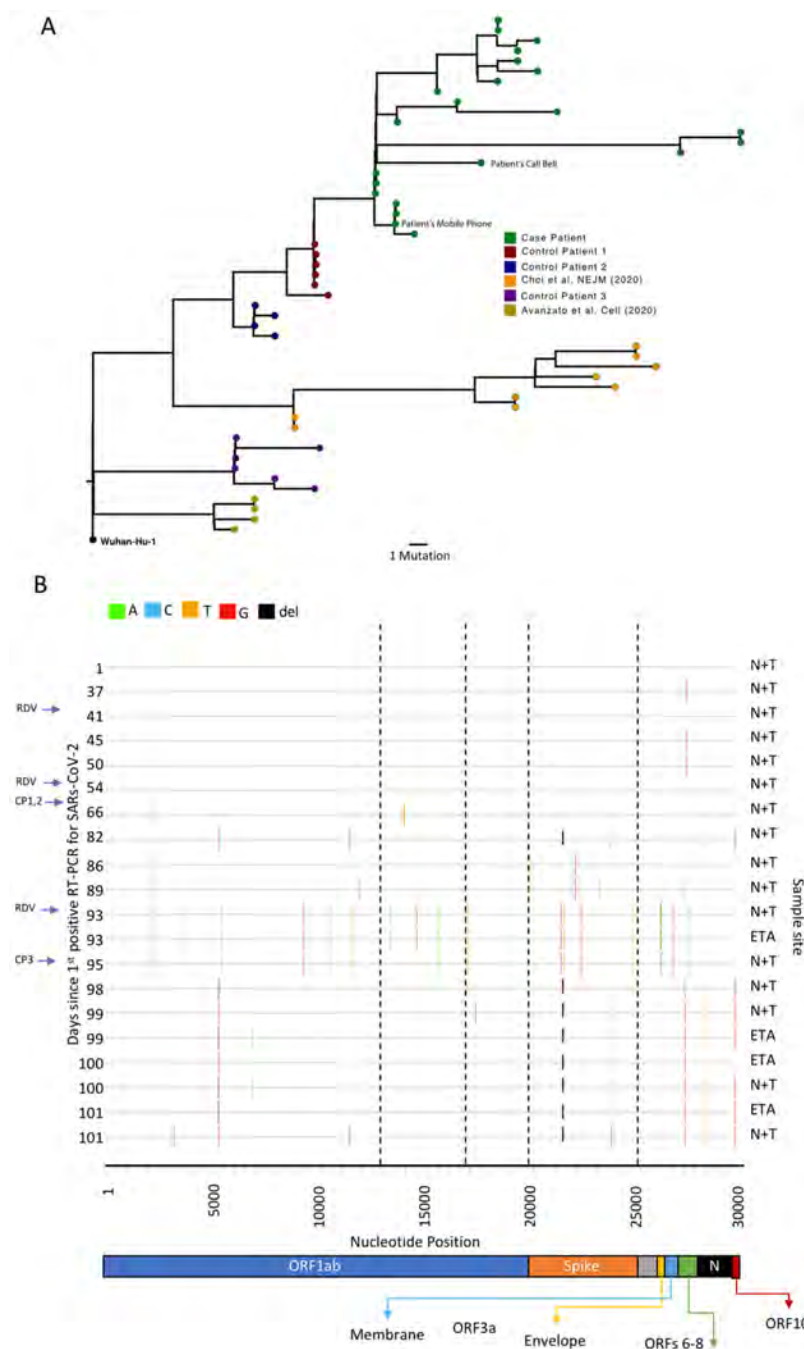

Extended Data Figure 5. Evidence for within-host cladal structure.

A. Pairwise distances between samples measured using the all-locus distance metric plotted against pairwise distances in time (measured in days) between samples being collected.

Internal distances between samples in the proposed main clade are shown in black, distances between samples in the main clade and samples collected on days 93 and 95 are shown in red, and internal distances between samples collected on days 93 and 95 are shown in green.

B. Pairwise distances between samples in the larger clade (black) and between these samples and those collected on days 93 and 95 (red). The median values of the distributions of these values are significantly different according to a Mann Whitney test. **C.** Pairwise distances between samples in the main clade, once those collected on days 86, 89, 93, 95 have been removed (black) and between these samples and those collected on days 86 and 89 (red).

The median values of the distributions of these values are not significantly different at the 5 level according to a Mann Whitney test.

Extended Data Figure 6.

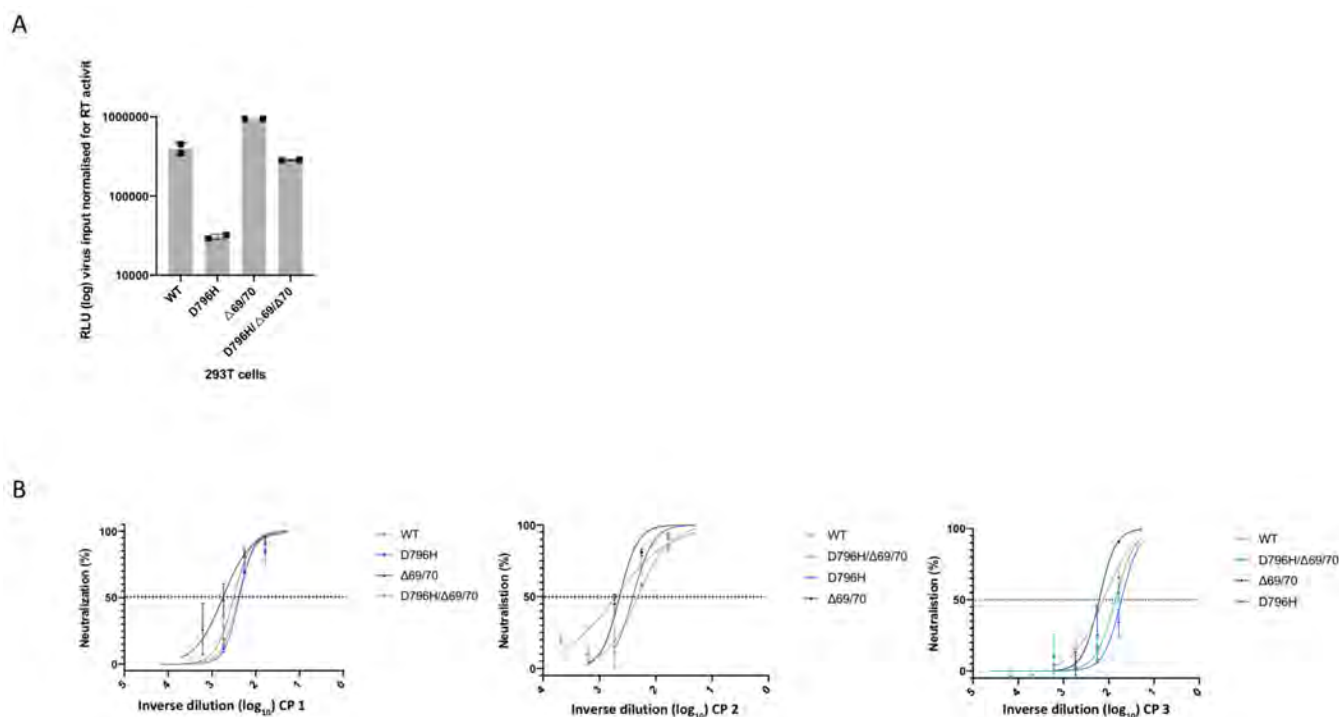

A. Close-view maximum-likelihood phylogenetic tree indicating the diversity of the case patient and three other long-term shedders from the local area (red, blue and purple), compared to recently published sequences from Choi et al (orange) and Avanzato et al (gold). Control patients generally showed limited diversity temporally, though the Choi et al sequences were highly divergent. Environmental samples (patient's call bell, and patient's mobile phone) are indicated. Tree branched have been collapsed where bootstrap support was <60.

B. Highlighter plot indicating nucleotide changes at consensus level in sequential respiratory samples compared to the consensus sequence at first diagnosis of COVID-19. Each row indicates the timepoint the sample was collected (number of days from first positive SARS-CoV-2 RT-PCR). Black dashed lines indicate the RNA-dependent RNA polymerase (RdRp) and Spike regions of the genome. There were few nucleotide substitutions between days 1-54, despite the patient receiving two courses of remdesivir. The first major changes in the spike genome occurred on day 82, following convalescent plasma given on days 63 and 65. The amino acid deletion in S1, H69/V70 is indicated by the black lines. Sites: Endotracheal aspirate (ETA) or Nose/throat swabs (N+T).

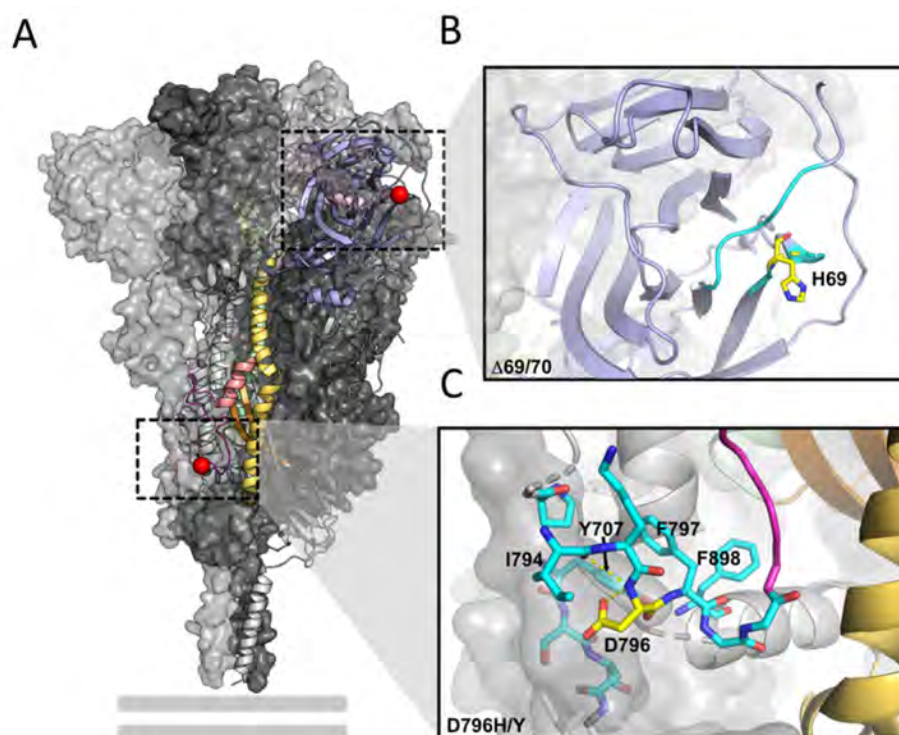

Extended Data 7. In vitro infectivity and neutralisation sensitivity of Spike pseudotyped lentiviruses.

A. infection of target 293T cells expressing TMPRSS2 and ACE2 receptors using equal amounts of virus as determined by reverse transcriptase activity. Data points represent technical replicates (n=2), with mean shown with error bars representing standard deviation. Data are representative of n=2 independent experiments (n=2). **B.** Representative Inverse dilution plots for Spike variants against convalescent plasma units 1-3. Data points represent mean neutralisation of technical replicates and error bars represent standard error of the mean of replicates. Data are representative of two independent experiments (n=2).

Extended Data Figure 8.

A. Neutralization potency of a panel of monoclonal antibodies targeting the RBD is not impacted by Spike mutations D796H or H69/V70. Lentivirus pseudotyped with SARS-CoV-2 Spike protein: WT (D614G background), D796H, H69/V70, D796H+ H69/V70 were produced in 293T cells and used to infect target Hela cells stably expressing ACE2 in the presence of serial dilutions of indicated monoclonal antibodies. Data are means of technical replicates with error bars representing SD. Data are representative of at least two independent experiments. RBD: receptor binding domain. **B. Classes of RBD binding antibodies and fold changes for Spike mutations D796H or H69/V70** are indicated based Bouwer et al. Clusters II, V contain only non-neutralising mAbs, smaller neutralising mAb clusters IV (n=2) and X (n=1) were not tested. Red indicates significant fold changes.

Mutation	Number of Sequences	Global Prevalence (%)
W64G	0	0.00
Δ H69/V70	12883	4.32
Y200H	7	<0.01
T240I	77	0.02
P330S	167	0.06
D796H	65	0.02
D796Y	141	0.05

Extended Data 9. Location of Spike mutations H69/Y70 and D796H.

A. The SARS-CoV-2 spike trimer (PDB ID: 6xr8) with two protomers represented as surfaces and one protomer represented as a ribbon. The NTD is coloured in light blue, the RBD in light pink, the fusion peptide in dark pink, the HR1 domain in yellow, the CH domain in pale green, and the CD domain in brown. The location of D796 and H69 are indicated by red spheres. The loop connecting D796 to the fusion peptide is coloured magenta to improve visibility. The double grey lines provide orientation relative to the membrane. **B.** A close-up of the region defined by the box around H69 in panel A. H69 is highlighted in yellow. Residues containing atoms that are within 6 Å of H69 are highlighted in cyan. **C.** A close-up of the region defined by the box around D796 in panel A. D796 is

highlighted in yellow. Residues containing atoms that are within 6 Å of D796 are highlighted in cyan. Hydrogen bonds are indicated by dashed yellow lines. Hydrophobic residues in the vicinity of D796 have been labelled. Y707 is from the neighbouring protomer. **D. Global prevalence of selected spike mutations detailed in this paper.** All high coverage sequences were downloaded from the GISAID database on 6th January and aligned using MAFFT; as of this date there were 298254 sequences available. The global prevalence of each of the six spike mutations W64G, H69/V70, Y200H, T240I, P330S and D796H were assessed by viewing the multiple sequence alignment in AliView, sorting by the column of interest, and counting the number of mutations.

Samuel C Robson⁵⁴ [Funding acquisition, Leadership and supervision, Metadata curation, Project administration, Samples and logistics, Sequencing and analysis, Software and analysis tools, and Visualisation], Nicholas J Loman⁸², Thomas R Connor^{51,110} [Funding acquisition, Leadership and supervision, Metadata curation, Project administration, Samples and logistics, Sequencing and analysis, and Software and analysis tools], Tanya Golubchik⁴⁶ [Leadership and supervision, Metadata curation, Project administration, Samples and logistics, Sequencing and analysis, Software and analysis tools, and Visualisation], Rocio T Martinez Nunez⁸³ [Funding acquisition, Metadata curation, Samples and logistics, Sequencing and analysis, Software and analysis tools, and Visualisation], Catherine Ludden¹²⁹ [Funding acquisition, Leadership and supervision, Metadata curation, Project administration, and Samples and logistics], Sally Corden¹¹⁰ [Funding acquisition, Leadership and supervision, Metadata curation, Samples and logistics, and Sequencing and analysis], Ian Johnston¹⁴⁰, David Bonsall⁴⁶ [Funding acquisition, Leadership and supervision, Project administration, Samples and logistics, and Sequencing and analysis], Colin P Smith¹²⁸, Ali R Awan⁶⁹ [Funding acquisition, Leadership and supervision, Sequencing and analysis, Software and analysis tools, and Visualisation], Giselda Bucca¹²⁸ [Funding acquisition, Samples and logistics, Sequencing and analysis, Software and analysis tools, and Visualisation], M. Estee Torok^{63,142} [Leadership and supervision, Metadata curation, Project administration, Samples and logistics, and Sequencing and analysis], Kordo Saeed^{122,151} [Leadership and supervision, Metadata curation, Project administration, Samples and logistics, and Visualisation], Jacqui A Prieto^{124,150} [Leadership and supervision, Metadata curation, Project administration, Samples and logistics, and Visualisation], David K Jackson¹⁴⁰ [Leadership and supervision, Metadata curation, Project administration, Sequencing and analysis, and Software and analysis tools], William L Hamilton⁶³ [Metadata curation, Project administration, Samples and logistics, Sequencing and analysis, and Software and analysis tools], Luke B Snell⁵² [Metadata curation, Project administration, Samples and logistics, Sequencing and analysis, and Visualisation], Catherine Moore¹¹⁰ [Funding acquisition, Leadership and supervision, Metadata curation, and Samples and logistics], Ewan M Harrison^{129,140} [Funding acquisition, Leadership and supervision, Project administration, and Samples and logistics], Sonia Goncalves¹⁴⁰ [Leadership and supervision, Metadata curation, Project administration, and Samples and logistics], Derek J Fairley^{44,113} [Leadership and supervision, Metadata

curation, Samples and logistics, and Sequencing and analysis], Matthew W Loose⁵⁹ [Leadership and supervision, Metadata curation, Samples and logistics, and Sequencing and analysis], Joanne Watkins¹¹⁰ [Leadership and supervision, Metadata curation, Samples and logistics, and Sequencing and analysis], Rich Livett¹⁴⁰ [Leadership and supervision, Metadata curation, Samples and logistics, and Software and analysis tools], Samuel Moses^{66,147} [Leadership and supervision, Metadata curation, Samples and logistics, and Visualisation], Roberto Amato¹⁴⁰ [Leadership and supervision, Metadata curation, Sequencing and analysis, and Software and analysis tools], Sam Nicholls⁸² [Leadership and supervision, Metadata curation, Sequencing and analysis, and Software and analysis tools], Matthew Bull¹¹⁰ [Leadership and supervision, Metadata curation, Sequencing and analysis, and Software and analysis tools], Darren L Smith^{1,99,146} [Leadership and supervision, Project administration, Samples and logistics, and Sequencing and analysis], Jeff Barrett¹⁴⁰ [Leadership and supervision, Sequencing and analysis, Software and analysis tools, and Visualisation], David M Aanensen⁵⁵ [Leadership and supervision, Sequencing and analysis, Software and analysis tools, and Visualisation], Martin D Curran¹⁰⁶ [Metadata curation, Project administration, Samples and logistics, and Sequencing and analysis], Surendra Parmar¹⁰⁶ [Metadata curation, Project administration, Samples and logistics, and Sequencing and analysis], Dinesh Aggarwal^{1,140,105} [Metadata curation, Project administration, Samples and logistics, and Sequencing and analysis], James G Shepherd⁸⁹ [Metadata curation, Project administration, Samples and logistics, and Sequencing and analysis], Matthew D Parker¹³⁴ [Metadata curation, Project administration, Sequencing and analysis, and Software and analysis tools], Sharon Glaysher¹⁰² [Metadata curation, Samples and logistics, Sequencing and analysis, and Visualisation], Matthew Bashton^{78,99} [Metadata curation, Sequencing and analysis, Software and analysis tools, and Visualisation], Anthony P Underwood⁵⁵ [Metadata curation, Sequencing and analysis, Software and analysis tools, and Visualisation], Nicole Pacchiarini¹¹⁰ [Metadata curation, Sequencing and analysis, Software and analysis tools, and Visualisation], Katie F Loveson¹¹⁸ [Metadata curation, Sequencing and analysis, Software and analysis tools, and Visualisation], Alessandro M Carabelli¹²⁹ [Project administration, Sequencing and analysis, Software and analysis tools, and Visualisation], Kate E Templeton^{94,131} [Funding acquisition, Leadership and supervision, and Metadata curation], Cordelia F Langford¹⁴⁰ [Funding acquisition, Leadership and supervision, and Project administration], John Sillitoe¹⁴⁰ [Funding acquisition, Leadership and supervision, and Project administration], Thushan I de Silva¹³⁴ [Funding acquisition, Leadership and supervision, and Project administration], Dennis Wang¹³⁴ [Funding acquisition, Leadership and supervision, and Project administration], Dominic Kwiatkowski^{140,148} [Funding acquisition, Leadership and supervision, and Sequencing and analysis], Andrew Rambaut¹³¹ [Funding acquisition, Leadership and supervision, and Sequencing and analysis], Justin O'Grady^{111,130} [Funding acquisition, Leadership and

supervision, and Sequencing and analysis], Simon Cottrell¹¹⁰ [Funding acquisition, Leadership and supervision, and Sequencing and analysis], Matthew T.G. Holden¹⁰⁹ [Leadership and supervision, Metadata curation, and Sequencing and analysis], Emma C Thomson⁸⁹ [Leadership and supervision, Metadata curation, and Sequencing and analysis], Husam Osman^{77,105} [Leadership and supervision, Project administration, and Samples and logistics], Monique Andersson¹⁰⁰ [Leadership and supervision, Project administration, and Samples and logistics], Anoop J Chauhan¹⁰² [Leadership and supervision, Project administration, and Samples and logistics], Mohammed O Hassan-Ibrahim⁴⁷ [Leadership and supervision, Project administration, and Samples and logistics], Mara Lawniczak¹⁴⁰ [Leadership and supervision, Project administration, and Sequencing and analysis], Alex Alderton¹⁴⁰ [Leadership and supervision, Samples and logistics, and Sequencing and analysis], Meera Chand¹⁰⁷ [Leadership and supervision, Samples and logistics, and Sequencing and analysis], Chrystala Constantinidou¹³⁵ [Leadership and supervision, Samples and logistics, and Sequencing and analysis], Meera Unnikrishnan¹³⁵ [Leadership and supervision, Samples and logistics, and Sequencing and analysis], Alistair C Darby¹³³ [Leadership and supervision, Samples and logistics, and Sequencing and analysis], Julian A Hiscox¹³³ [Leadership and supervision, Samples and logistics, and Sequencing and analysis], Steve Paterson¹³³ [Leadership and supervision, Samples and logistics, and Sequencing and analysis], Inigo Martincorena¹⁴⁰ [Leadership and supervision, Sequencing and analysis, and Software and analysis tools], David L Robertson⁸⁹ [Leadership and supervision, Sequencing and analysis, and Software and analysis tools], Erik M Volz⁸⁰ [Leadership and supervision, Sequencing and analysis, and Software and analysis tools], Andrew J Page¹¹¹ [Leadership and supervision, Sequencing and analysis, and Software and analysis tools], Oliver G Pybus⁶⁴ [Leadership and supervision, Sequencing and analysis, and Software and analysis tools], Andrew R Bassett¹⁴⁰ [Leadership and supervision, Sequencing and analysis, and Visualisation], Cristina V Ariani¹⁴⁰ [Metadata curation, Project administration, and Samples and logistics], Michael H Spencer Chapman^{129,140} [Metadata curation, Project administration, and Samples and logistics], Kathy K Li⁸⁹ [Metadata curation, Project administration, and Samples and logistics], Rajiv N Shah⁸⁹ [Metadata curation, Project administration, and Samples and logistics], Natasha G Jesudason⁸⁹ [Metadata curation, Project administration, and Samples and logistics], Yusri Taha⁹¹ [Metadata curation, Project administration, and Samples and logistics], Martin P McHugh⁹⁴ [Metadata curation, Project administration, and Sequencing and analysis], Rebecca Dewar⁹⁴ [Metadata curation, Project administration, and Sequencing and analysis], Aminu S Jahun⁶⁵ [Metadata curation, Samples and logistics, and Sequencing and analysis], Claire McMurray⁸² [Metadata curation, Samples and logistics, and Sequencing and analysis], Sarojini Pandey¹²⁵ [Metadata curation, Samples and logistics, and Sequencing and analysis], James P McKenna⁴⁴ [Metadata

curation, Samples and logistics, and Sequencing and analysis], Andrew Nelson^{99,146} [Metadata curation, Samples and logistics, and Sequencing and analysis], Gregory R Young^{78,99} [Metadata curation, Samples and logistics, and Sequencing and analysis], Clare M McCann^{99,146} [Metadata curation, Samples and logistics, and Sequencing and analysis], Scott Elliott¹⁰² [Metadata curation, Samples and logistics, and Sequencing and analysis], Hannah Lowe⁶⁶ [Metadata curation, Samples and logistics, and Visualisation], Ben Temperton¹³² [Metadata curation, Sequencing and analysis, and Software and analysis tools], Sunando Roy¹²³ [Metadata curation, Sequencing and analysis, and Software and analysis tools], Anna Price⁵¹ [Metadata curation, Sequencing and analysis, and Software and analysis tools], Sara Rey¹¹⁰ [Metadata curation, Sequencing and analysis, and Software and analysis tools], Matthew Wyles¹³⁴ [Metadata curation, Sequencing and analysis, and Software and analysis tools], Stefan Rooke¹³¹ [Metadata curation, Sequencing and analysis, and Visualisation], Sharif Shaaban¹⁰⁹ [Metadata curation, Sequencing and analysis, and Visualisation], Mariateresa de Cesare¹³⁹ [Project administration, Samples and logistics, Sequencing and analysis], Laura Letchford¹⁴⁰ [Project administration, Samples and logistics, and Software and analysis tools], Siona Silveira¹²² [Project administration, Samples and logistics, and Visualisation], Emanuela Pelosi¹²² [Project administration, Samples and logistics, and Visualisation], Eleri Wilson-Davies¹²² [Project administration, Samples and logistics, and Visualisation], Myra Hosmillo⁶⁵ [Samples and logistics, Sequencing and analysis, and Software and analysis tools], Áine O'Toole¹³¹ [Sequencing and analysis, Software and analysis tools, and Visualisation], Andrew R Hesketh¹²⁸ [Sequencing and analysis, Software and analysis tools, and Visualisation], Richard Stark¹³⁵ [Sequencing and analysis, Software and analysis tools, and Visualisation], Louis du Plessis⁶⁴ [Sequencing and analysis, Software and analysis tools, and Visualisation], Chris Ruis¹²⁹ [Sequencing and analysis, Software and analysis tools, and Visualisation], Helen Adams⁴⁵ [Sequencing and analysis, Software and analysis tools, and Visualisation], Yann Bourgeois¹¹⁷ [Sequencing and analysis, Software and analysis tools, and Visualisation], Stephen L Michell¹³² [Funding acquisition, and Leadership and supervision], Dimitris Gramatopoulos^{125,153} [Funding acquisition, and Leadership and supervision], Jonathan Edgeworth⁵³ [Funding acquisition, and Leadership and supervision], Judith Breuer^{71,123} [Funding acquisition, and Leadership and supervision], John A Todd¹³⁹ [Funding acquisition, and Leadership and supervision], Christophe Fraser⁴⁶ [Funding acquisition, and Leadership and supervision], David Buck¹³⁹ [Funding acquisition, and Project administration], Michaela John⁵⁰ [Funding acquisition, and Project administration], Gemma L Kay¹¹¹ [Leadership and supervision, and Metadata curation], Steve Palmer¹⁴⁰ [Leadership and supervision, and Project administration], Sharon J Peacock^{129,105} [Leadership and supervision, and Project administration], David Heyburn¹¹⁰ [Leadership and supervision, and Project administration], Danni Weldon¹⁴⁰ [Leadership and supervision, and

Samples and logistics], Esther Robinson^{105,77} [Leadership and supervision, and Samples and logistics], Alan McNally^{82,127} [Leadership and supervision, and Samples and logistics], Peter Muir¹⁰⁵ [Leadership and supervision, and Samples and logistics], Ian B Vipond¹⁰⁵ [Leadership and supervision, and Samples and logistics], John BoYes⁷⁰ [Leadership and supervision, and Samples and logistics], Venkat Sivaprakasam⁸⁷ [Leadership and supervision, and Samples and logistics], Tranprit Salluja¹¹⁶ [Leadership and supervision, and Samples and logistics], Samir Dervisevic⁹⁵ [Leadership and supervision, and Samples and logistics], Emma J Meader⁹⁵ [Leadership and supervision, and Samples and logistics], Naomi R Park¹⁴⁰ [Leadership and supervision, and Sequencing and analysis], Karen Oliver¹⁴⁰ [Leadership and supervision, and Sequencing and analysis], Aaron R Jeffries¹³² [Leadership and supervision, and Sequencing and analysis], Sascha Ott¹³⁵ [Leadership and supervision, and Sequencing and analysis], Ana da Silva Filipe⁸⁹ [Leadership and supervision, and Sequencing and analysis], David A Simpson¹¹³ [Leadership and supervision, and Sequencing and analysis], Chris Williams¹¹⁰ [Leadership and supervision, and Sequencing and analysis], Jane AH Masoli^{114,132} [Leadership and supervision, and Visualisation], Bridget A Knight^{114,132} [Metadata curation, and Samples and logistics], Christopher R Jones^{114,132} [Metadata curation, and Samples and logistics], Cherian Koshy⁴² [Metadata curation, and Samples and logistics], Amy Ash⁴² [Metadata curation, and Samples and logistics], Anna Casey¹¹² [Metadata curation, and Samples and logistics], Andrew Bosworth^{105,77} [Metadata curation, and Samples and logistics], Liz Ratcliffe¹¹² [Metadata curation, and Samples and logistics], Li Xu-McCrae⁷⁷ [Metadata curation, and Samples and logistics], Hannah M Pymont¹⁰⁵ [Metadata curation, and Samples and logistics], Stephanie Hutchings¹⁰⁵ [Metadata curation, and Samples and logistics], Lisa Berry¹²⁵ [Metadata curation, and Samples and logistics], Katie Jones¹²⁵ [Metadata curation, and Samples and logistics], Fenella Halstead⁸⁷ [Metadata curation, and Samples and logistics], Thomas Davis⁶² [Metadata curation, and Samples and logistics], Christopher Holmes⁵⁷ [Metadata curation, and Samples and logistics], Miren Iturriza-Gomara¹³³ [Metadata curation, and Samples and logistics], Anita O Lucaci¹³³ [Metadata curation, and Samples and logistics], Paul Anthony Randell^{79,145} [Metadata curation, and Samples and logistics], Alison Cox^{79,145} [Metadata curation, and Samples and logistics], Pinglawathee Madona^{79,145} [Metadata curation, and Samples and logistics], Kathryn Ann Harris⁷¹ [Metadata curation, and Samples and logistics], Julianne Rose Brown⁷¹ [Metadata curation, and Samples and logistics], Tabitha W Mahungu¹¹⁵ [Metadata curation, and Samples and logistics], Dianne Irish-Tavares¹¹⁵ [Metadata curation, and Samples and logistics], Tanzina Haque¹¹⁵ [Metadata curation, and Samples and logistics], Jennifer Hart¹¹⁵ [Metadata curation, and Samples and logistics], Eric Witele¹¹⁵ [Metadata curation, and Samples and logistics], Melisa Louise Fenton¹¹⁶ [Metadata curation, and Samples and logistics], Steven Liggett¹²⁰ [Metadata curation, and Samples and logistics], Clive Graham⁹⁷ [Metadata curation, and

Samples and logistics], Emma Swindells⁹⁸ [Metadata curation, and Samples and logistics], Jennifer Collins⁹¹ [Metadata curation, and Samples and logistics], Gary Eltringham⁹¹ [Metadata curation, and Samples and logistics], Sharon Campbell⁵⁸ [Metadata curation, and Samples and logistics], Patrick C McClure¹³⁸ [Metadata curation, and Samples and logistics], Gemma Clark⁵⁶ [Metadata curation, and Samples and logistics], Tim J Sloan¹⁰¹ [Metadata curation, and Samples and logistics], Carl Jones⁵⁶ [Metadata curation, and Samples and logistics], Jessica Lynch^{43,152} [Metadata curation, and Samples and logistics], Ben Warne⁴⁹ [Metadata curation, and Sequencing and analysis], Steven Leonard¹⁴⁰ [Metadata curation, and Sequencing and analysis], Jillian Durham¹⁴⁰ [Metadata curation, and Sequencing and analysis], Thomas Williams¹³¹ [Metadata curation, and Sequencing and analysis], Sam T Haldenby¹³³ [Metadata curation, and Sequencing and analysis], Nathaniel Storey⁷¹ [Metadata curation, and Sequencing and analysis], Nabil-Fareed Alikhan¹¹¹ [Metadata curation, and Sequencing and analysis], Nadine Holmes⁵⁹ [Metadata curation, and Sequencing and analysis], Christopher Moore⁵⁹ [Metadata curation, and Sequencing and analysis], Matthew Carlile⁵⁹ [Metadata curation, and Sequencing and analysis], Malorie Perry¹¹⁰ [Metadata curation, and Sequencing and analysis], Noel Craine¹⁴⁰ [Metadata curation, and Sequencing and analysis], Ronan A Lyons¹⁴⁰ [Metadata curation, and Sequencing and analysis], Angela H Beckett⁵⁴ [Metadata curation, and Sequencing and analysis], Salman Goudarzi¹¹⁸ [Metadata curation, and Sequencing and analysis], Christopher Fearn¹¹⁸ [Metadata curation, and Sequencing and analysis], Kate Cook¹¹⁸ [Metadata curation, and Sequencing and analysis], Hannah Dent¹¹⁸ [Metadata curation, and Sequencing and analysis], Hannah Paul¹¹⁸ [Metadata curation, and Sequencing and analysis], Robert Davies¹⁴⁰ [Metadata curation, and Software and analysis tools], Beth Blane¹⁴⁰ [Project administration, and Samples and logistics], Sophia T Girgis¹⁴⁰ [Project administration, and Samples and logistics], Mathew A Beale¹⁴⁰ [Project administration, and Samples and logistics], Katherine L Bellis^{140,129} [Project administration, and Samples and logistics], Matthew J Dorman¹⁴⁰ [Project administration, and Samples and logistics], Eleanor Drury¹⁴⁰ [Project administration, and Samples and logistics], Leanne Kane¹⁴⁰ [Project administration, and Samples and logistics], Sally Kay¹⁴⁰ [Project administration, and Samples and logistics], Samantha McGuigan¹⁴⁰ [Project administration, and Samples and logistics], Rachel Nelson¹⁴⁰ [Project administration, and Samples and logistics], Liam Prestwood¹⁴⁰ [Project administration, and Samples and logistics], Shavanthi Rajatileka¹⁴⁰ [Project administration, and Samples and logistics], Rahul Batra¹⁴⁰ [Project administration, and Samples and logistics], Rachel J Williams¹²³ [Project administration, and Samples and logistics], Mark Kristiansen¹²³ [Project administration, and Samples and logistics], Angie Green¹³⁹ [Project administration, and Samples and logistics], Anita Justice¹⁴⁰ [Project administration, and Samples and logistics], Adhyana I.K Mahanama^{122,143} [Project administration, and Samples and logistics],

Buddhini Samaraweera^{122,143} [Project administration, and Samples and logistics], Nazreen F Hadjirin¹²⁹ [Project administration, and Sequencing and analysis], Joshua Quick⁸² [Project administration, and Sequencing and analysis], Radoslaw Poplawski⁸² [Project administration, and Software and analysis tools], Leanne M Kermack¹²⁹ [Samples and logistics, and Sequencing and analysis], Nicola Reynolds⁴⁸ [Samples and logistics, and Sequencing and analysis], Grant Hall⁶⁵ [Samples and logistics, and Sequencing and analysis], Yasmin Chaudhry¹⁴⁰ [Samples and logistics, and Sequencing and analysis], Malte L Pinckert⁶⁵ [Samples and logistics, and Sequencing and analysis], Iliana Georgana¹⁴⁰ [Samples and logistics, and Sequencing and analysis], Robin J Moll¹⁴⁰ [Samples and logistics, and Sequencing and analysis], Alicia Thornton¹⁰⁷ [Samples and logistics, and Sequencing and analysis], Richard Myers¹⁰⁷ [Samples and logistics, and Sequencing and analysis], Joanne Stockton¹⁴⁰ [Samples and logistics, and Sequencing and analysis], Charlotte A Williams¹⁴⁰ [Samples and logistics, and Sequencing and analysis], Wen C Yew¹⁴⁰ [Samples and logistics, and Sequencing and analysis], Alexander J Trotter¹¹¹ [Samples and logistics, and Sequencing and analysis], Amy Trebes¹⁴⁰ [Samples and logistics, and Sequencing and analysis], George MacIntyre-Cockett¹³⁹ [Samples and logistics, and Sequencing and analysis], Alec Birchley¹¹⁰ [Samples and logistics, and Sequencing and analysis], Alexander Adams¹¹⁰ [Samples and logistics, and Sequencing and analysis], Amy Plimmer¹⁴⁰ [Samples and logistics, and Sequencing and analysis], Bree Gatica-Wilcox¹¹⁰ [Samples and logistics, and Sequencing and analysis], Caoimhe McKerr¹¹⁰ [Samples and logistics, and Sequencing and analysis], Ember Hilvers¹¹⁰ [Samples and logistics, and Sequencing and analysis], Hannah Jones¹¹⁰ [Samples and logistics, and Sequencing and analysis], Hibo Asad¹¹⁰ [Samples and logistics, and Sequencing and analysis], Jason Coombes¹⁴⁰ [Samples and logistics, and Sequencing and analysis], Johnathan M Evans¹¹⁰ [Samples and logistics, and Sequencing and analysis], Laia Fina¹¹⁰ [Samples and logistics, and Sequencing and analysis], Lauren Gilbert¹¹⁰ [Samples and logistics, and Sequencing and analysis], Lee Graham¹¹⁰ [Samples and logistics, and Sequencing and analysis], Michelle Cronin¹⁴⁰ [Samples and logistics, and Sequencing and analysis], Sara Kumziene-SummerhaYes¹¹⁰ [Samples and logistics, and Sequencing and analysis], Sarah Taylor¹¹⁰ [Samples and logistics, and Sequencing and analysis], Sophie Jones¹⁴⁰ [Samples and logistics, and Sequencing and analysis], Danielle C Groves¹³⁴ [Samples and logistics, and Sequencing and analysis], Peijun Zhang¹³⁴ [Samples and logistics, and Sequencing and analysis], Marta Gallis¹³⁴ [Samples and logistics, and Sequencing and analysis], Stavroula F Louka¹³⁴ [Samples and logistics, and Sequencing and analysis], Igor Starinskij⁸⁹ [Samples and logistics, and Software and analysis tools], Chris Jackson⁸⁸ [Sequencing and analysis, and Software and analysis tools], Marina Gourtovaia¹⁴⁰ [Sequencing and analysis, and Software and analysis tools], Gerry Tonkin-Hill¹⁴⁰ [Sequencing and analysis, and Software and analysis tools], Kevin Lewis¹⁴⁰

[Sequencing and analysis, and Software and analysis tools], Jaime M Tovar-Corona¹⁴⁰ [Sequencing and analysis, and Software and analysis tools], Keith James¹⁴⁰ [Sequencing and analysis, and Software and analysis tools], Laura Baxter¹³⁵ [Sequencing and analysis, and Software and analysis tools], Mohammad T Alam¹⁴⁰ [Sequencing and analysis, and Software and analysis tools], Richard J Orton⁸⁹ [Sequencing and analysis, and Software and analysis tools], Joseph Hughes⁸⁹ [Sequencing and analysis, and Software and analysis tools], Sreenu Vattipally¹⁴⁰ [Sequencing and analysis, and Software and analysis tools], Manon Ragonnet-Cronin⁸⁰ [Sequencing and analysis, and Software and analysis tools], Fabricia F Nascimento⁸⁰ [Sequencing and analysis, and Software and analysis tools], David Jorgensen⁸⁰ [Sequencing and analysis, and Software and analysis tools], Olivia Boyd⁸⁰ [Sequencing and analysis, and Software and analysis tools], Lily Geidelberg¹⁴⁰ [Sequencing and analysis, and Software and analysis tools], Alex E Zarebski⁶⁴ [Sequencing and analysis, and Software and analysis tools], Jayna Raghwan¹⁴⁰ [Sequencing and analysis, and Software and analysis tools], Moritz UG Kraemer⁶⁴ [Sequencing and analysis, and Software and analysis tools], Joel Southgate^{51,110} [Sequencing and analysis, and Software and analysis tools], Benjamin B Lindsey¹³⁴ [Sequencing and analysis, and Software and analysis tools], Timothy M Freeman¹³⁴ [Sequencing and analysis, and Software and analysis tools], Jon-Paul Keatley¹⁴⁰ [Software and analysis tools, and Visualisation], Joshua B Singer¹⁴⁰ [Software and analysis tools, and Visualisation], Leonardo de Oliveira Martins¹⁴⁰ [Software and analysis tools, and Visualisation], Corin A Yeats⁵⁵ [Software and analysis tools, and Visualisation], Khalil Abudahab^{140,140} [Software and analysis tools, and Visualisation], Ben EW Taylor¹⁴⁰ [Software and analysis tools, and Visualisation], Mirko Menegazzo⁵⁵ [Software and analysis tools, and Visualisation], John Danesh¹⁴⁰ [Leadership and supervision], Wendy Hogsden⁸⁷ [Leadership and supervision], Sahar Eldirdi⁶² [Leadership and supervision], Anita Kenyon⁶² [Leadership and supervision], Jenifer Mason¹⁴⁰ [Leadership and supervision], Trevor I Robinson⁸⁴ [Leadership and supervision], Alison Holmes^{140,144} [Leadership and supervision], James Price^{140,140} [Leadership and supervision], John A Hartley¹²³ [Leadership and supervision], Tanya Curran¹⁴⁰ [Leadership and supervision], Alison E Mather¹¹¹ [Leadership and supervision], Giri Shankar¹¹⁰ [Leadership and supervision], Rachel Jones¹¹⁰ [Leadership and supervision], Robin Howe¹¹⁰ [Leadership and supervision], Sian Morgan⁵⁰ [Leadership and supervision], Elizabeth Wastenge¹⁴⁰ [Metadata curation], Michael R Chapman^{1,129,140} [Metadata curation], Siddharth Mookerjee^{79,144} [Metadata curation], Rachael Stanley⁹⁵ [Metadata curation], Wendy Smith⁵⁶ [Metadata curation], Timothy Peto¹⁰⁰ [Metadata curation], David Eyre¹⁰⁰ [Metadata curation], Derrick Crook¹⁰⁰ [Metadata curation], Gabrielle Vernet⁷⁴ [Metadata curation], Christine Kitchen⁵¹ [Metadata curation], Huw Gulliver⁵¹ [Metadata curation], Ian Merrick⁵¹ [Metadata curation], Martyn Guest⁵¹ [Metadata curation], Robert Munn¹⁴⁰ [Metadata curation], Declan T

Bradley^{140,113} [Metadata curation], Tim Wyatt¹⁰⁴ [Metadata curation], Charlotte Beaver¹⁴⁰ [Project administration], Luke Foulser¹⁴⁰ [Project administration], Sophie Palmer¹⁴⁰ [Project administration], Carol M Churcher¹²⁹ [Project administration], Ellena Brooks¹⁴⁰ [Project administration], Kim S Smith¹²⁹ [Project administration], Katerina Galai¹⁴⁰ [Project administration], Georgina M McManus¹²⁹ [Project administration], Frances Bolt^{79,144} [Project administration], Francesc Coll⁶⁰ [Project administration], Lizzie Meadows¹⁴⁰ [Project administration], Stephen W Attwood⁶⁴ [Project administration], Alisha Davies¹⁴⁰ [Project administration], Elen De Lacy¹¹⁰ [Project administration], Fatima Downing¹¹⁰ [Project administration], Sue Edwards¹⁴⁰ [Project administration], Garry P Scarlett¹¹⁷ [Project administration], Sarah Jeremiah¹²⁴ [Project administration], Nikki Smith¹³⁴ [Project administration], Danielle Leek¹²⁹ [Samples and logistics], Sushmita Sridhar^{140,140} [Samples and logistics], Sally Forrest¹²⁹ [Samples and logistics], Claire Cormie¹⁴⁰ [Samples and logistics], Harmeet K Gill¹²⁹ [Samples and logistics], Joana Dias¹⁴⁰ [Samples and logistics], Ellen E Higginson¹²⁹ [Samples and logistics], Mailis Maes¹²⁹ [Samples and logistics], Jamie Young¹²⁹ [Samples and logistics], Michelle Wantoch¹⁴⁰ [Samples and logistics], Sanger Covid Team¹⁴⁰ [Samples and logistics], Dorota Jamroz¹⁴⁰ [Samples and logistics], Stephanie Lo¹⁴⁰ [Samples and logistics], Minal Patel¹⁴⁰ [Samples and logistics], Verity Hill¹⁴⁰ [Samples and logistics], Claire M Bewshea¹³² [Samples and logistics], Sian Ellard^{114,132} [Samples and logistics], Cressida Auckland¹¹⁴ [Samples and logistics], Ian Harrison¹⁰⁷ [Samples and logistics], Chloe Bishop¹⁰⁷ [Samples and logistics], Vicki Chalker¹⁰⁷ [Samples and logistics], Alex Richter¹²⁶ [Samples and logistics], Andrew Beggs¹²⁶ [Samples and logistics], Angus Best¹²⁷ [Samples and logistics], Benita Percival¹²⁷ [Samples and logistics], Jeremy Mirza¹²⁷ [Samples and logistics], Oliver Megram¹²⁷ [Samples and logistics], Megan Mayhew¹²⁷ [Samples and logistics], Liam Crawford¹²⁷ [Samples and logistics], Fiona Ashcroft¹⁴⁰ [Samples and logistics], Emma Moles-Garcia¹²⁷ [Samples and logistics], Nicola Cumley¹²⁷ [Samples and logistics], Richard Hopes¹⁰⁵ [Samples and logistics], Patawee Asamaphan¹⁴⁰ [Samples and logistics], Marc O Niebel¹⁴⁰ [Samples and logistics], Rory N Gunson¹⁴¹ [Samples and logistics], Amanda Bradley⁹³ [Samples and logistics], Alasdair Maclean⁹³ [Samples and logistics], Guy Mollett⁹³ [Samples and logistics], Rachel Blacow⁹³ [Samples and logistics], Paul Bird⁵⁷ [Samples and logistics], Thomas Helmer⁵⁷ [Samples and logistics], Karlie Fallon⁵⁷ [Samples and logistics], Julian Tang¹⁴⁰ [Samples and logistics], Antony D Hale¹⁴⁰ [Samples and logistics], Louissa R Macfarlane-Smith¹⁴⁰ [Samples and logistics], Katherine L Harper⁹⁰ [Samples and logistics], Holli Carden¹⁴⁰ [Samples and logistics], Nicholas W Machin^{86,105} [Samples and logistics], Kathryn A Jackson¹³³ [Samples and logistics], Shazaad SY Ahmad^{86,105} [Samples and logistics], Ryan P George⁸⁶ [Samples and logistics], Lance Turtle¹⁴⁰ [Samples and logistics], Elaine O'Toole⁸⁴ [Samples and logistics], Joanne Watts⁸⁴ [Samples and logistics], Cassie Breen⁸⁴ [Samples and logistics], Angela Cowell¹⁴⁰ [Samples and

logistics], Adela Alcolea-Medina^{73,137} [Samples and logistics], Themoula Charalampous^{140,83} [Samples and logistics], Amita Patel¹⁴⁰ [Samples and logistics], Lisa J Levett⁷⁶ [Samples and logistics], Judith Heaney⁷⁶ [Samples and logistics], Aileen Rowan¹⁴⁰ [Samples and logistics], Graham P Taylor⁸⁰ [Samples and logistics], Divya Shah⁷¹ [Samples and logistics], Laura Atkinson¹⁴⁰ [Samples and logistics], Jack CD Lee¹⁴⁰ [Samples and logistics], Adam P Westhorpe¹²³ [Samples and logistics], Riaz Jannoo¹⁴⁰ [Samples and logistics], Helen L Lowe¹²³ [Samples and logistics], Angeliki Karamani¹²³ [Samples and logistics], Leah Ensell¹²³ [Samples and logistics], Wendy Chatterton⁷⁶, Monika Pusok⁷⁶ [Samples and logistics], Ashok Dadrah¹¹⁶ [Samples and logistics], Amanda Symmonds¹¹⁶ [Samples and logistics], Graciela Sluga⁸⁵ [Samples and logistics], Zoltan Molnar¹¹³ [Samples and logistics], Paul Baker¹²⁰ [Samples and logistics], Stephen Bonner¹²⁰ [Samples and logistics], Sarah Essex¹²⁰ [Samples and logistics], Edward Barton⁹⁷ [Samples and logistics], Debra Padgett⁹⁷ [Samples and logistics], Garren Scott⁹⁷ [Samples and logistics], Jane Greenaway¹⁴⁰ [Samples and logistics], Brendan Al Payne¹⁴⁰ [Samples and logistics], Shirelle Burton-Fanning⁹¹ [Samples and logistics], Sheila Waugh⁹¹ [Samples and logistics], Veena Raviprakash⁵⁸ [Samples and logistics], Nicola Sheriff⁵⁸ [Samples and logistics], Victoria Blakey¹⁴⁰ [Samples and logistics], Lesley-Anne Williams⁵⁸ [Samples and logistics], Jonathan Moore⁶⁸ [Samples and logistics], Susanne Stonehouse⁶⁸ [Samples and logistics], Louise Smith¹⁴⁰ [Samples and logistics], Rose K Davidson¹³⁰ [Samples and logistics], Luke Bedford⁶⁷ [Samples and logistics], Lindsay Coupland⁹⁵ [Samples and logistics], Victoria Wright¹⁴⁰ [Samples and logistics], Joseph G Chappell¹³⁸ [Samples and logistics], Theocharis Tsoleridis¹³⁸ [Samples and logistics], Jonathan Ball¹³⁸ [Samples and logistics], Manjinder Khakh¹⁴⁰ [Samples and logistics], Vicki M Fleming¹⁴⁰ [Samples and logistics], Michelle M Lister¹⁴⁰ [Samples and logistics], Hannah C Howson-Wells⁵⁶ [Samples and logistics], Louise Berry⁵⁶ [Samples and logistics], Tim Boswell⁵⁶ [Samples and logistics], Amelia Joseph⁵⁶ [Samples and logistics], Iona Willingham⁵⁶ [Samples and logistics], Nichola Duckworth¹⁰¹ [Samples and logistics], Sarah Walsh¹⁰¹ [Samples and logistics], Emma Wise^{140,152} [Samples and logistics], Nathan Moore^{140,152} [Samples and logistics], Matilde Mori^{140,140,152} [Samples and logistics], Nick Cortes^{140,152} [Samples and logistics], Stephen Kidd^{140,152} [Samples and logistics], Rebecca Williams⁷⁴ [Samples and logistics], Laura Gifford¹¹⁰ [Samples and logistics], Kelly Bicknell¹⁰² [Samples and logistics], Sarah Wyllie¹⁰² [Samples and logistics], Allyson Lloyd¹⁰² [Samples and logistics], Robert Impey¹⁴⁰ [Samples and logistics], Cassandra S Malone¹⁴⁰ [Samples and logistics], Benjamin J Cogger⁴⁷ [Samples and logistics], Nick Levene¹⁰³ [Samples and logistics], Lynn Monaghan¹⁴⁰ [Samples and logistics], Alexander J Keeley¹⁴⁰ [Samples and logistics], David G Partridge^{140,134} [Samples and logistics], Mohammad Raza^{119,134} [Samples and logistics], Cariad Evans^{140,134} [Samples and logistics], Kate Johnson^{119,134} [Samples and logistics], Emma Betteridge¹⁴⁰ [Sequencing and analysis], Ben W Farr¹⁴⁰

Acknowledgements

We are immensely grateful to the patient and his family. We would also like to thank the staff at CUH and the NIHR Cambridge Clinical Research Facility. We would like to thank Dr Ruthiran Kugathasan and Professor Wendy Barclay for helpful discussions and Dr Martin Curran, Dr William Hamilton, and Dr. Dominic Sparkes. We would like to thank Prof Andres Floto and Prof Ferdia Gallagher. We thank Dr James Voss for the kind gift of HeLa cells stably expressing ACE2. We would like to thank James Nathan for RBD protein and Leo James for N protein. COG-UK is supported by funding from the Medical Research Council (MRC) part of UK Research & Innovation (UKRI), the National Institute of Health Research (NIHR) and Genome Research Limited, operating as the Wellcome Sanger Institute. RKG is supported by a Wellcome Trust Senior Fellowship in Clinical Science (WT108082AIA). LEM is supported by a Medical Research Council Career Development Award (MR/R008698/1).

SAK is supported by the Bill and Melinda Gates Foundation via PANGAEA grant: OPP1175094. DAC is supported by a Wellcome Trust Clinical PhD Research Fellowship. CJRI acknowledges MRC funding (ref: MC_UU_00002/11). This research was supported by the National Institute for Health Research (NIHR) Cambridge Biomedical Research Centre, the Cambridge Clinical Trials Unit (CCTU) and by the UCL Coronavirus Response Fund and made possible through generous donations from UCL's supporters, alumni, and friends (LEM). JAGB is supported by the Medical Research Council (MC_UP_1201/16). IG is a Wellcome Senior Fellow and supported by the Wellcome Trust (207498/Z/17/Z). DDP is supported by NIH GM083127.

Data Availability

Long-read sequencing data that support the findings of this study have been deposited in the NCBI SRA database with the accession codes SAMN16976824 - SAMN16976846 under BioProject PRJNA682013 (<https://www.ncbi.nlm.nih.gov/bioproject/PRJNA682013>). Short reads and data used to construct figures were deposited at https://github.com/Steven-Kemp/sequence_files. All data are also available from the corresponding author.

Code Availability

The SAMFIRE package Version 1.06 was used for filtering and calling variants from the Illumina data. It is available at <https://github.com/cjri/samfire/> for review. Additional code was used to validate the variant frequencies and can be found at <https://github.com/PollockLaboratory/AnCovMulti>.

Figure 1.

Analysis of 23 Patient derived whole SARS-CoV-2 genome sequences in context of local sequences and other cases of chronic SARS-CoV-2 shedding. Circularised maximum-likelihood phylogenetic tree rooted on the Wuhan-Hu-1 reference sequence, showing a subset of 250 local SARS-CoV-2 genomes from GISAID. This diagram highlights significant diversity of the case patient (green) compared to three other local patients with prolonged shedding (blue, red and purple sequences). All “United Kingdom / English” SARS-CoV-2 genomes were downloaded from the GISAID database and a random subset of 250 selected as background.

Figure 2. Whole genome variant trajectories showing amino acids and relationship to treatments. Data based on Illumina short read ultra deep sequencing at 1000x coverage. Variants shown reached a frequency of at least 10% in at least 2 samples. Treatments indicated are convalescent plasma (CP) and Remdesivir (RDV). Variants described in the text are designated by labels using the same colouring as the position in the genome. Variants labelled are represented by dashed lines. **A.** Variants detected in the patient from days 1-82. *D796H (light blue) is at the same frequency as NSP3 K902N (orange) therefore it is hidden beneath **B.** Variants detected in the patient from days 82-101.

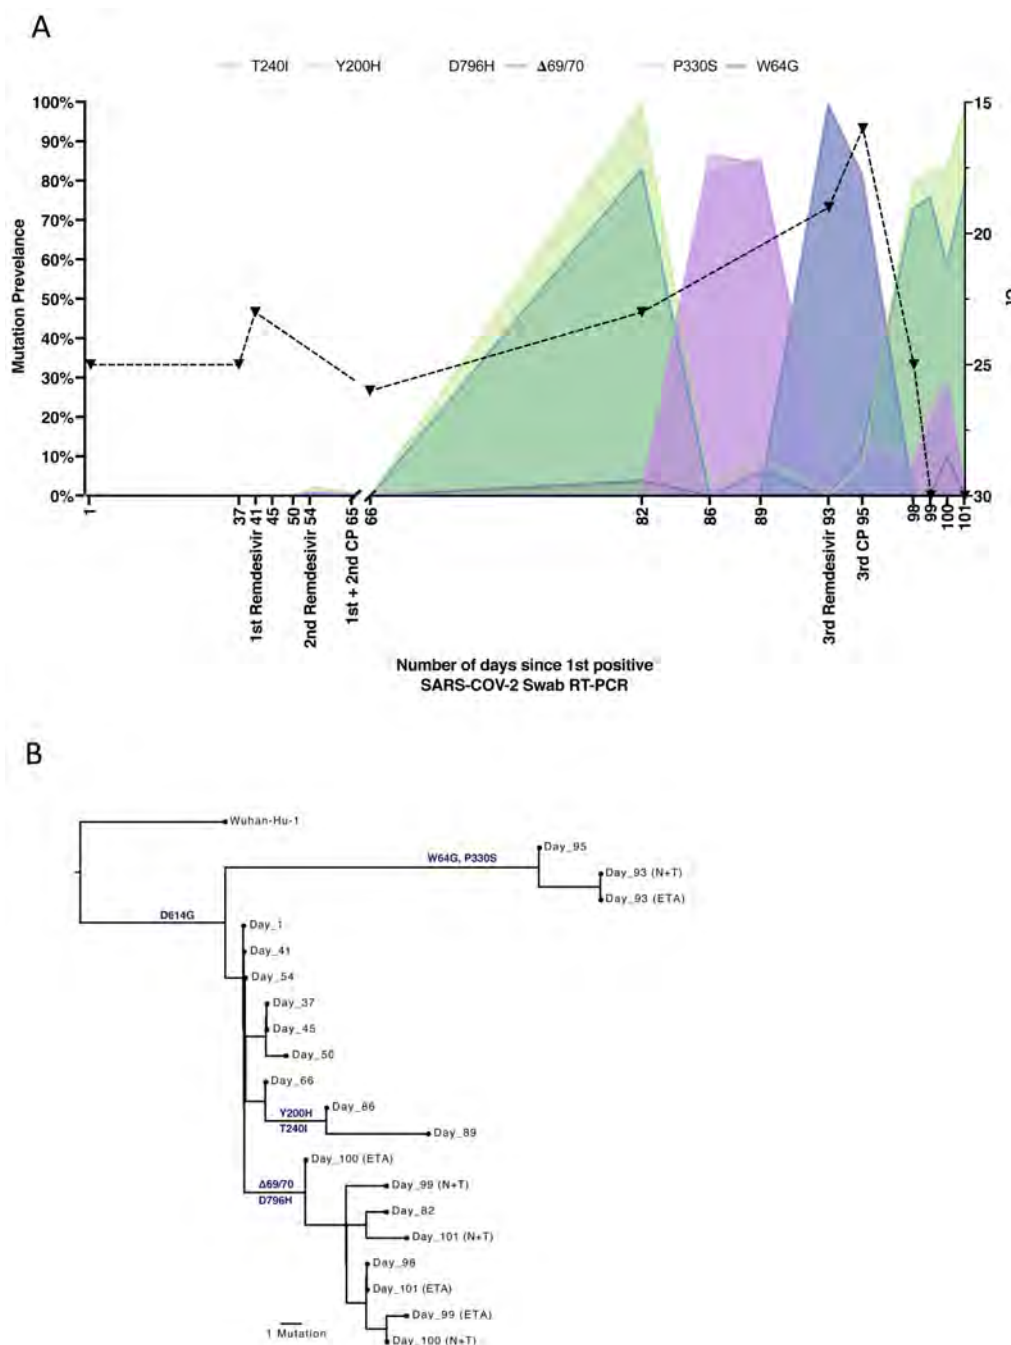

Figure 3. Longitudinal variant frequencies and phylogenetic relationships for virus populations bearing six Spike (S) mutations

A. At baseline, all six S variants (Illumina sequencing) except for H69/V70 were absent (<1% and <20 reads). Approximately two weeks after receiving two units of convalescent plasma (CP), viral populations carrying H69/V70 and D796H mutants rose to frequencies >80% but decreased significantly four days later. This population was replaced by a population bearing Y200H and T240I, detected in two samples over a period of 6 days. These viral populations were then replaced by virus carrying W64G and P330S mutations in

Spike, which both dominated at day 93. Following a 3rd course of remdesivir and an additional unit of convalescent plasma, the H69/V70 and D796H virus population re-emerged to become the dominant viral strain reaching variant frequencies of >75%. Pairs of mutations arose and disappeared simultaneously indicating linkage on the same viral haplotype. CT values from respiratory samples are indicated on the right y-axis (black dashed line and triangles). Where there were duplicate readings on the same day, to remain consistent, N+T samples were plotted **B**. Maximum likelihood phylogenetic tree of the case patient with day of sampling indicated. Spike mutations defining each of the clades are shown ancestrally on the branches on which they arose. On dates where multiple samples were collected, these are indicated as endotracheal aspirate (ETA) and Nose + throat swabs (N+T).

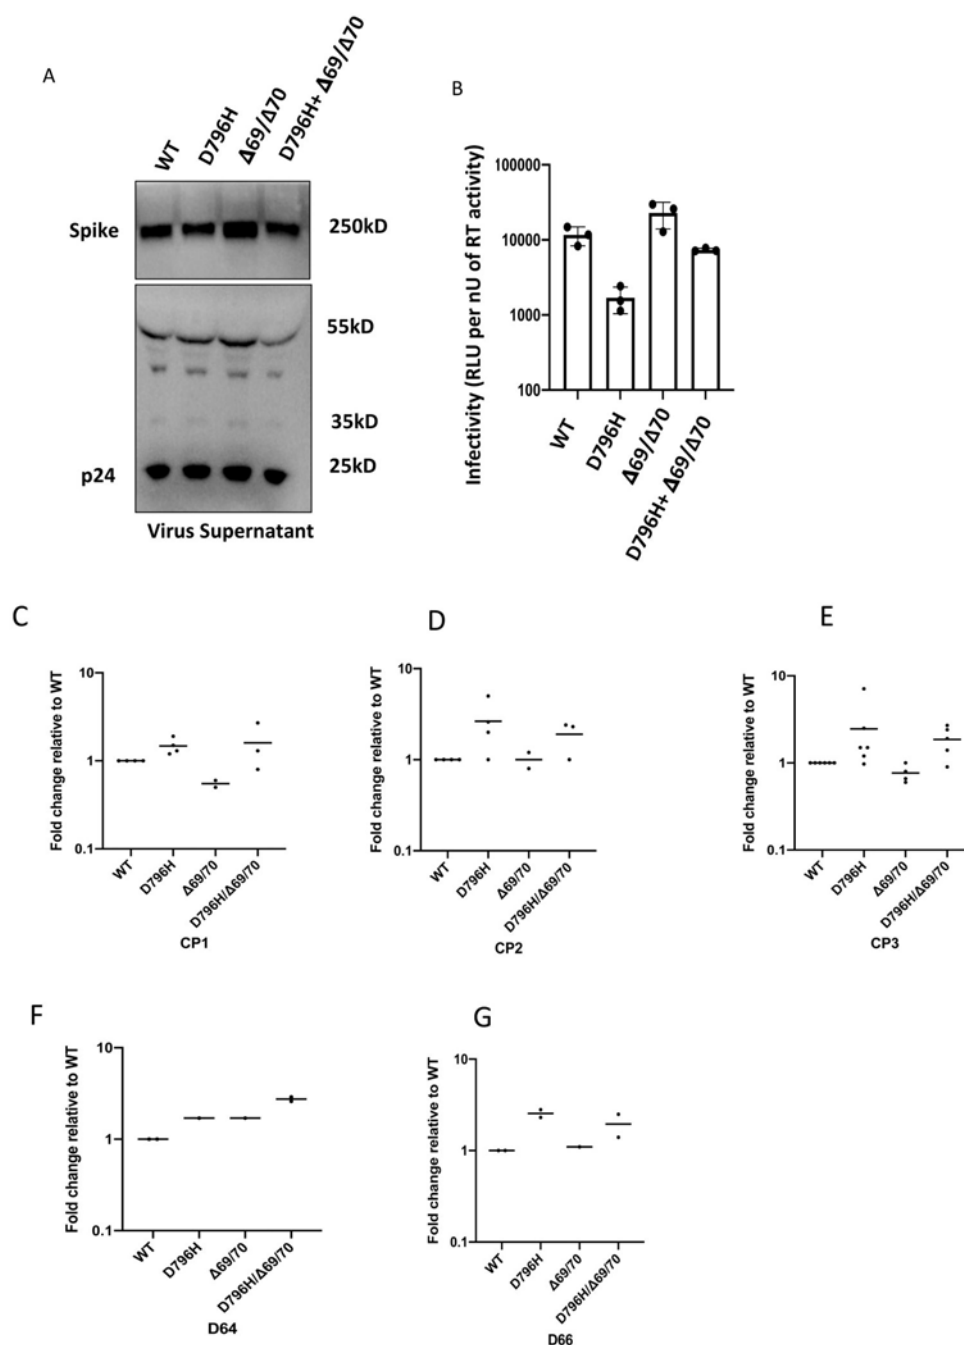

Figure 4. Spike mutant D796H + H69/V70 infectivity and sensitivity convalescent plasma (CP).

A. western blot of virus pellets after centrifugation of supernatants from cells transfected with lentiviral pseudotyping plasmids including Spike protein. Blots are representative of two independent transfections. **B.** Single round Infectivity of luciferase expressing lentivirus pseudotyped with SARS-CoV-2 Spike protein (WT versus mutant) on 293T cells co-transfected with ACE2 and TMPRSS2 plasmids. Infectivity is corrected for reverse transcriptase activity in virus supernatant as measured by real time PCR. Data points represent technical replicates (n=3) with mean and error bars representing standard error of

mean; data are representative of two independent experiments **C-E**. convalescent plasma (CP units 1-3) neutralization potency against pseudovirus virus bearing Spike mutants D796H, H69/V70 and D796H + H69/V70 **F, G** patient serum neutralisation potency against pseudovirus virus bearing Spike mutants D796H, H69/V70 and D796H + H69/V70. Patient serum was taken at indicated Day (D). Indicated is serum dilution required to inhibit 50% of virus infection (ID₅₀), expressed as fold change relative to WT. Data points represent means of technical replicates and each data point is an independent experiment (n=2-6). Mean of data points in C-G is shown by horizontal bars.

ABSTRACT

Background: Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)-infected pneumonia emerged in Wuhan, China in December 2019. In this retrospective multicenter study, we investigated the clinical course and outcomes of novel coronavirus disease 2019 (COVID-19) from early cases in Republic of Korea.

Methods: All of the cases confirmed by real time polymerase chain reaction were enrolled from the 1st to the 28th patient nationwide. Clinical data were collected and analyzed for changes in clinical severity including laboratory, radiological, and virologic dynamics during the progression of illness.

Results: The median age was 40 years (range, 20–73 years) and 15 (53.6%) patients were male. The most common symptoms were cough (28.6%) and sore throat (28.6%), followed by fever (25.0%). Diarrhea was not common (10.7%). Two patients had no symptoms. Initial chest X-ray (CXR) showed infiltration in 46.4% of the patients, but computed tomography scan confirmed pneumonia in 88.9% (16/18) of the patients. Six patients (21.4%) required

supplemental oxygen therapy, but no one needed mechanical ventilation. Lymphopenia was more common in severe cases. Higher level of C-reactive protein and worsening of chest radiographic score was observed during the 5–7 day period after symptom onset. Viral shedding was high from day 1 of illness, especially from the upper respiratory tract (URT).

Conclusion: The prodromal symptoms of COVID-19 were mild and most patients did not have limitations of daily activity. Viral shedding from URT was high from the prodromal phase. Radiological pneumonia was common from the early days of illness, but it was frequently not evident in simple CXR. These findings could be plausible explanations for the easy and rapid spread of SARS-CoV-2 in the community.

INTRODUCTION

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)-infected pneumonia has been initially identified in Wuhan, China since December 2019.¹ A total number of 693,224 laboratory-confirmed cases have been documented globally as of March 30th, 2020, including 33,106 deaths.² After experiencing the largest outbreak of Middle East respiratory syndrome (MERS) outside the Arabian Peninsula in 2015,³ the Korean government has maintained a strong quarantine system for emerging infectious diseases imported from foreign countries. The first novel coronavirus disease 2019 (COVID-19) case in Korea was a traveler from Wuhan, China in January 19th, 2020.⁴ While the spread of COVID-19 was limited before February 20,^{5,6} a huge outbreak occurred among a religious group in the southern part of Korea, Daegu, and the number of COVID-19 cases in Korea reached 6,593 on March 6th, 2020.^{7,8}

While clinical and epidemiological features of COVID-19 have been described in China by several investigations,⁹⁻¹⁴ most of them focused on SARS-CoV-2-infected pneumonia in China. There is still uncertainty about the clinical course and outcomes of COVID-19, especially outside of China where patients can be detected in the early course of disease by the quarantine system. Recently, the Korea Centers for Disease Control and Prevention (KCDC) reported epidemiological features of the earliest 28 COVID-19 cases in Republic of Korea.¹⁵ We performed this study to describe the clinical characteristics of COVID-19 in Republic of Korea, including radiological and virologic dynamics during the progression of illness.

METHODS

Study design and participants

Korea National Committee for Clinical Management of COVID-19 (KNCCMC) was organized in early February 2020 and consisted of infectious disease specialists or physicians of each hospital who took care of the confirmed COVID-19 patients. KNCCMC developed a standardized clinical record form (CRF) which was modified from the World Health Organization Global 2019-novel coronavirus clinical characterization CRF.¹⁶ Individual cases were reviewed and treatment and discharge plans were discussed during regular video conference calls three times a week. All of cases nationwide were enrolled in this study from the 1st to the 28th patient. Participating hospitals were as follows: Seoul National University Hospital, National Medical Center, and Seoul Medical Center, Seoul; Incheon Medical

Center, Incheon; Seoul National University Bundang Hospital and Armed Forces Capital Hospital, Seongnam; Myongji Hospital, Goyang; Gyeonggi Provincial Medical Center Ansong Hospital, Anseong; Wonkwang University Hospital, Iksan; Chonnam National University Hospital and Chosun University Hospital, Gwangju, Republic of Korea.

Case definitions

According to the definition of the KCDC,⁷ a suspected COVID-19 patient was defined as someone fulfilling both of the following criteria: 1) a presence of at least one condition among fever; respiratory symptoms such as cough, sore throat, or dyspnea; or radiographic evidence of pneumonia, 2) a recent visit to countries where SARS-CoV-2 transmission in the community has been reported including Wuhan city, China or recent close contact with a confirmed COVID-19 patient within 14 days before illness onset. A confirmed case was defined as a patient with positive results by real time reverse transcription polymerase chain reaction (RT-PCR) assay for SARS-CoV-2 in upper respiratory specimen (nasopharyngeal and oropharyngeal swab), with or without lower respiratory specimen (sputum). The patients who had no symptoms but had been screened for COVID-19 due to a strong epidemiologic link were also enrolled when they were laboratory-confirmed.

Viral diagnostic methods

Respiratory samples from the patients were sent to the KCDC and RT-PCR for detecting SARS-CoV-2 was performed as in previous study.¹⁷ In brief, RNA was extracted from clinical samples with a QIAamp® viral RNA mini kit (QIAGEN, Hilden, Germany). The primer and probe sequences used for RNA-dependent RNA polymerase gene detection were: 5'-GTGARATGGTCATGTGTGGCGG-3' (Forward), 5'-CARATGTAAASACACTATTAGCATA-3' (Reverse) and 5'-CAGGTGGAACCTCATCAGGAGATGC-3' (Probe in 5-FAM/3'-BHQ format) and the primer and probe sequences used for *E* gene detection were: 5'-ACAGGTACGTTAATAGTTAATAGCGT-3' (Forward), 5'-ATATTGCAGCAGTACGCACACA-3' (Reverse) and 5'-ACACTAGCCATCCTTACTGCGCTTCG-3' (Probe in 5-FAM/3'-BHQ format). Reverse transcription was performed at 50°C for 30 minutes, followed by inactivation of the reverse transcriptase at 95°C for 10 minutes. PCR amplification was performed with 40 cycles at 95°C for 15 seconds and 60°C for 1 minute using an ABI 7500 Fast instrument (Thermo Fisher Scientific, Waltham, MA, USA).

Clinical data collection and severity evaluation

Primary physicians from each participating hospital retrospectively collected clinical medical record data then two infectious disease physicians from KNCCMC reassessed the accuracy of the raw data. Patients were hospitalized in the isolation units in each hospital from January 19th, 2020, with final follow-up for the study on February 17th, 2020. Epidemiologic, demographic, and clinical information including laboratory and radiologic findings were obtained. Clinical severity and changes according to days after first symptom onset were assessed as follows: 1, no limit of daily activity; 2, limit of daily activity but no need for supplemental O₂ therapy; 3, need for supplemental O₂ therapy via nasal prong; 4, need for supplemental O₂ therapy via facial mask; 5, need for high flow supplemental O₂ therapy or non-invasive ventilation; 6, need for invasive ventilation; 7, multi-organ failure or need for extracorporeal membrane oxygenation (ECMO) therapy; 8, death.

Chest radiograph scoring was performed as described in a previous study¹⁸; in brief, serial chest radiographs were retrospectively reviewed in consensus by four physicians who were

unaware of the clinical conditions of the patients. Each lung was divided into the upper, middle, and lower zone, and infiltrations on each zone were scored from 0 to 4, with a total range of 0 to 24.

Ethics statement

The Institutional Review Board (IRB) at Seoul National University Hospital reviewed and approved the study protocol (IRB registration No. H-2002-042-1100). After that, the IRB at each participating hospital approved it. The board waived the requirement for written consent.

RESULTS

Patients and clinical characteristics

The study population included 28 hospitalized patients with confirmed COVID-19. The median age of the 28 patients was 40 years (interquartile range, 28–54; range, 20–73), and 15 (53.6%) were men. Of the 28 patients, five (17.9%) had one or more coexisting medical condition and diabetes was most common (**Table 1**). The most common symptoms at the time of admission for isolation were cough (8, 28.6%) and sore throat (8, 28.6%), followed by fever, myalgia, and headache (7, 25.0%). Diarrhea was present in three patients (10.7%) among initial symptoms. Two cases were asymptomatic when they were confirmed as COVID-19.

Clinical course and outcomes

During the hospitalization, six patients (21.4%) required oxygen supplement therapy: four with nasal cannula and two with face mask. No one required mechanical ventilator or ECMO therapy. Nineteen patients (67.9%) received lopinavir/ritonavir for antiviral therapy. Ultimately, pneumonia was present in 22 patients (78.5%) and the proportion of pneumonia was 91.3% (21/23) among the patients who received a CT scan (**Table 2**). Seventeen patients (60.7%) developed fever and became afebrile during the hospitalization and the median day of defervescence was 9 days (range, 3–18) after symptom onset (**Supplementary Fig. 1**). By February 17, 10 patients were off isolation or discharged, and the median day of off-isolation/discharge was 18.5 days after symptom onset (range, 11–27).

Chronological changes of COVID-19

Except for 2 patients who showed no symptoms, six among 26 patients showed clinical deterioration during the hospitalization and needed supplemental oxygen therapy (**Supplementary Fig. 2**). The others showed little limitation in daily activity during the hospitalization.

While neutrophilia or neutropenia was not common regardless of clinical severity (**Fig. 1A and B**), lymphopenia (defined as $\leq 1.0 \times 10^9/L$) was more common in severe cases (33.3%, 2/6) than mild cases (18.2%, 4/22) during the clinical course (**Fig. 1C and D**). High levels of C-reactive protein in the blood were more frequently observed in severe cases (**Fig. 1E and F**) as the clinical course became worse during the 5–7 day period after symptom onset.

We could evaluate viral kinetics by serial RT-PCR of respiratory specimens from 9 patients from the early course of illness. Viral shedding from upper respiratory tract (URT) and lower respiratory tract (LRT) was shown in **Fig. 2A and B** as cycle threshold (Ct) value, respectively (**Supplementary Table 1**). Viral shedding was high during the first 5 days of illness and higher in URT than LRT. It decreased after day 7 of illness.

Table 1. Clinical characteristics of 28 patients with COVID-19 at the time of admission for isolation

Characteristics	Values
Age, yr	42.6 ± 13.4

COVID-19 = coronavirus disease 2019, ID = illness day, CT = computed tomography, CXR = chest X-ray, LPV/r = lopinavir/ritonavir, DM = diabetes mellitus.

^aOnly CXRs were performed.

Infiltration on initial chest X-ray was observed in 13 patients (46.4%), but pneumonia was confirmed in most patients who underwent computed tomography (CT) scan initially (16/18, 88.9%) (Table 1). The chest radiographic scores remained relatively stable during the first week of illness. However, around day 7 of illness, the scores began to increase in some patients, suggesting progression of pneumonia (Fig. 2C).

DISCUSSION

We report the clinical course and outcomes of the first 28 patients with COVID-19 in Republic of Korea. The clinical severity was mild symptomatic or asymptomatic in 78.6% (22/28) of the patients. The most common prodromal symptoms were sore throat, cough, fever, and myalgia, which was suggestive of common cold. Although radiological pneumonia was detected in the majority (22/28, 78.6%) of the patients, only 27.3% (6/22) of them required supplemental oxygen therapy. Radiological pneumonia was detected as early as from the 1st day of illness onset, and was even identified in patients who did not have any symptoms of the LRT infection, such as cough, sputum, chest pain, or dyspnea. Although they had radiological pneumonia, they did not feel unwell and were able to carry on their daily activities as usual (“walking pneumonia”). The titers of SARS-CoV-2 shedding from the URT were very high from the prodromal phase of illness until day 5 of illness.

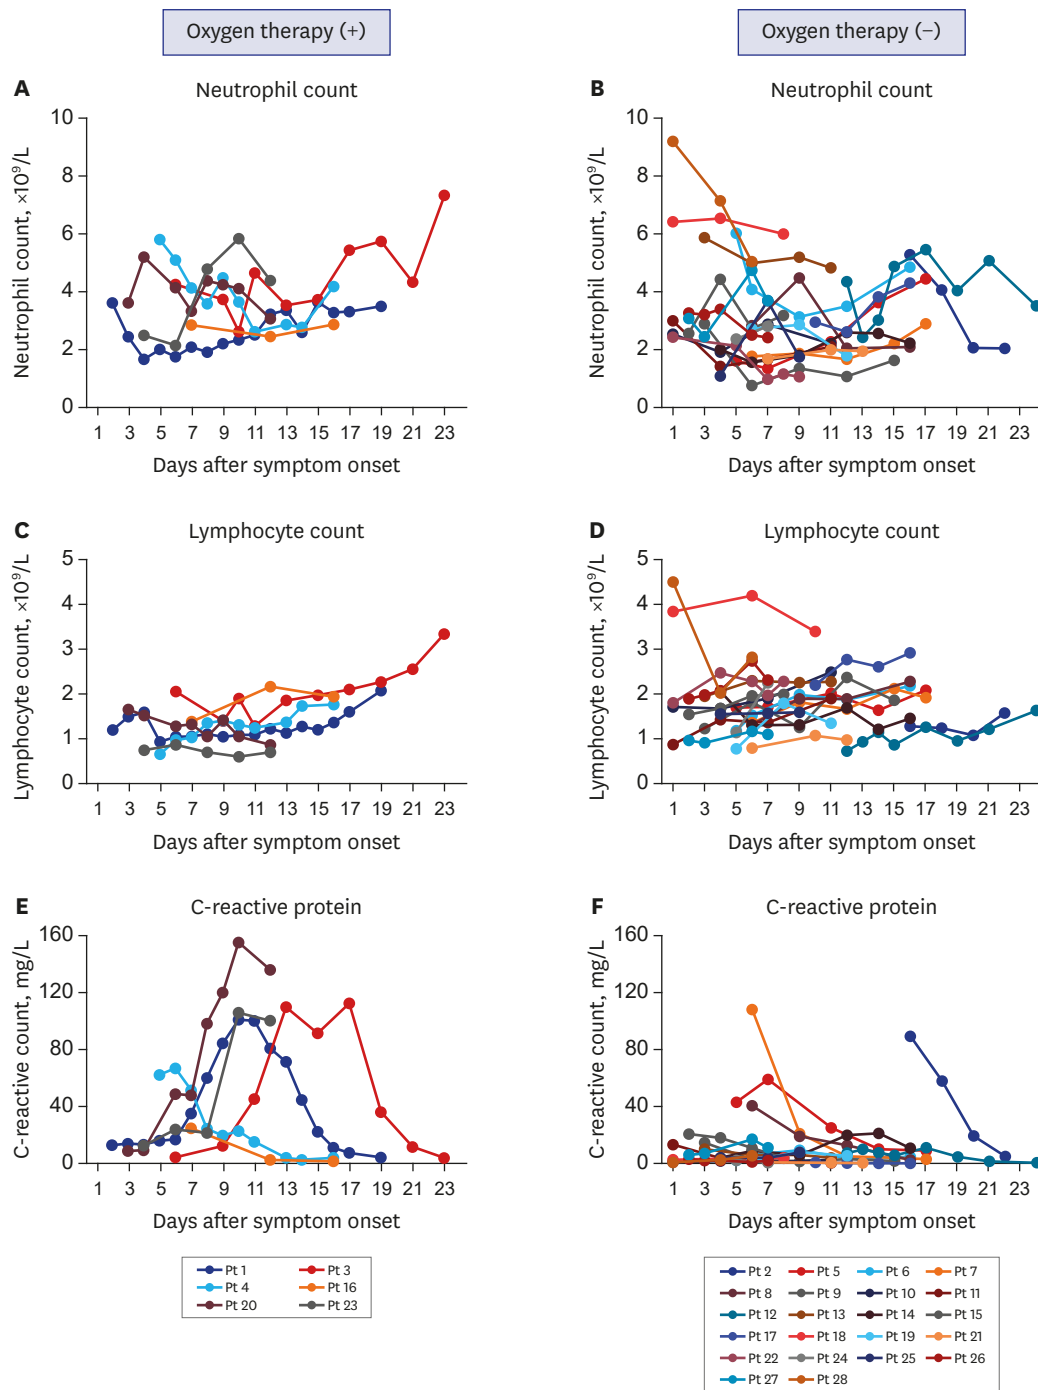

Fig. 1. Changes in laboratory data according to severity over time in 28 patients with COVID-19. Changes in peripheral blood neutrophil counts is shown in (A) and (B) according to requirement of O_2 therapy, respectively. Changes in peripheral blood lymphocyte counts is shown in (C) and (D). Changes in CRP is shown in (E) and (F).

COVID-19 = coronavirus disease 2019, CRP = C-reactive protein, Pt = patient.

In our patient cohort, the clinical features of COVID-19 during the prodromal phase were insidious and mild. Fever was absent in 75.0% of the patients at the time of admission. Throat symptoms, such as pain, discomfort and globus sensation and cough were ranked as relatively common, but only 1/3 had these symptoms. As the prodromal symptoms were

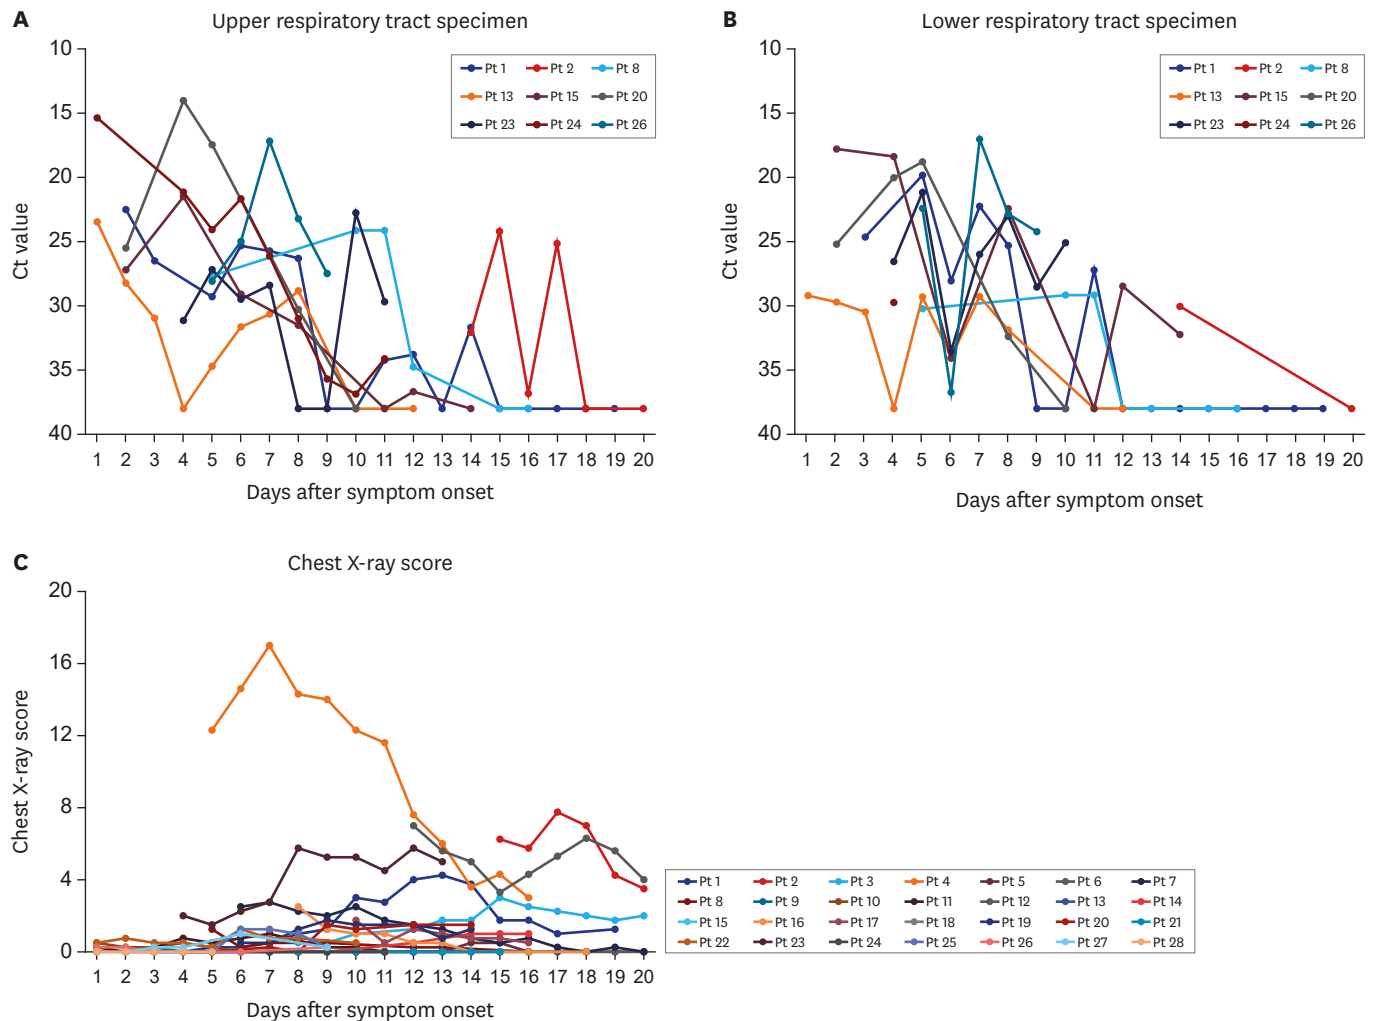

Fig. 2. Changes in SARS-CoV-2 Ct value of RT-PCR in respiratory specimens and radiologic features over time. Changes of Ct value of SARS-CoV-2 RNA (envelope gene, E) in nasopharyngeal with or without oropharyngeal specimen is shown in (A) in 9 patients with COVID-19. Changes of Ct value of SARS-CoV-2 RNA (E) in lower respiratory specimen (expectorate sputum) is shown in (B). Progression of pneumonia in 28 patients is shown in (C). Each lung was divided into the upper, middle, and lower zones, and infiltrates on each zone were scored from 0 to 4 (maximum CXR score, 24). SARS-CoV-2 = severe acute respiratory syndrome coronavirus 2, Ct = cycle threshold, RT-PCR = real time reverse transcription polymerase chain reaction, COVID-19 = coronavirus disease 2019, Pt = patient, CXR = chest X-ray.

mild and did not begin abruptly, most of the patients were not able to tell exactly when they had become ill. And because of this benign nature of the prodromal symptoms, they did not realize that they had been infected with SARS-CoV-2, and went out to carry on usual activities, while spreading the virus inadvertently.

The defining clinical characteristic of COVID-19 was an early development of radiological pneumonia. During the prodromal phase, only 1/3 of our patients developed any clinical features suggesting pneumonia, such as cough, sputum, or chest discomfort. Chest radiographs on hospitalization did not reveal any infiltrates in more than 50% of patients. However, chest CT scans, which were performed on hospitalization or within 1–2 days, showed infiltrates in the lungs suggesting viral pneumonia in 16/18 (88.9%) patients (Table 1). If we had not taken CT scans of the lungs, we would have easily missed the pneumonia diagnosis.⁴ The radiological pneumonia from CT scan was detected as early as day 1 of illness onset. The

most common findings of CT scans were bilateral, ground-glass opacity in the periphery of the lungs as described in previous studies.^{9,11,12} Despite radiological pneumonia, the patients were clinically stable and mobile during the first week of illness (“walking pneumonia”). We assessed the progression of COVID-19 pneumonia using the chest radiograph scoring, and it remained stable during the first week of illness, but increased around the day 7 of illness. This pattern of pneumonia progression was also noted in patients with MERS-CoV infection.¹⁸ The early onset of the lung infiltrates and few clinical manifestations of LRT infection may suggest that the virus can invade into the LRT, evading innate immune mechanisms and replicate before adaptive immune response begins to play a role. A tissue biopsy and immunohistopathological studies of the lungs may elucidate this unique and interesting clinical feature of SARS-CoV-2 infection.

Gastrointestinal manifestations were relatively uncommon in our patient cohort. While 10% of the patients had diarrhea, 3% had vomiting, and 3% had abdominal pain at presentation, all of them revealed other common symptoms of acute respiratory illness. Overall, diarrhea was present in 39% (11/28) of patients during hospitalization from the admission in this study. As diarrhea is an adverse effect of lopinavir/ritonavir, we reassessed the frequency of diarrhea according to the patients being treated with lopinavir/ritonavir or not, and 53% (10/19) and 11% (1/9) of our patients had diarrhea, respectively (data not shown). In Chinese patients, the frequency of diarrhea ranged 2%–10%.^{9,11,12} It is important to note that receptor binding is a major determinant of tissue tropism for a coronavirus.¹⁹ A recent study showed that SARS-CoV-2 used angiotensin converting enzyme II as a cellular entry receptor,^{20,21} as SARS-CoV.¹⁹ Therefore, it is plausible that SARS-CoV-2 may be able to replicate in the gastrointestinal epithelial cells and be excreted in the stool. Recently, China CDC reported that they isolated SARS-CoV-2 from a stool sample taken 15 days after illness onset of a laboratory confirmed patient.²² The possibilities of fecal-to-oral transmission and opportunistic aerosol transmission of SARS-CoV-2 remain to be determined.²³

It is important to note that the virus titers in the respiratory specimens peaked on early days after illness onset (**Fig. 2A and B**). Of the seven infectors of our cohort, two transmitted the virus on the first day of illness, one on the 8th day of illness, and 4 via household transmission. The Ct values of the URT specimens ranged from 18–25 in the 4 infectors within the 5 days of illness: 18.74, 18.33, 25.12, and 21.5 for each patient. Our data suggest that the viral shedding from the URT may reach its peak during the first 3–5 days after illness onset. A recent study on virus shedding kinetics is also in line with our finding.²⁴ This “shift to the left” pattern of virus shedding kinetics is strikingly different from that of SARS-CoV, which shows an inverted V pattern, with its peak at day 10 of illness.²⁵ Also of note is that 57.1% (4/7) of infectors had cough or sputum, in contrast to only 23.8% (5/21) of non-infectors having cough. These findings suggest that the transmissions of SARS-CoV-2 may occur easily and begin from the prodromal phase of illness, just like common cold or influenza viruses. Considering that the median time from symptom onset to isolation of the patients was 3 days, and that high titers of virus shedding began from day 1 of illness with the peak around day 3–5 of illness, early detection and isolation strategy may be relatively less effective in containing the virus in COVID-19.

The clinical outcomes of most patients in this study were not complicated. As of 17 February 2020, no patient required supplemental oxygen therapy with mechanical ventilation nor any organ-supporting treatments in intensive care unit. A total of 10 cases have fully recovered

from the infection and have been discharged from hospital. Of the 18 confirmed cases who are still in hospital, most are stable or improving.

There are some limitations in our study. Only 28 patients from our cohort were included in this study. However, we gathered and analyzed the detailed clinical information about all of the first 28 cases nationwide in Republic of Korea. Moreover, some cases were confirmed during the surveillance test for COVID-19 after exposure to SARS-CoV-2. The proportion of elderly patients and frequency of underlying conditions were small, and therefore the first 28 patients from the early phase of the COVID-19 outbreak in Korea had relatively favorable outcomes.²⁶ Most of the enrolled patients would be healthier than the population of recent larger outbreaks showing worse outcomes, mostly in the elderly group. The results regarding outcomes in this study should be interpreted cautiously. In most cases, we did not perform virologic tests for coinfection of other respiratory viruses such as influenza.

Our study suggests that (1) the prodromal symptoms of SARS-CoV-2 infection were mild, (2) radiological pneumonia was very common, and developed from the early days of illness, (3) pneumonia may progress at day 7 of illness, (4) high titers of the virus shed from the URT during the prodromal phase (5), and the median time from symptom onset to defervescence was 10 days and to off-isolation 18.5 days.

ACKNOWLEDGMENTS

We thank Yu Mi Jung MS (Medical Record Team, National Medical Center) who designed the case record form to collect data.

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Cell Host & Microbe

Infection and Rapid Transmission of SARS-CoV-2 in Ferrets

Graphical Abstract

In Brief

The outbreak of coronavirus disease 2019 (COVID-19) caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) rapidly spreads, leading to a pandemic infection. Kim et al. show that ferrets are highly susceptible to SARS-CoV-2 infection and effectively transmit the virus by direct or indirect contact, recapitulating human infection and transmission.

Highlights

- SARS-CoV-2-infected ferrets exhibit elevated body temperature and virus replication
- SARS-CoV-2 is shed in nasal washes, saliva, urine and feces
- SARS-CoV-2 is effectively transmitted to naive ferrets by direct contact
- SARS-CoV-2 infection leads acute bronchiolitis in infected ferrets

SUMMARY

The outbreak of coronavirus disease 2019 (COVID-19) caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) emerged in China and rapidly spread worldwide. To prevent SARS-CoV-2 dissemination, understanding the *in vivo* characteristics of SARS-CoV-2 is a high priority. We report a ferret model of SARS-CoV-2 infection and transmission that recapitulates aspects of human disease. SARS-CoV-2-infected ferrets exhibit elevated body temperatures and virus replication. Although fatalities were not observed, SARS-CoV-2-infected ferrets shed virus in nasal washes, saliva, urine, and feces up to 8 days post-infection. At 2 days post-contact, SARS-CoV-2 was detected in all naive direct contact ferrets. Furthermore, a few naive indirect contact ferrets were positive for viral RNA, suggesting airborne transmission. Viral antigens were detected in nasal turbinate, trachea, lungs, and intestine with acute bronchiolitis present in infected lungs. Thus, ferrets represent an infection and transmission animal model of COVID-19 that may facilitate development of SARS-CoV-2 therapeutics and vaccines.

Coronaviruses (CoVs) are a large family of viruses that cause respiratory and intestinal infections in animals and humans (Masters and Perlman, 2013). Of the four genera—alphacoronavirus, betacoronavirus, gammacoronavirus, and deltacoronavirus—alphacoronavirus and betacoronavirus are commonly associated with respiratory illness in humans and gastroenteritis in animals (Cui et al., 2019). CoVs were not typically considered to be highly pathogenic in humans until the outbreaks of Severe Acute Respiratory Syndrome CoV (SARS-CoV) (Zhong et al., 2003), Middle East Respiratory Syndrome CoV (MERS-CoV) (Zaki et al., 2012), and more recently, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2).

In late December of 2019, a novel coronavirus disease (COVID-19) was identified in Wuhan City, Hubei Province, China from patients with severe pneumonia (Zhu et al., 2020). Deep sequencing analysis of lower respiratory tract samples revealed the identity of the causative agent as a newly emerged strain of betacoronavirus, temporarily named 2019 novel coronavirus (2019-nCoV) and later renamed as severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) by the International Committee on Taxonomy of Viruses (ICTV) (ICTV, 2020). As of March 23, there have

been approximately 81,601 confirmed cases of COVID-19 in China with over 3,276 deaths (WHO, 2020b). The SARS-CoV-2 has been found to have high human-to-human transmission through close contact with infected patients, leading to rapid global spread by infected travelers from China. As of March 23, 2020, SARS-CoV-2 cases have been confirmed in at least 171 countries with a steady increase in the number of laboratory confirmed cases (251,329 cases) outside of China suggesting that non-pharmaceutical intervention strategies have not ultimately been successful in limiting spread. Therefore, an animal model that recapitulates the COVID-19 clinical symptoms in human infection is urgently needed in order to decipher the transmission routes and pathobiology of this virus and to allow testing of pharmaceutical interventions.

Given that SARS-CoV-2 shares higher sequence homology with SARS-CoV (79% homology) than with MERS-CoV (50% homology), the entry receptor for SARS-CoV, human Angiotensin-converting enzyme 2 (hACE2), was considered as a receptor candidate for SARS-CoV-2 (Lu et al., 2020). Correspondingly, Bao et al. (2020) reported weight loss and virus replication in lungs of hACE2 transgenic mice following SARS-CoV-2

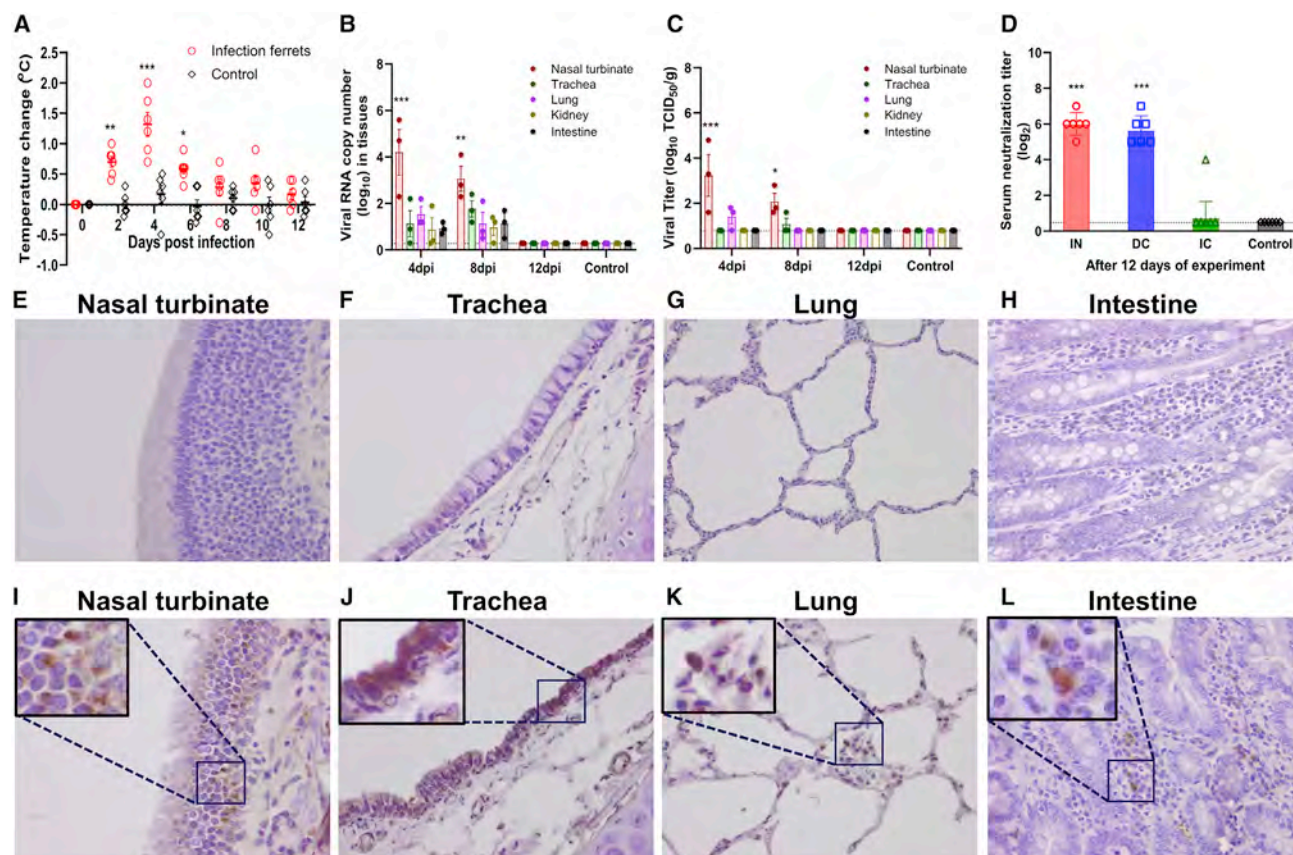

Figure 1. Temperature Changes, Weight Loss, Survival, Viral Shedding, and Immunohistochemistry of Tissues of NMC-nCoV02-Infected Ferrets

(A–C) Six ferrets were inoculated intranasally with $10^{5.5}$ TCID₅₀ of virus. (A) Temperature changes, (B) number of viral RNA copies, and (C) infectious virus titers were measured in tissues of NMC-nCoV02-infected ferrets ($n = 6$ /group). Each tissue ($n = 3$ per group) was collected at 4, 8, and 12 dpi. Viral loads in nasal turbinate, trachea, lung, kidney, and intestine were titrated using quantitative real-time PCR and TCID₅₀. Data are presented as mean \pm SEM.

(D) Serum neutralizing (SN) antibody titers (GMT) against NMC-nCoV02 (100 TCID₅₀) were measured onto Vero cells after 12 days of experiment ($n = 6$ per group). Data are presented as geometric mean \pm SD. Tissues were harvested on day 4 after inoculation and immunohistochemistry was performed with a mouse polyclonal antibody.

(E–H) Tissues of PBS control ferrets; (E) nasal turbinate, (F) trachea, (G) lung, and (H) intestine.

(I–L) Tissues of NMC-nCoV02 infected ferrets: (I) Nasal turbinate, (J) Trachea, (K) lung, and (L) Intestine.

The presence of NMC-nCoV02 antigen was determined by IHC with mouse polyclonal antibody. Magnification $\times 400$. Asterisks indicate statistical significance compared with PBS control group by the two-way ANOVA with Sidak's multiple comparisons test (A), the two way ANOVA with Dunnett's multiple comparisons test (B and C), or one-way ANOVA Dunnett's multiple comparisons test (* indicates $p < 0.05$, ** indicates $p < 0.001$, and *** indicates $p < 0.0001$).

infection; however, no other clinical symptoms such as cough or fever were observed. In order to understand the rapid spreading characteristics of SARS-CoV-2, additional animal models that mimic high human-to-human transmission of SARS-CoV-2 infections are warranted. Given that ferret ACE2 has been shown to contain critical SARS-CoV binding residues (Wan et al., 2020), we performed infection and direct and indirect contact transmission studies using a ferret model previously developed for influenza virus infections (Park et al., 2018; Bouvier, 2015).

To demonstrate ferret-to-ferret transmission in an experimental setting, ferrets ($n = 2$) were inoculated via the intranasal (IN) route with $10^{5.5}$ TCID₅₀ of NMC-nCoV02, a strain that was isolated from a COVID-19-confirmed patient in South Korea in February of 2020. To evaluate the transmission mode of the virus, naive ferrets ($n = 2$ /group) were placed in direct contact (DC) (co-housed) or indirect contact (IC) (housed in cages with a

permeable partition separating them from infected ferrets) with infected ferrets two days after the primary infection. Clinical features of SARS-CoV-2 infections were recorded. This study was repeated in three independent trials (total $n = 24$; direct infection [$n = 6$], DC [$n = 6$], IC [$n = 6$], and PBS control [$n = 6$] ferrets).

NMC-nCoV02-infected ferrets had elevated body temperatures, from 38.1°C to 40.3°C, between 2 and 8 dpi; these returned to normal by 8 dpi (Figure 1A). While reduced activity was observed in NMC-nCoV02-infected ferrets between 2 and 6 dpi with occasional coughs, there was no detectable body weight loss, nor were there any fatalities during the experimental period. Interestingly, all six DC ferrets showed increased body temperatures ($\sim 39^\circ\text{C}$) with reduced activity between 4 and 6 days post contact (dpc) and no detectable body weight loss (Figures S1A and S1B). However, none of the IC ferrets showed increased body temperature or weight loss over the 12 days of the studies (Figures S1C

Table 1. Quantitation of Viral RNA in Specimens (Serum, Feces, Nasal Wash, Saliva, and Urine) from Each Group of Ferrets

^aVirus spike RNA gene detection limit and viral titer limit were 0.3 log₁₀ copies/mL and 0.8 log₁₀ TCID₅₀/mL, respectively.

^bIsolated viruses from nasal wash samples inoculated in ferrets.

and S1D). These data indicate that the efficient establishment of COVID-19 clinical features in ferrets exposed to infected animals requires direct contact, recapitulating human-to-human transmission.

To investigate SARS-CoV-2 replication and shedding in each group of ferrets, we collected blood, nasal washes, saliva, urine, and fecal specimens every other day for 12 days. Collected ferret secretions were resuspended in cold phosphate-buffered saline (PBS) containing antibiotics (5% penicillin/streptomycin; GIBCO). For virus titration, total RNA was extracted from the collected samples using the RNeasy Mini kit (QIAGEN, Hilden, Germany) according to the manufacturer's instructions (QIAGEN, 2012) and cDNA was synthesized with a cDNA synthesis kit (Omniscrypt Reverse Transcriptase; QIAGEN, Hilden, Germany). To quantitate viral RNA copy number, quantitative real-time RT-PCR (qRT-PCR) was performed targeting the spike (Table 1) and ORF1a (Table S1) genes as previously described (Zhu et al., 2020) using the SYBR Green kit (iQTM SYBR Green supermix kit, Bio-Rad, Hercules, CA, USA). The number of viral RNA copies was calculated by comparison to the number of copies of a standard control. In the NMC-nCoV2 infected group, viral spike RNA was detected in all specimens at 2 dpi. The highest amount of viral RNA was detected in nasal washes and peaked at 4 dpi (3.83 log₁₀ copies/mL), persisting until 8 dpi before dropping below detection limits at 10 dpi (Table 1).

The virus was also detected in saliva specimens from 2 dpi (1.73 log₁₀ copies/mL) through 8 dpi. Although viral spike RNA was detected in sera of infected ferrets, the viral copy number was low (peaked titer 0.35 log₁₀ copies/mL) and dropped below detection limits earlier than in nasal wash and saliva specimens. To evaluate the infectious virus titer in each specimen, collected nasal washes and saliva specimens were inoculated onto Vero cells for virus isolation. In IN infected ferret group, NMC-nCoV2 was isolated from both saliva and nasal washes specimens as early as 2 dpi and persisted until 4 and 6 dpi, respectively (Table 1). Nasal washes specimens showed higher virus titers (1.83–2.88 log₁₀ TCID₅₀/mL) than saliva specimens (0.82–0.92 log₁₀ TCID₅₀/mL). In DC ferret group, virus was isolated from the nasal washes at 4 dpc (2.4 log₁₀ TCID₅₀/mL) and 6 dpc (1.0 log₁₀ TCID₅₀/mL) but not in saliva specimens (Table 1). Because gastrointestinal involvement is a characteristic of coronavirus infections of animals and humans (Leung et al., 2003), we also collected fecal and urine specimens. Viral RNA was detected in a majority of collected specimens in both IN-infected and DC groups as early as 2 dpc (Table 1). Similarly to the IN infected group, the DC group had the highest virus copy numbers (3.27 log₁₀ copies/mL) in nasal washes, with RNA detected through 8 dpc. In addition, viral RNA was detected in saliva and fecal specimens of the DC group for 8 days, whereas the urine

specimens contained detectable viral RNA until 4 dpc. For the IC group, 2 out of 6 ferrets were positive for viral RNA in nasal washes and fecal specimens at 4 dpc, although viral RNA copy numbers were lower (0.53 and 0.52 log₁₀ copies/mL, respectively) than in DC ferrets. Due to the cytotoxicity of urine and fecal specimens of ferrets, we could not assess virus isolation and titer in Vero cells. To evaluate the presence of infectious NMC-nCoV2 in urine and fecal specimens, urine or fecal specimens (at 4 dpi) of IN-infected DC or IC ferrets were centrifuged to remove the debris, and the supernatants were inoculated into naive ferrets (n = 3) per each specimen. Nasal washes from specimen-inoculated ferrets were collected at 2, 4, and 6 dpi and infected onto Vero cells for virus isolation. Noticeably, NMC-nCoV2 was isolated from the nasal wash specimens of 2 out of 3 urine-specimen-treated or fecal-specimen-treated ferrets (Table 1). However, we failed to re-isolate virus from the ferrets infected with the fecal specimens of IC ferrets. These results indicate that ferret is highly susceptible for the infection of SARS-CoV-2 derived from body fluids, and infectious SARS-CoV-2 sheds through urine and fecal specimens of infected ferrets.

To assess the replication of SARS-CoV-2 in ferret organs, an additional 12 ferrets were infected with NMC-nCoV2 or PBS via the IN route and 3 ferrets were sacrificed at 4, 8, and 12 dpi. Nasal turbinate, trachea, lung, kidney, and intestine tissues were collected using individual scissors to avoid cross contamination. The highest viral RNA levels were detected in nasal turbinate (4.2 log₁₀ copies/g) and lung tissue (1.53 log₁₀ copies/g) at 4 dpi. Viral RNA was also detected in intestine (0.93 log₁₀ copies/g) and kidney (0.87 log₁₀ copies/g) at 4 dpi. At 8 dpi, viral RNA was still detected in nasal turbinate, trachea, lungs, kidney, and intestine (Figure 1B). In correlation with viral RNA copy numbers (Figure 1B), the highest infectious virus titer was detected in nasal turbinate (3.23 log₁₀ TCID₅₀/g) and lung tissue (1.4 log₁₀ TCID₅₀/g) at 4 dpi, whereas infectious virus recovery failed from trachea, kidney, and intestine tissues, which carried less than 1.13 log₁₀ viral RNA copies/g (Figure 1C). Finally, infectious NMC-nCoV2 was isolated from nasal turbinate (2.07 log₁₀ TCID₅₀/g) and trachea (1.07 log₁₀ TCID₅₀/g) at 8 dpi but not from other tissues at 8 dpi (Figure 1C). However, both viral RNA detection and virus recovery failed in all tested tissues at 12 dpi. These results suggest that virus isolation from infected tissues is closely related to viral RNA copy number.

To further confirm viral replication in infected ferrets, immunohistochemistry (IHC) and histopathological examinations were conducted (Figure 1 and Figure S2). Briefly, tissue samples were collected from NMC-nCoV2 infected or PBS-treated ferrets at 4 dpi and incubated in 10% neutral-buffered formalin for virus inactivation and tissue fixation before they were embedded in paraffin. The embedded tissues were sectioned and dried for 3 days at room temperature. To detect the viral antigens by IHC, mouse polyclonal antibody raised by the immunization of mice with inactivated NMC-nCoV2 virions was used as a primary antibody. Slides were viewed using the Olympus BX53 (Olympus, Tokyo, Japan) microscope with DP controller software to capture images. IHC analyses showed that a number of cells in the nasal turbinate, trachea, lung, and intestine sections of NMC-nCoV2-infected ferrets (Figures 1I–1L), but not

PBS-treated control ferrets (Figures 1E–1H), were positive for SARS-CoV-2 antigen. Further, the lung histopathology showed that, compared with PBS-treated ferrets, NMC-nCoV2-infected ferrets at 4 dpi showed increased immune infiltration and cell debris in the alveolar wall, bronchial epithelium, and bronchial lumen (Figure S2), evidencing acute bronchiolitis by NMC-nCoV2 infection.

After 12 days of infection, all remaining ferrets, including IN infection (n = 6), DC (n = 6), and IC (n = 6), had returned to normal ranges of body temperature and body weight, and all specimens were negative for viral RNA. To evaluate the seroconversion rate of each group, sera were collected from all remaining ferrets and a serum-neutralizing (SN) antibody assay against NMC-nCoV2 (100 TCID₅₀) was conducted on Vero cells. Although IN infection group showed the highest mean SN titers compared the other groups, the SN titers of both IN infection and DC groups ranged between 32 and 128 (Figure 1D). On the other hand, only 1 of 6 IC ferrets showed a positive SN titer of 16. Taken together, this demonstrates the presence of SARS-CoV-2 in multiple sources from infected ferrets, potentially explaining the rapid transmission to naive hosts in close contact with the infected hosts.

Given the rapid geographical spread of COVID-19, the WHO declared the SARS-CoV-2 outbreak a public health emergency of international concern (PHEIC) on the 30th of January, 2020 (WHO, 2020a) and labeled the COVID-19 outbreak a pandemic by the 12th of March, 2020 (WHO, 2020). Most confirmed COVID-19 patients at this time reported close epidemiological association (direct or indirect) with other COVID-19 patients. Interestingly, a growing number of individuals with no travel history to China and no direct contact with infected patients have become infected (Lim et al., 2020). To understand how this virus rapidly spreads within a community, and to inform infection control messaging, it is essential to develop an experimental animal model that can support the active infection, shedding, and transmission of SARS-CoV-2 to sentinel animals. In this study, we established an infection and transmission ferret animal model for COVID-19. The SARS-CoV-2 was found to efficiently infect ferrets and induce moderate increases in body temperature (~38.5–40.3°C). Moreover, we were able to detect viral RNA in blood (for 4 dpi), nasal washes (for 8 dpi), urine (for 8 dpi), and fecal (for 8 dpi) specimens. Findings suggest that SARS-CoV-2 can be shed through multiple routes of body discharge specimens, with these potentially serving as sources for viral transmission to those in close contact with infected individuals.

Interestingly, ferrets in direct contact with SARS-CoV-2-infected ferrets were positive for SARS-CoV-2 infection as early as 2 dpc, suggesting that rapid transmission occurred even prior to infected ferrets reaching their highest viral RNA copy numbers in nasal washes at 4 dpi. Transmission also occurred prior to peak body temperature and body weight loss in infected animals, which is consistent with the infectiousness of individuals during asymptomatic periods. With regard to potential airborne transmission of SARS-CoV-2, viral RNA was detected in nasal washes and fecal specimens in IC ferrets and persisted for 4 days after indirect contact; only one of the two positive animals seroconverted. These data show that airborne transmission is likely but is considerably less robust than direct contact transmission.

Following the fortuitous discovery of the natural susceptibility of ferrets to human influenza viruses, ferret models were found to highly reproduce the human disease manifestation of several respiratory viruses, including respiratory syncytial virus, parainfluenzaviruses, and SARS-CoV-1 (Capraro et al., 2008; Chan et al., 2018; Enkirch and von Messling, 2015; Park et al., 2018). In addition to the presence of the respective viral receptors, the anatomic proportions of the ferret upper and lower respiratory tracts, the density of submucosal glands in the bronchial wall, and the number of generations of terminal bronchioles all reproduce the condition in the human respiratory tract (Enkirch and von Messling, 2015). This further supports the significance of ferrets as animal model for human respiratory viral infection. We demonstrated that SARS-CoV-2-infected ferrets showed high virus titers in upper respiratory tracts (nasal washes) and consequently transmitted to naive ferrets by direct contact at high efficiency, suggesting that SARS-CoV-2 ferret model recapitulates aspects of human infection and transmission. Further, as suspected in recent COVID-19 patients (Kim et al., 2020; Xu et al., 2020), we detected the infectious viruses in urine and fecal specimens of virus-infected ferrets. However, there are also limitations in the SARS-CoV-2 ferret model, as SARS-CoV-2 infected ferrets showed only mild clinical symptoms and relatively lower virus titers in lungs of infected animals than SARS-CoV-1-infected or MERS-CoV-infected hACE2 or hDPP4 transgenic mice (Glass et al., 2004 and Li et al., 2017). On the other hand, it is also possible that SARS-CoV-2 replicates weaker but persists longer *in vivo* than SARS-CoV-1, ultimately leading an asymptomatic carrier with a persistent infection to effectively spread the virus. Therefore, given the rapid spreading characteristics of SARS-CoV-2 in humans, ferret model would be a useful tool to evaluate the efficacy of prophylactic anti-virals and preventive vaccines.

STAR★METHODS

Detailed methods are provided in the online version of this paper and include the following:

ACKNOWLEDGEMENT

All animal experiments were approved by the Medical Research Institute, a member of the Laboratory Animal Research Center of Chungbuk National University (LARC) (approval number CBNUA-1352-20-02), and were conducted in strict accordance and adherence to relevant policies regarding animal handling as mandated under the Guidelines for Animal Use and Care of the Korea Center for Disease Control (K-CDC). Viruses were handled in an enhanced biosafety level 3 (BSL3) containment laboratory as approved by the Korean Centers for Disease Control and Prevention (KCDC-14-3-07).

This work was supported by National Research Foundation of Korea (NRF-2018M3A9H4056536, 2020R1A2C 3008339), the Korea Research Institute of Bioscience and Biotechnology (KRIBB) Research Initiative Program (KGM9942011), the National Institute of Health (AI140705, AI140718, AI152190, and AI116585), and the National Institute of Allergy and Infectious Diseases (Centers of Excellence for Influenza Research and Surveillance [CEIRS] contract number HHSN272201400006C).

RESOURCE AVAILABILITY

Lead Contact

Further information and requests for resources and reagents should be directed to and will be fulfilled by the Lead Contact, Young Ki Choi (choiki55@chungbuk.ac.kr).

Materials Availability

All unique/stable reagents generated in this study are available from the Lead Contact with a completed Materials Transfer Agreement.

Data Code and Availability

This study did not generate any unique datasets or code.

EXPERIMENTAL MODEL AND SUBJECT DETAILS

Experimental Animals

Male and female ferrets, 12- to 20- month old and sero-negative for influenza A viruses, MERS-CoV, and SARS-CoV (ID Bio Corporation) were maintained in the isolator (woori IB Corporation) in BSL3 of Chungbuk National University. All ferrets were group housed with a 12 h light/dark cycle and allowed access to diet and water. All animal studies were carried out in accordance with protocols approved by the Institutional Animal Care and Use Committee (IACUC) in Chungbuk National University.

Growth and Isolation of Virus

Virus was isolated from an isolate of SARS-CoV-2 from a COVID-19 confirmed patient in Korea. To infect the animal, viruses were propagated on the Vero cells in the DMEM medium (GIBCO) supplemented with 1% penicillin/streptomycin (GIBCO) and TPCK trypsin (0.5ug/mL; Worthington Biochemical) at 37°C for 72 h. Propagated viruses were stored at –80°C freezer for future usage.

METHOD DETAILS

Study Design for Animal-to-Animal Transmission

12–24 month old male and female ferrets, which were confirmed as Influenza A (H1N1, H3N1), MERS-CoV, and SARS-CoV antibody free ferrets by the standard enzyme-linked immunosorbent assay (ELISA) previously described elsewhere (El-Duah et al., 2019; Park et al., 2014; Woo et al., 2005), were infected through intranasal (IN) route with NMC2019-nCoV02 virus, an isolate of SARS-CoV-2 from a COVID-19 confirmed patient in Korea, 2020 February, at a dose of $10^{5.5}$ TCID₅₀ per ferrets (n = 2). At one-day post-infection, one naive direct contact (DC) and indirect contact (IC) ferrets were introduced into the cage, while IC ferrets were separated from inoculated animals with a partition, which allowed air to move, and without direct contact between animals. This study was conducted with three independent trials. Blood, fecal, nasal wash, saliva, and urine specimens were collected every other day for 12 days from each group of ferrets to detect SARS-CoV-2. Further, to investigate whether each collected specimen contained infectious live virus, we inoculated it onto Vero cells.

To access the replication of the virus in ferrets following SARS-CoV-2 infection in various organs, additional 9 ferrets were infected with SARS-CoV-2 by IN route. Three ferrets were sacrificed at 4, 8 and 12 dpi were and their lung, liver, spleen, kidney, and intestinal tissues were collected with individual scissors to avoid cross contamination.

Quantitative Real-Time RT-PCR (qRT-PCR) to Detect SARS-CoV-2 RNA

Collected ferret secretions were resuspended with cold phosphate-buffered saline (PBS) containing antibiotics (5% penicillin/streptomycin; GIBCO). For virus titration, total RNA was extracted from the collected samples using the RNeasy Mini® kit (QIAGEN, Hilden, Germany) according to the manufacturer's instructions. A cDNA synthesis kit (Omniscript Reverse Transcriptase; QIAGEN, Hilden, Germany) was used to synthesize single strand cDNA using total viral RNA. To quantify viral RNA and viral copy number, quantitative real-time RT-PCR (qRT-PCR) was performed for the partial Spike gene (Table 1) and ORF1a (Table S1) with the SYBR Green kit (iQ™ SYBR Green supermix kit, Bio-Rad, Hercules, CA, USA), and the number of viral RNA copies was calculated and compared to the number of copies of the standard control.

Immunohistochemistry (IHC)

Tissue samples were collected from PBS control and NMC-nCoV02 infected ferrets and incubated in 10% neutral-buffered formalin for fixation before they were embedded in paraffin based to standard procedures. The embedded tissues were sectioned and dried for 3 days at room temperature. To detect the viral antigen by immunohistochemistry, mouse polyclonal antibody developed by inactivated NMC-nCoV02 was used as the primary antibody. Antigen was visualized using the biotin-avidin system (Vector Labs). Slides were viewed using the Olympus IX 71 (Olympus, Tokyo, Japan) microscope with DP controller software to capture images.

QUANTIFICATION AND STATISTICAL ANALYSIS

Statistical Analysis

The statistical significance of infected and contact samples compared with naive sample was assessed by two-way ANOVA with Sidaks multiple comparisons test and one way ANOVA Dunnett's multiple comparisons test. While for the comparison of the significance of viral copy number or titer among samples, we use the two-way ANOVA with Dunnett's multiple comparisons test.

Data plotting, interpolation and statistical analysis were performed using GraphPad Prism 8.2 (GraphPad Software, La Jolla, CA). Statistical details of experiments are described in the figure legends. A p value less than 0.05 is considered statistically significant.

Asymptomatic and Presymptomatic SARS-CoV-2 Infections in Residents of a Long-Term Care Skilled Nursing Facility — King County, Washington, March 2020

Jernigan, MD¹; Public Health – Seattle & King County; CDC COVID-19 Investigation Team

On March 27, 2020, this report was posted as an MMWR Early Release on the MMWR website (<https://www.cdc.gov/mmwr>).

Older adults are susceptible to severe coronavirus disease 2019 (COVID-19) outcomes as a consequence of their age and, in some cases, underlying health conditions (1). A COVID-19 outbreak in a long-term care skilled nursing facility (SNF) in King County, Washington that was first identified on February 28, 2020, highlighted the potential for rapid spread among residents of these types of facilities (2). On March 1, a health care provider at a second long-term care skilled nursing facility (facility A) in King County, Washington, had a positive test result for SARS-CoV-2, the novel coronavirus that causes COVID-19, after working while symptomatic on February 26 and 28. By March 6, seven residents of this second facility were symptomatic and had positive test results for SARS-CoV-2. On March 13, CDC performed symptom assessments and SARS-CoV-2 testing for 76 (93%) of the 82 facility A residents to evaluate the utility of symptom screening for identification of COVID-19 in SNF residents. Residents were categorized as asymptomatic or symptomatic at the time of testing, based on the absence or presence of fever, cough, shortness of breath, or other symptoms on the day of testing or during the preceding 14 days. Among 23 (30%) residents with positive test results, 10 (43%) had symptoms on the date of testing, and 13 (57%) were asymptomatic. Seven days after testing, 10 of these 13 previously asymptomatic residents had developed symptoms and were recategorized as presymptomatic at the time of testing. The reverse transcription–polymerase chain reaction (RT-PCR) testing cycle threshold (Ct) values indicated large quantities of viral RNA in asymptomatic, presymptomatic, and symptomatic residents, suggesting the potential for transmission regardless of symptoms. Symptom-based screening in SNFs could fail to identify approximately half of residents with COVID-19. Long-term care facilities should take proactive steps to prevent introduction of SARS-CoV-2 (3). Once a confirmed case is identified in an SNF, all residents should be placed on isolation precautions if possible (3), with considerations for extended use or reuse of personal protective equipment (PPE) as needed (4).

Immediately upon identification of the index case in facility A on March 1, nursing and administrative leadership instituted visitor restrictions, twice-daily assessments of COVID-19 signs and symptoms among residents, and fever screening of all health care personnel at the start of each shift. On March 6, Public Health – Seattle and King County, in collaboration with CDC, recommended infection prevention and control measures, including isolation of all symptomatic residents and use of gowns, gloves, eye protection, facemasks, and hand hygiene for health care personnel entering symptomatic residents' rooms. A data collection tool was developed to ascertain symptom status and underlying medical conditions for all residents.

On March 13, the symptom assessment tool was completed by facility A's nursing staff members by reviewing screening records of residents for the preceding 14 days and by clinician interview of residents at the time of specimen collection. For residents with significant cognitive impairment, symptoms were obtained solely from screening records. A follow-up symptom assessment was completed 7 days later by nursing staff members. Nasopharyngeal swabs were obtained from all 76 residents who agreed to testing and were present in the facility at the time; oropharyngeal swabs were also collected from most residents, depending upon their cooperation. The Washington State Public Health Laboratory performed one-step real-time RT-PCR assay on all specimens using the SARS-CoV-2 CDC assay protocol, which determines the presence of the virus through identification of two genetic markers, the N1 and N2 nucleocapsid protein gene regions (5). The Ct, the cycle number during RT-PCR testing when detection of viral amplicons occurs, is inversely correlated with the amount of RNA present; a Ct value <40 cycles denotes a positive result for SARS-CoV-2, with a lower value indicating a larger amount of viral RNA.

Residents were assessed for stable chronic symptoms (e.g., chronic, unchanged cough) as well as typical and atypical signs and symptoms of COVID-19. Typical COVID-19 signs and symptoms include fever, cough, and shortness of breath (3); potential atypical symptoms assessed included sore throat,

Summary

What is already known about this topic?

Once SARS-CoV-2 is introduced in a long-term care skilled nursing facility (SNF), rapid transmission can occur.

What is added by this report?

Following identification of a case of coronavirus disease 2019 (COVID-19) in a health care worker, 76 of 82 residents of an SNF were tested for SARS-CoV-2; 23 (30.3%) had positive test results, approximately half of whom were asymptomatic or presymptomatic on the day of testing.

What are the implications for public health practice?

Symptom-based screening of SNF residents might fail to identify all SARS-CoV-2 infections. Asymptomatic and presymptomatic SNF residents might contribute to SARS-CoV-2 transmission. Once a facility has confirmed a COVID-19 case, all residents should be cared for using CDC-recommended personal protective equipment (PPE), with considerations for extended use or reuse of PPE as needed.

chills, increased confusion, rhinorrhea or nasal congestion, myalgia, dizziness, malaise, headache, nausea, and diarrhea. Residents were categorized as asymptomatic (no symptoms or only stable chronic symptoms) or symptomatic (at least one new or worsened typical or atypical symptom of COVID-19) on the day of testing or during the preceding 14 days. Residents with positive test results and were asymptomatic at time of testing were reevaluated 1 week later to ascertain whether any symptoms had developed in the interim. Those who developed new symptoms were recategorized as presymptomatic. Ct values were compared for the recategorized symptom groups using one-way analysis of variance (ANOVA) for all residents with positive test results for SARS-CoV-2. Analyses were conducted using SAS statistical software (version 9.4; SAS Institute).

On March 13, among the 82 residents in facility A; 76 (92.7%) underwent symptom assessment and testing; three (3.7%) refused testing, two (2.4%) who had COVID-19 symptoms were transferred to a hospital before testing, and one (1.2%) was unavailable. Among the 76 tested residents, 23 (30.3%) had positive test results.

Demographic characteristics were similar among the 53 (69.7%) residents with negative test results and the 23 (30.3%) with positive test results (Table 1). Among the 23 residents with positive test results, 10 (43.5%) were symptomatic, and 13 (56.5%) were asymptomatic. Eight symptomatic residents had typical COVID-19 symptoms, and two had only atypical symptoms; the most common atypical symptoms reported were malaise (four residents) and nausea (three). Thirteen (24.5%) residents who had negative test results also reported typical and atypical COVID-19 symptoms during the 14 days preceding testing.

One week after testing, the 13 residents who had positive test results and were asymptomatic on the date of testing were reassessed; 10 had developed symptoms and were recategorized as presymptomatic at the time of testing (Table 2). The most common signs and symptoms that developed were fever (eight residents), malaise (six), and cough (five). The mean interval from testing to symptom onset in the presymptomatic residents was 3 days. Three residents with positive test results remained asymptomatic.

Real-time RT-PCR Ct values for both genetic markers among residents with positive test results for SARS-CoV-2 ranged from 18.6 to 29.2 (symptomatic [typical symptoms]), 24.3 to 26.3 (symptomatic [atypical symptoms only]), 15.3 to 37.9 (presymptomatic), and 21.9 to 31.0 (asymptomatic) (Figure). There were no significant differences between the mean Ct values in the four symptom status groups ($p = 0.3$).

Discussion

Sixteen days after introduction of SARS-CoV-2 into facility A, facility-wide testing identified a 30.3% prevalence of infection among residents, indicating very rapid spread, despite early adoption of infection prevention and control measures. Approximately half of all residents with positive test results did not have any symptoms at the time of testing, suggesting that transmission from asymptomatic and presymptomatic residents, who were not recognized as having SARS-CoV-2 infection and therefore not isolated, might have contributed to further spread. Similarly, studies have shown that influenza in the elderly, including those living in SNFs, often manifests as few or atypical symptoms, delaying diagnosis and contributing to transmission (6–8). These findings have important implications for infection control. Current interventions for preventing SARS-CoV-2 transmission primarily rely on presence of signs and symptoms to identify and isolate residents or patients who might have COVID-19. If asymptomatic or presymptomatic residents play an important role in transmission in this population at high risk, additional prevention measures merit consideration, including using testing to guide cohorting strategies or using transmission-based precautions for all residents of a facility after introduction of SARS-CoV-2. Limitations in availability of tests might necessitate taking the latter approach at this time.

Although these findings do not quantify the relative contributions of asymptomatic or presymptomatic residents to SARS-CoV-2 transmission in facility A, they suggest that these residents have the potential for substantial viral shedding. Low Ct values, which indicate large quantities of viral RNA, were identified for most of these residents, and there was no statistically significant difference in distribution of Ct values among the symptom status groups. Similar Ct values were reported in asymptomatic adults in China who were known to

TABLE 1. Demographics and reported symptoms for residents of a long-term care skilled nursing facility at time of testing* (N = 76), by SARS-CoV-2 test results — facility A, King County, Washington, March 2020

Characteristic	Initial SARS-CoV-2 test results	
	Negative, no. (%)	Positive, no. (%)

† Unknown for one resident with negative test results.

§ Typical symptoms include fever, cough, and shortness of breath.

¶ Atypical symptoms include chills, malaise, sore throat, increased confusion, rhinorrhea or nasal congestion, myalgia, dizziness, headache, nausea, and diarrhea.

** Residents might have multiple conditions.

transmit SARS-CoV-2 (9). Studies to determine the presence of viable virus from these specimens are currently under way.

SNFs have additional infection prevention and control challenges compared with those of assisted living or independent living long-term care facilities. For example, SNF residents might be in shared rooms rather than individual apartments, and there is often prolonged and close contact between residents and health care providers related to the residents' medical conditions and cognitive function. The index patient in this outbreak was a health care provider, which might have contributed to rapid spread in the facility. In addition, health care personnel in all types

of long-term care facilities might have limited experience with proper use of PPE. Symptom ascertainment and room isolation can be exceptionally challenging in elderly residents with neurologic conditions, including dementia. In addition, symptoms of COVID-19 are common and might have multiple etiologies in this population; 24.5% of facility A residents with negative test results for SARS-CoV-2 reported typical or atypical symptoms.

The findings in this report are subject to at least two limitations. First, accurate symptom ascertainment in persons with cognitive impairment and other disabilities is challenging; however, this limitation is estimated to be representative of

TABLE 2. Follow-up symptom assessment 1 week after testing for SARS-CoV-2 among 13 residents of a long-term care skilled nursing facility who were asymptomatic on March 13, 2020 (date of testing) and had positive test results — facility A, King County, Washington, March 2020

Symptom status 1 week after testing	No. (%)
Asymptomatic	3 (23.1)
Developed new symptoms	10 (76.7)

Confusion	4 (30.8)
Rhinorrhea/Congestion	4 (30.8)
Shortness of breath	3 (23.1)
Diarrhea	3 (23.1)
Sore throat	1 (7.7)
Nausea	1 (7.7)
Dizziness	1 (7.7)

symptom data collected in most SNFs, and thus, these findings might be generalizable. Second, because this analysis was conducted among residents of an SNF, it is not known whether findings apply to the general population, including younger persons, those without underlying medical conditions, or similarly aged populations in the general community.

This analysis suggests that symptom screening could initially fail to identify approximately one half of SNF residents with SARS-CoV-2 infection. Unrecognized asymptomatic and presymptomatic infections might contribute to transmission in these settings. During the current COVID-19 pandemic, SNFs and all long-term care facilities should take proactive steps to prevent introduction of SARS-CoV-2, including restricting visitors except in compassionate care situations, restricting nonessential personnel from entering the building, asking staff members to monitor themselves for fever and other symptoms, screening all staff members at the beginning of their shift for fever and other symptoms, and supporting staff member sick leave, including for those with mild symptoms (3). Once a facility has a case of COVID-19, broad strategies should be implemented to prevent transmission, including restriction of resident-to-resident interactions, universal use of facemasks for all health care personnel while in the facility, and if possible, use of CDC-recommended PPE for the care of all residents (i.e., gown, gloves, eye protection, N95 respirator, or, if not available, a face mask) (3). In settings where PPE supplies are limited, strategies for extended PPE use and limited reuse should be employed (4). As testing availability improves, consideration might be given to test-based strategies for identifying residents with SARS-CoV-2 infection for the purpose of cohorting, either in designated units within a facility or in a separate facility designated for residents with COVID-19. During the COVID-19 pandemic, collaborative efforts are crucial to protecting the most vulnerable populations.

Middle East respiratory syndrome coronavirus (MERS-CoV) is a lineage C betacoronavirus, and infections with this virus can result in acute respiratory syndrome with renal failure. Globally, MERS-CoV has been responsible for 877 laboratory-confirmed infections, including 317 deaths, since September 2012. As there is a paucity of information regarding the molecular pathogenesis associated with this virus or the identities of novel antiviral drug targets, we performed temporal kinome analysis on human hepatocytes infected with the Erasmus isolate of MERS-CoV with peptide kinome arrays. bioinformatics analysis of our kinome data, including pathway overrepresentation analysis (ORA) and functional network analysis, suggested that extracellular signal-regulated kinase (ERK)/mitogen-activated protein kinase (MAPK) and phosphoinositol 3-kinase (PI3K)/serine-threonine kinase (AKT)/mammalian target of rapamycin (mTOR) signaling responses were specifically modulated in response to MERS-CoV infection *in vitro* throughout the course of infection. The overrepresentation of specific intermediates within these pathways determined by pathway and functional network analysis of our kinome data correlated with similar patterns of phosphorylation determined through Western blot array analysis. In addition, analysis of the effects of specific kinase inhibitors on MERS-CoV infection in tissue culture models confirmed these cellular response observations. Further, we have demonstrated that a subset of licensed kinase inhibitors targeting the ERK/MAPK and PI3K/AKT/mTOR pathways significantly inhibited MERS-CoV replication *in vitro* whether they were added before or after viral infection. Taken together, our data suggest that ERK/MAPK and PI3K/AKT/mTOR signaling responses play important roles in MERS-CoV infection and may represent novel drug targets for therapeutic intervention strategies.

Middle East respiratory syndrome (MERS) is a viral respiratory disease that results from infection with the MERS coronavirus (MERS-CoV) and was first identified in a patient with acute pneumonia and renal failure in Jeddah, Kingdom of Saudi Arabia, in June 2012 (1). Subsequently, there have been 877 laboratory-confirmed MERS-CoV infections to date, including 317 deaths (<http://www.who.int/csr/don/16-october-2014-mers/en/>), resulting in a case fatality rate of 30%, with all cases directly or indirectly being linked to the Middle East region (2). Recent announcements of laboratory-confirmed cases of MERS-CoV infection in patients in the United States and the Netherlands have further exacerbated concerns regarding the global evolution of this epidemic (3).

MERS-CoV belongs to the same genus (*Betacoronavirus*) as severe acute respiratory syndrome (SARS) coronavirus (SARS-CoV), which was responsible for the global SARS pandemic of 2002 and 2003 that affected more than 8,000 people (4), and the human coronaviruses (HCoVs) HKU1 and OC43, which cause mild to moderate respiratory disease (5). Further, MERS-CoV is the first lineage 2c betacoronavirus shown to infect humans (6, 7). Although the natural reservoir for MERS-CoV has yet to be determined, it has been suggested that bats are a likely candidate, given the similarity of MERS-CoV to bat coronaviruses (8). Recent evidence has also suggested that dromedary camels may act as an intermediate host for MERS-CoV, as supported by serological, genetic, and epidemiological evidence as well as the recent isolation of the virus (9, 10). Animal-to-human transmission has

largely been suspected to be the primary contributor to the recent outbreaks of MERS-CoV. Although human-to-human transmission has been reported in several case clusters, there is currently no evidence for sustained community transmission (11). MERS-CoV infections have been associated with severe lower respiratory tract infections, including acute respiratory syndrome with renal failure. Interestingly, the severity of disease presentation appears to be related to underlying comorbidities, as MERS-CoV infections in healthy individuals appear to result primarily in mild to asymptomatic disease (1, 12, 13).

Though appreciable efforts have been made to identify novel

antiviral therapeutics for MERS-CoV, there are currently no approved therapeutic interventions available, and treatment is based on supportive care (14). Initial investigations of interferon (IFN) demonstrated that alpha interferon (IFN- α), IFN- γ , and IFN- β were able to inhibit MERS-CoV replication (15, 16). Subsequent studies demonstrated that among the different interferons, IFN- β had the strongest inhibitory activity against MERS-CoV (17). Mycophenolic acid, IFN- β , and ribavirin have been demonstrated to have strong inhibitory activities against MERS-CoV *in vitro* (17, 18), and Falzarano et al. demonstrated that the administration of IFN- α 2b and ribavirin resulted in synergistic antiviral activities both *in vitro* and *in vivo* in rhesus macaques (19). Josset and colleagues employed systems-level gene expression analysis of MERS-CoV infection *in vitro* and identified that IFN- α 5 and IFN- β were specifically upregulated by MERS-CoV infection (20).

Surveys of the host response to infection through either genomic or proteomic technologies have previously been employed to characterize microbial pathogenesis and identify novel therapeutic targets (21–24). The incorporation of systems-level analysis to such investigations provides a unique opportunity to identify specific host or pathogen responses that are modulated during the course of infection. A global transcriptome analysis of host responses to MERS-CoV and SARS-CoV infection suggested that MERS-CoV modulated transcriptional changes in the host differently from the way in which SARS-CoV did, although viral replication kinetics were similar for both viruses (20). Subsequent systems-level analysis of the transcriptome data suggested that changes in the host transcriptome in response to either MERS-CoV or SARS-CoV may be related to the activation state of cell signaling networks. Further, the authors demonstrated that the identification of specific cellular intermediates through upstream regulator analysis could be used to predict potential host targets for therapeutic intervention. However, many cellular processes are regulated independently of changes in transcriptional or translational regulation through kinase-mediated modulation of cell signaling networks. Characterization of the activation state of cellular host kinases, or the kinome, provides a mechanism to identify the individual kinases and/or signaling networks that are of central importance to disease progression or resolution. Previously, we demonstrated the utility of species-specific kinome analysis with peptide kinome arrays for characterizing the modulation of host cell signaling networks, including responses to infection (25, 26).

Here, we have characterized the temporal host kinome response of human hepatocytes to infection with MERS-CoV isolate HCoV-EMC/2012 (MERS-CoV) and identified specific cell signaling networks and kinases that are modulated during the course of infection and may represent novel antiviral targets. As it has previously been demonstrated that Huh7 hepatocytes are highly permissive to MERS-CoV (27) and it is postulated that targets found to be overrepresented in our data sets would potentially represent conserved targets across multiple permissive cell types, we have focused on these cells for our analysis. Subsequent systems biology approaches, including pathway overrepresentation analysis (ORA) and functional network analysis (FNA), were used to identify and compare the specific kinome and cell signaling responses that were modulated throughout the course of MERS-CoV infection. Analysis of our kinome data suggested that extracellular signal-regulated kinase (ERK)/mitogen-activated protein kinase (MAPK) and phosphoinositol 3-kinase (PI3K)/ser-

ine-threonine kinase (AKT)/mammalian target of rapamycin (mTOR) signaling responses were specifically modulated in response to MERS-CoV infection *in vitro*. The phosphorylation patterns of specific intermediates within these pathways in the kinome array data correlated with the phosphorylation patterns from Western blot dot arrays. In addition, we confirmed these cellular responses through analysis of the effects of inhibition of these pathways or their intermediates on MERS-CoV infection in tissue culture models. Further, we have demonstrated that a subset of the licensed kinase inhibitors targeting the ERK/MAPK and PI3K/AKT/mTOR pathways significantly inhibited MERS-CoV propagation *in vitro* whether they were added before or after viral infection. Taken together, our investigation demonstrates that ERK/MAPK and PI3K/AKT/mTOR signaling responses play a critical role in MERS-CoV pathogenesis and may be potential targets for therapeutic intervention strategies.

MATERIALS AND METHODS

Cells and virus. Huh7 is a hepatocyte-derived epithelial-like cell line, and Huh7 cells were maintained in Dulbecco's minimal essential medium (DMEM; Sigma-Aldrich) supplemented with 10% (vol/vol) heat-inactivated fetal bovine serum (FBS) in a 37°C humidified incubator with 5% (vol/vol) CO₂. MERS-CoV isolate HCoV-EMC/2012 (MERS-CoV), kindly provided by Rocky Mountain Laboratories (NIH/NIHAIID) and the Viroscience Laboratory, Erasmus Medical Center (Rotterdam, Netherlands), was used for all experiments and propagated as reported previously (28).

Chemical inhibitors. The United States Food and Drug Administration (FDA)-licensed drugs tested (sorafenib, everolimus, dabrafenib, cabozantinib, afatinib, selumetinib, trametinib, and miltefosine) were purchased from Selleck Chemicals. Additional kinase inhibitors tested included AG490, PKC-412, GF109203X, SB203580, wortmannin, Bay 11-7082, GW5074, PP2, and rapamycin (sirolimus), as well as an inhibitor of nitric oxide synthase 2 (NOS2), L-nitro-arginine methyl ester (L-NAME). All were purchased from Enzo Scientific. The inhibitors were reconstituted according to the manufacturers' recommendations in either water or dimethyl sulfoxide (DMSO).

Viral infections for kinome analysis. Huh7 cells were plated in 6-well plates in fresh DMEM supplemented with 2% (vol/vol) FBS and rested for 24 h prior to infection. Cells were infected with MERS-CoV at a multiplicity of infection (MOI) of 0.05 for 1 h at 37°C in 5% CO₂ with periodic rocking. Following incubation, Huh7 cells were washed twice with phosphate-buffered saline (PBS) to remove unbound virus, replenished with fresh DMEM supplemented with 2% (vol/vol) FBS, and incubated at 37°C in 5% CO₂. MERS-CoV-infected and mock-infected cells and cell culture supernatant were harvested at identified time points (1, 6, and 24 h postinfection [p.i.]) for subsequent kinome analysis. Plaque assays were performed on Vero E6 cells as reported previously (17).

Kinome analysis with peptide arrays. The design, construction, and application of peptide arrays were based upon a previously reported protocol (29). Briefly, MERS-CoV-infected and mock-infected Huh7 cells were scraped and pelleted at 1, 6, and 24 h p.i. Following this, the cell supernatants were discarded and the cell pellets were lysed with 100 μ l of lysis buffer (20 mM Tris-HCl, pH 7.5, 150 mM NaCl, 1 mM EDTA, 1 mM EGTA, 1% Triton X-100, 2.5 mM sodium pyrophosphate, 1 mM Na₂VO₄, 1 mM NaF, 1 μ g/ml leupeptin, 1 μ g/ml aprotinin, 1 mM phenylmethylsulfonyl fluoride) and incubated on ice for 10 min, followed by centrifugation to remove cell debris. Cell lysates were transferred to fresh microcentrifuge tubes, and the total protein from the cell lysates was measured using a bicinchoninic acid (BCA) assay (Pierce) to calculate cell lysate volumes to ensure the loading of equal amounts of total protein onto the arrays. Activation mix (50% glycerol, 50 μ M ATP, 60 mM MgCl₂, 0.05% Brij 35, 0.25 mg/ml bovine serum albumin) was added to the cell lysate fractions, the mixture was spotted onto human kinome arrays (JPT Tech-

nologies), and the arrays were incubated for 2 h at 37°C as described previously (22). The kinome arrays were subsequently washed once with PBS containing 1% Triton X-100, followed by a single wash in deionized H₂O. The peptide arrays were held on dry ice and subjected to gamma irradiation (5 Mrd) to inactivate any residual virus following removal from biocontainment. Kinome arrays were submerged in PRO-Q Diamond phosphoprotein stain (Invitrogen) with gentle agitation in the dark for 1 h. Following staining, the arrays were washed in destain (20% acetonitrile, 50 mM sodium acetate, pH 4.0 [Sigma-Aldrich]) 3 times for 10 min per wash, with the addition of fresh destain each time. A final wash was performed with deionized H₂O, and the arrays were placed in 50-ml conical tubes to air dry for 20 min. The remaining moisture was removed by centrifugation of the arrays at 300 × *g* for 3 min. Array images were acquired using a PowerScanner microarray scanner (Tecan) at 532 to 560 nm with a 580-nm filter to detect dye fluorescence. Images were collected using GenePix (version 6.0) software (MDS). Signal intensity values were collected using GenePix (version 6.0) software (MDS). All data processing and subsequent analysis were performed using Platform for Integrated, Intelligent Kinome Analysis (PIIKA) software (<http://sapphire.usask.ca/sapphire/piika>) (29, 30) as described previously (22).

Pathway overrepresentation analysis and functional network analysis. Pathway overrepresentation analysis of differentially phosphorylated proteins was performed using InnateDB software, a publically available resource that predicts biological pathways on the basis of experimental fold change data sets in humans, mice, and bovines (31). Pathways are assigned a probability (*P*) value on the basis of the number of genes present for a particular pathway as well as the degree to which they are differentially expressed or modified relative to their expression under a control condition. For our investigation, input data were limited to peptides that demonstrated consistent responses across the biological replicates (*P* < 0.05) as well as statistically significant changes in expression from that under the control condition (*P* < 0.20), as reported previously (29). Additionally, functional networks were created using Ingenuity Pathway Analysis (IPA) software (Ingenuity Systems, Redwood City, CA). Protein identifiers and the respective phosphorylation fold change values and *P* values were uploaded and mapped to their corresponding protein objects in the IPA knowledge base. Networks of these proteins were algorithmically generated on the basis of their connectivity and assigned a score. Proteins are represented as nodes, and the biological relationship between two nodes is represented as an edge (a solid line for direct relationships and a dotted line for indirect relationships). The intensity of the node color indicates the degree of upregulation (red) or downregulation (green) of phosphorylation. Proteins in uncolored nodes were not identified as being differentially expressed in our experiment and were integrated into the computationally generated networks on the basis of the evidence stored in the IPA knowledge database indicating a relevance to this network.

Western blot array analysis of protein phosphorylation. Huh7 cells were infected with MERS-CoV or mock infected, as described above. Cells from infected or mock-infected cells were harvested at 1, 6, or 24 h p.i., lysed in SDS loading buffer without bromophenol blue (200 mM Tris-HCl, pH 6.8, 8% SDS, 40% glycerol, 4% β-mercaptoethanol, 50 mM EDTA), and boiled for 20 min at 95°C to inactivate remaining virus (as approved within facility-specific standard operating procedures). Following inactivation, supernatants were removed from biocontainment and boiled again for 20 min at 95°C for subsequent analysis. The protein concentration was determined using a BCA protein assay kit (Pierce), according to the manufacturer's instructions. Equal amounts of protein from mock-infected or MERS-CoV-infected samples were loaded onto PathScan intracellular signaling antibody array membranes (Cell Signaling Technologies) and analyzed according to the manufacturer's instructions. Images were acquired using a Syngene G:Box Chemi system (Syngene), and quantification of antibody spot intensities was performed using the ImageJ software suite (32).

Cytotoxicity assays. Kinase inhibitor cytotoxicity was determined using the Cytotox colorimetric assay, which measures the amount of lactate dehydrogenase (LDH; Promega) released from treated cells, following the manufacturer's instructions. Huh7 cells were incubated with each of the drugs for 24 h in a 37°C incubator with 5% CO₂ using the inhibitory concentrations used in the assays below. The cell culture supernatants were then used in the Cytotox 96-well assay, and the absorbance at 490 nm was read with a M1000 Tecan plate reader.

Cell-based ELISA for analysis of inhibition of MERS-CoV infection by kinase inhibitors. Huh7 cells were plated in black, opaque-bottom 96-well plates and allowed to rest for 24 h prior to infection and treatments. The cells were pretreated for either 1 h prior to infection or 2 h postinfection with kinase inhibitors at final concentrations of 0.1, 1, and 10 μM. The final concentration of DMSO was 0.1% for all experimental conditions. Cells were infected with MERS-CoV at an MOI of 0.05 and allowed to incubate for 48 h at 37°C in 5% CO₂ prior to fixation. After 48 h, the cells were fixed with 10% neutral buffered formalin (NBF) for 30 min, the NBF was changed, and the cells were fixed for an additional 24 h at 4°C to ensure viral inactivation following facility-specific standard operating procedures. Viral inhibition was then determined utilizing a cell-based enzyme-linked immunosorbent assay (ELISA) as described by Hart et al. (17).

Plaque reduction assay for analysis of inhibition of MERS-CoV infection by kinase inhibitors. To determine the antiviral activity of the kinase inhibitors, Huh7 cells were incubated with select kinase inhibitors (10 μM) for 1 h prior to infection with MERS-CoV. Cells were infected with MERS-CoV at an MOI of 0.05 for 1 h at 37°C in 5% CO₂ with periodic rocking. Following incubation, Huh7 cells were washed twice with PBS to remove unbound virus, replenished with fresh DMEM supplemented with 2% (vol/vol) FBS, and incubated at 37°C in 5% CO₂ with or without readministration of the same kinase inhibitor (10 μM). Cell supernatants from the infected and mock-infected cells were harvested 48 h p.i., and the inhibitory activity of the kinase inhibitor-treated cells was assessed by plaque reduction assay as described previously (17).

RESULTS

Temporal kinome analysis of MERS-CoV-infected hepatocytes.

To gain insight into potential host signaling networks or kinases that are modulated during MERS-CoV infection and that may represent novel therapeutic targets, we performed temporal kinome analysis of MERS-CoV-infected Huh7 human hepatocytes. Previously, de Wilde et al. demonstrated that Huh7 cells were highly permissive to MERS-CoV infection (27), and we postulated that host signaling networks or individual proteins identified by our analysis may be broadly conserved across multiple cell types targeted by MERS-CoV. In addition, we employed a low multiplicity of infection (MOI = 0.01) to identify host signaling networks or intermediates in an effort to recapitulate circumstances in which host cells would encounter small amounts of virus (i.e., during the initial phases of natural infection). Cells were harvested at multiple time points (1, 6, and 24 h) postinfection (p.i.) alongside time-matched, mock-infected control cells. Kinome analysis with peptide arrays relies on the phosphorylation of specific kinase targets (immobilized peptides) on the arrays by active kinases in a cell lysate (22). Our arrays contained 340 unique peptides representing key phosphorylation events from a broad spectrum of cell signaling pathways and processes. The kinome data were extracted from the arrays and analyzed using the PIIKA software tool (29, 30). Hierarchical clustering analysis demonstrated that the MERS-CoV-infected sample harvested at 1 h p.i. clustered between the mock-infected samples, whereas the MERS-CoV samples harvested at 6 h and 24 h p.i. clustered outside the mock-infected samples, suggesting an increased diversity in the host

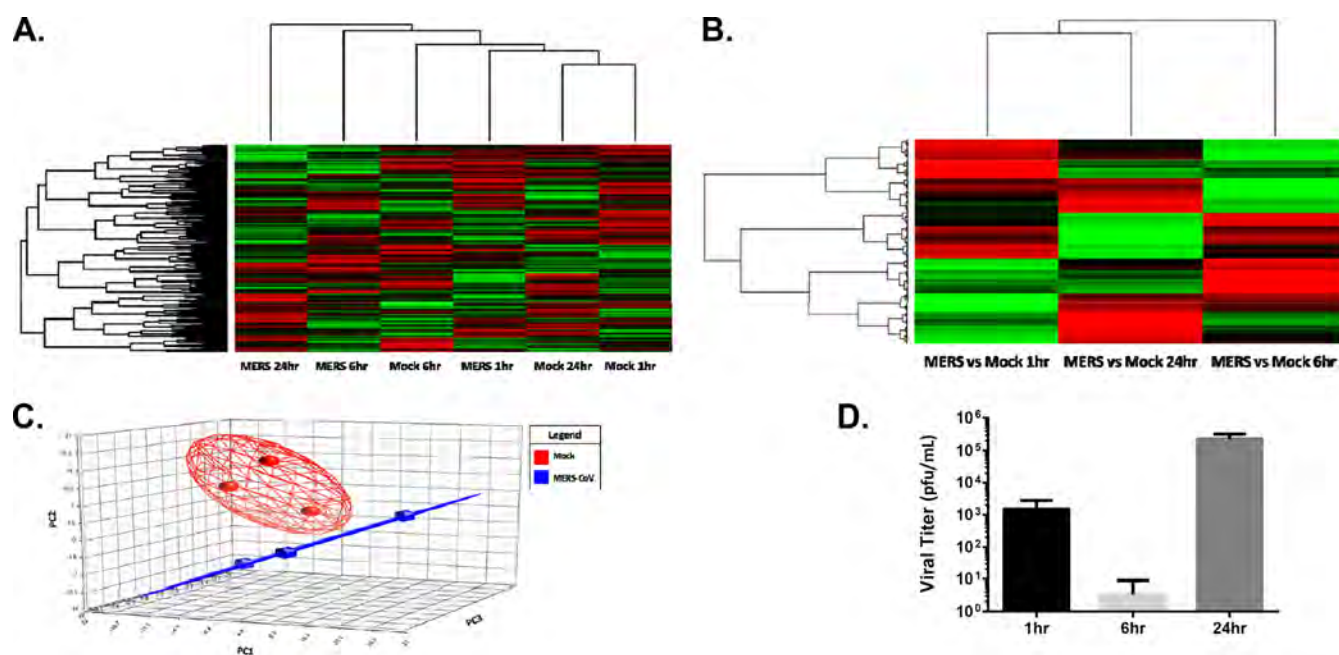

FIG 1 Heat maps and hierarchical clustering of host kinome responses to MERS-CoV infection. Peptide phosphorylation was assessed by densitometry. The results were scaled and normalized using GeneSpring (version 6.0) software. For hierarchical clustering, $1 -$ Pearson correlation coefficient was used as the distance metric and the McQuitty method was used as the linkage method. (A) Hierarchical clustering of the MERS-CoV-infected kinome data sets alongside the mock-infected control data sets. (B) Cluster analysis of the MERS-CoV-infected kinome data sets following background subtraction of the time-matched mock-infected control data sets. Spots demonstrating a significant differential phosphorylation between the MERS-CoV-infected and mock-infected control were compiled into a data set for each time point for comparative analysis. The lines at the top of the heat maps indicate the relative similarity between the conditions listed along the bottom edge of the heat maps. Line length indicates the degree of similarity, with shorter lines equating to stronger similarity. The lines on the left side of the heat maps indicate the relative similarity of the signal between the 300 individual peptide targets on the arrays. Red indicates increased phosphorylation; green indicates decreased phosphorylation. (C) Principal component analysis of the mock- and MERS-CoV-infected kinome data sets. (D) MERS-CoV titers from infected cells at each time point during the experiment.

response compared with that of the mock-infected samples at these time points (Fig. 1A). The results of clustering analysis of the kinome data following biological subtraction of the time-matched mock-infected kinome data sets from their MERS-CoV-infected counterparts are presented in Fig. 1B. Further, principal component analysis (PCA) of the kinome data for the mock- and MERS-CoV-infected samples demonstrated complete separation of the data sets into two individual clusters (Fig. 1C). Titration of cell culture supernatants from our kinome analysis by plaque assay also demonstrated that these cells were productively infected during the course of our analysis (Fig. 1D). It should be noted that the viral titers determined at 1 h p.i. represent the amount of virus remaining in the supernatant at this time point prior to washing of the cells.

Systems analysis of temporal kinome data. To gain biological insight into the molecular host response to MERS-CoV infection, we employed pathway overrepresentation analysis (ORA) with both the InnateDB and the IPA software suites. Pathway overrepresentation analysis with InnateDB was performed in an effort to identify specific signaling pathways that were modulated throughout the course of MERS-CoV infection. Analysis of the upregulated signaling pathways at all time points demonstrated that MERS-CoV infection modulated a broad range of cellular functions (see Table S1 in the supplemental material). Pathway ORA demonstrated that infection resulted in the modulation of host signaling pathways at 1 h p.i. Notably, multiple cell signaling pathways related to cell proliferation (cancer/carcinoma, growth fac-

tor signaling) and cell growth and differentiation (p53 effectors, Wnt signaling) were upregulated, while multiple proinflammatory signaling pathways (tumor necrosis factor alpha [TNF- α] and interleukin-1 [IL-1]) and innate immune response signaling pathways (Toll-like receptor [TLR] signaling) were downregulated at this time point. The signaling pathways identified to be modulated at 6 h and 24 h p.i. decreased in overall breadth and complexity compared to the breadth and complexity of the pathways identified to be modulated at the 1-h time point (see Table S1 in the supplemental material). In particular, by the 24-h time point the majority of upregulated signaling pathways were related to cell junctions (adherens junction and tight junction pathways) and Wnt-, transforming growth factor β -, or PI3K/AKT/mTOR-mediated signaling responses, with the concomitant downregulation of multiple innate immune response-related signaling pathways, including interleukin-, interferon- and TLR-related signaling pathways (see Table S1 in the supplemental material). We also observed specific trends within the signaling pathway data sets for each of the three time points. Pathways at the 1-h-p.i. time point had an overrepresentation of PI3K/AKT/mTOR pathway intermediates (including AKT1, mTOR, PDPK1, PIK3R1, PIK3R2, and RPS6KB1), ERK/MAPK pathway intermediates (including MAP2K1, MAPK3, and MAPK14), and NF- κ B pathway intermediates (IKBKB, IKBKG, and NFKB1) within many of the signaling pathways identified. These trends also appeared to be largely conserved in both the 6-h-p.i. and 24-h-p.i. signaling pathway data, suggesting a potentially critical role for these pathways

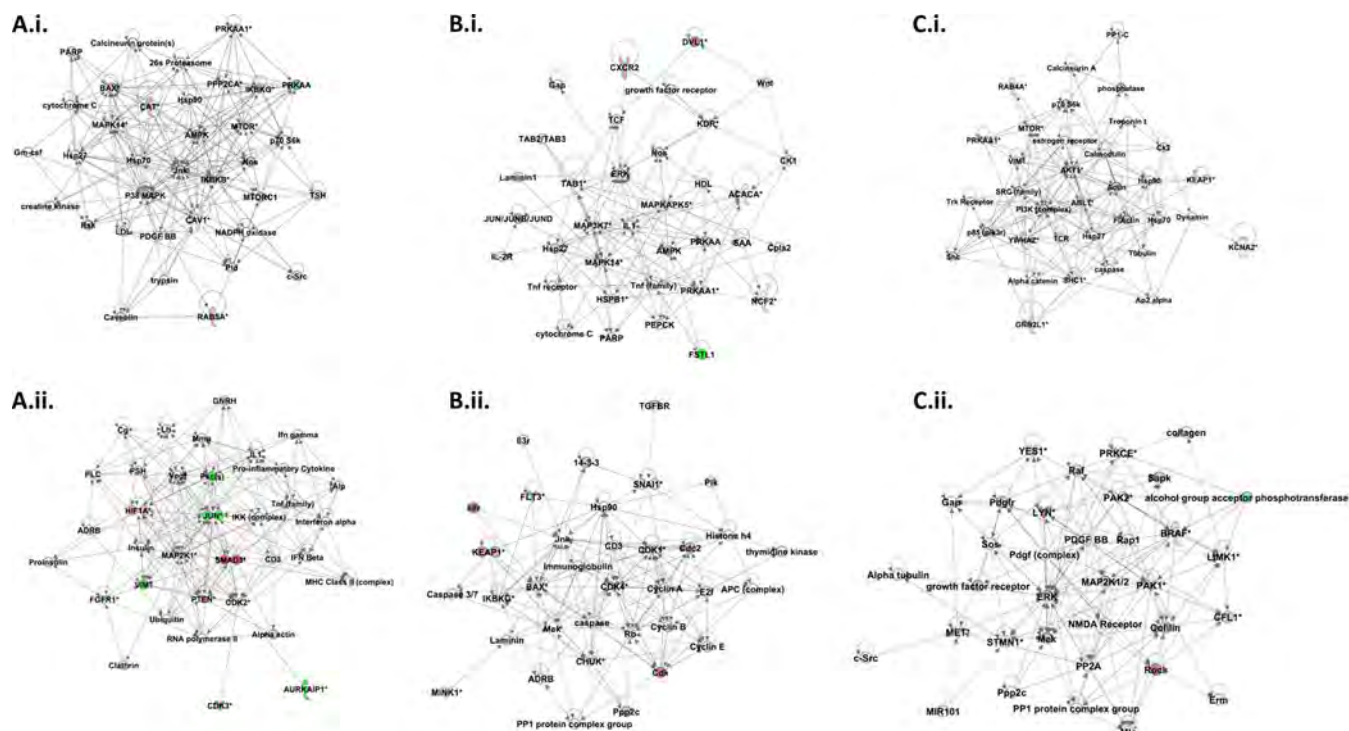

FIG 2 Functional network analysis of temporal kinase responses to MERS-CoV infection in Huh7 cells. Following PIKA, kinase data sets comparing MERS-CoV-infected cells to mock-infected cells were uploaded to IPA for functional network analysis to identify kinases of potential pharmacological interest. The top two functional networks from each time point are presented. (A) Results at 1 h postinfection. (i) Network 1 (cell morphology, cellular function and maintenance, and carbohydrate metabolism); (ii) network 2 (embryonic development, organ development, organismal development). (B) Results at 6 h postinfection. (i) Network 1 (gene expression, RNA damage and repair, RNA posttranscriptional modification); (ii) network 2 (cell morphology, cellular function and maintenance, cell cycle). (C) Results at 24 h postinfection. (i) Network 1 (cancer, hematological disease, cell death and survival); (ii) network 2 (posttranslational modification, cell morphology, cellular assembly and organization). Red nodes, upregulation of phosphorylation; green nodes, downregulation of phosphorylation; PARP, procytic acidic repetitive protein; CAT, chloramphenicol acetyltransferase; Cm-csf, granulocyte-macrophage colony-stimulating factor; LDL, low-density lipoprotein; PDGF BB, platelet-derived growth factor with two B chains; GNRH, gonadotropin-releasing hormone; PLC, phospholipase C; FSH, follicle-stimulating hormone; Vegf, vascular endothelial growth factor; IKK, I κ B kinase; MHC, major histocompatibility complex; CDK2, cyclin-dependent kinase 2; TCF, T cell factor; HDL, high-density lipoprotein; IL2R, interleukin-2 receptor; PEPCK, phosphoenolpyruvate carboxykinase; FSTL1, follistatin-like 1; PP1C, phosphatase 1 catalytic subunit; TCR, T cell receptor; Pdgfr, platelet-derived growth factor receptor; NMDA, *N*-methyl-D-aspartate. Solid lines represent direct interactions between proteins, and dashed lines represent indirect interactions.

and intermediates in MERS-CoV infection. These signaling pathway trends were also confirmed by kinome analysis at 24 h p.i. in MRC5 cells, providing further evidence for a central role for PI3K/AKT/mTOR and ERK/MAPK signaling intermediates (data not shown).

Although these pathway identities were informative, we sought further insight into a broader biological role for these intermediates through functional network analysis (FNA) using the Ingenuity Pathway Analysis software suite. FNA does not limit genes or proteins to specific signaling pathways and instead provides predicted biological networks in which signaling intermediates are grouped on the basis of similarities in overall cellular responses and direct or indirect molecular interactions. The top two functional networks for each time point are presented in Fig. 2. FNA demonstrated that multiple intermediates within the ERK/MAPK signaling pathway (including ERK1 [MAP2K1], p38 [MAPK14], and MEK) and the PI3K/AKT/mTOR signaling pathway were conserved across multiple time points (Fig. 2A to C). It was also noted that ERK1/2 formed central nodes at both 1 h (Fig. 2Aii) and 24 h (Fig. 2Cii) postinfection, while AKT, PI3K, and mTOR formed a central core of the top network found at 24 h postinfection (Fig. 2Ci).

Comparative analysis of the significantly modulated phosphorylation events from our MERS-CoV kinome data by Venn analysis demonstrated that 14 kinases were conserved among data sets from the three p.i. time points (see Table S2 and Fig. S1A in the supplemental material). Interestingly, FNA of this peptide list resulted in multiple ERK/MAPK and PI3K/AKT/mTOR signaling pathway intermediates forming central components of the network, further suggesting that these pathways may be important components of the cellular events that accompany MERS-CoV infection (see Fig. S1B in the supplemental material). The associated biological functions of this network were identified to be cellular movement, cell death and survival, and the cell cycle.

Based on the trends discovered in our systems analysis of the kinome data, we chose to focus primarily on those signaling pathways or intermediates that were identified as being broadly conserved across our kinome analysis. Western blot analysis with Western blot arrays of protein phosphorylation demonstrated that MERS-CoV infection resulted in the modulation of ERK1/2 phosphorylation in a pattern that matched that found on the kinome arrays. The pattern of mTOR and AKT phosphorylation also matched that found from our kinome analysis. Further, the phosphorylation of downstream targets of mTOR, including S6

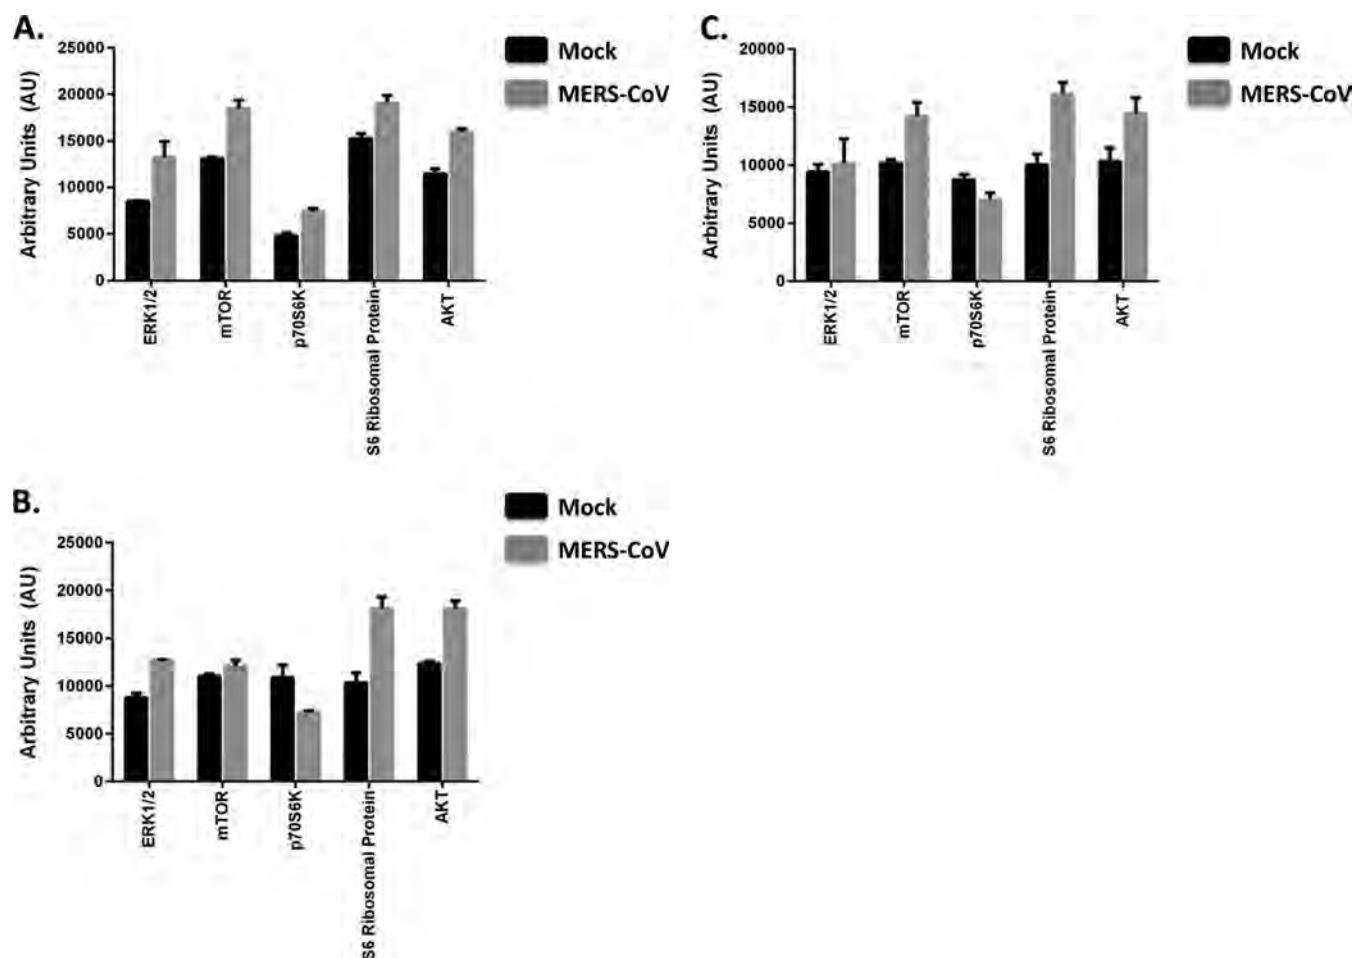

FIG 3 Western blot array analysis of select phosphorylation events in MERS-CoV-infected and mock-infected cells. Pixel intensities for selected spots on the array (in arbitrary units) are presented on the y axis. Results are presented as the mean \pm SD. (A) Results at 1 h postinfection; (B) results at 6 h postinfection; (C) results at 24 h postinfection. The results represent those from one experiment (mean \pm SD, $n = 3$), and the experiment was repeated twice.

ribosomal protein (S6RP) and p70S6 kinase (P70S6K), was also upregulated in a pattern that largely matched that of mTOR phosphorylation (Fig. 3A to C). Importantly, this type of phosphorylation analysis is largely qualitative rather than quantitative; however, the overall trends from our kinome analysis were in agreement with the trends found in our Western blot array analysis.

Kinase inhibitors targeting PI3K/AKT/mTOR and ERK/MAPK signaling inhibit MERS-CoV infection. Following our bioinformatics analysis of the kinome data, we sought further insight into the relationship between the host kinases or signaling networks that were overrepresented in our kinome data. As ERK/MAPK and PI3K/AKT/mTOR formed central components of multiple functional networks and signaling pathways within our analysis, we assessed the effect of selective inhibition of these kinases on MERS-CoV infection through a modified ELISA. Using our modified ELISA, we previously demonstrated that inhibition of MERS-CoV correlated with decreased viral titers through traditional plaque reduction assays (17). Thus, we chose to assess the effect of select kinase inhibitors targeting the PI3/AKT and ERK/MAPK pathways against MERS-CoV infection through this assay. We also selected inhibitors for specific kinases or signaling path-

ways identified from individual time points in our analysis (including protein kinase C [PKC]-, NF- κ B-, nitric oxide synthase [NOS]-, and Src-mediated signaling responses). These host components either were found within the functional networks formed from our kinome data or were present within signaling pathways found in our pathway ORA. Importantly, at the highest concentration of kinase inhibitors tested (10 μ M), all kinase inhibitors, with the exception of PKC-412 and Ro 31-8220 (20% and 23% cytotoxicity, respectively), had negligible (<10%) cytotoxic effects, as assessed by measurement of the level of lactate dehydrogenase, which is released during cell lysis (data not shown). For our analysis, we first examined the effects of kinase inhibitors when added 1 h prior to MERS-CoV infection *in vitro* using the same MOI used for the generation of the kinome data (MOI = 0.05). Inhibition of PI3K/AKT signaling with wortmannin resulted in 40% inhibition of MERS-CoV infection at the highest concentration tested, and inhibition decreased to 22% at submicromolar concentrations (Fig. 4A). In addition, treatment of cells with rapamycin, an inhibitor of mTOR, inhibited MERS-CoV infection by 61% at 10 μ M and 24% at the lowest concentration tested (0.1 μ M). Inhibitors for additional kinases that did not form critical components of signaling and/or the functional net-

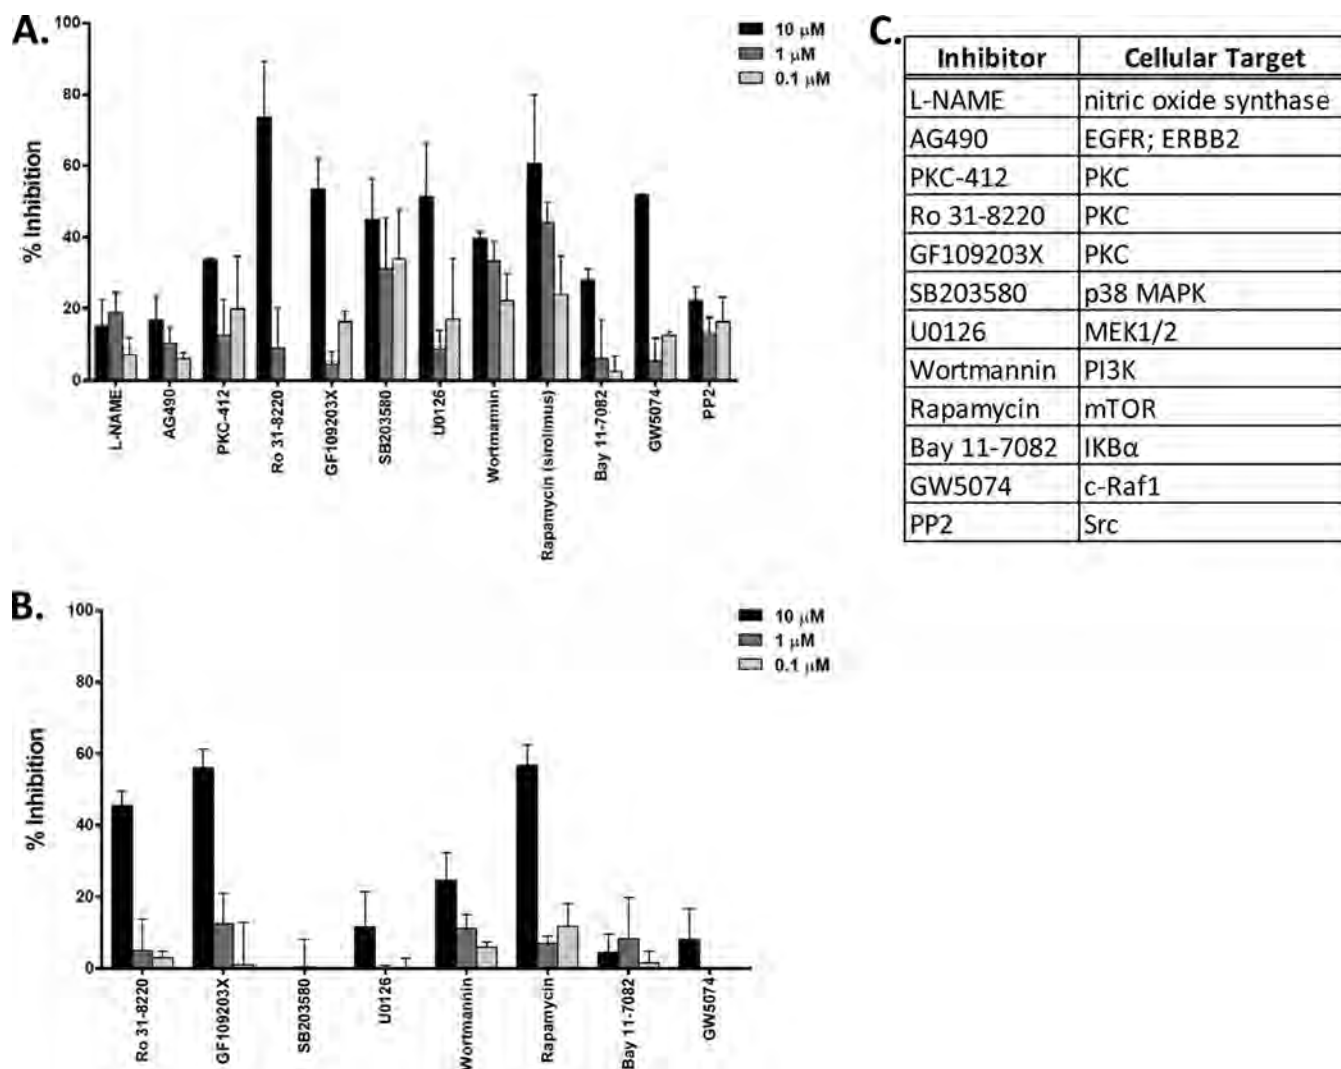

FIG 4 Inhibition of MERS-CoV infection by kinase inhibitors. Kinase inhibitors were added either preinfection (-1 h) or postinfection ($+2$ h) at the concentrations listed. Results are presented as the mean \pm SD. (A) Preinfection addition of kinase inhibitors targeting signaling pathways/kinases identified from bioinformatics analysis of temporal kinome data; (B) postinfection addition of kinase inhibitors selected from panel A. The cytotoxicities for all compounds at the highest concentration tested (10 μ M) were $<10\%$, with the exception of those of PKC-412 and Ro 31-8220 (20% and 23%, respectively). (C) Kinase inhibitor targets from this analysis. The results represent those from three experimental repeats (mean \pm SD, $n = 3$), with two technological repeats being performed in each experiment. EGFR, epidermal growth factor receptor.

work were also examined and had negligible effects on MERS-CoV infection. Taken together, these data provide further support for a role for the PI3K/AKT/mTOR signaling pathway during MERS-CoV infection.

Next, we examined the effects of ERK/MAPK pathway inhibitors. Pretreatment of cells with inhibitors of ERK/MAPK signaling resulted in the inhibition of MERS-CoV infection: SB203580 (p38 MAPK) and U0126 (MEK1/2) had similar inhibitory activities against MERS-CoV at 10 μ M (45% and 51% inhibition, respectively). Pretreatment of cells with 10 μ M GW5074, an inhibitor of Raf, a kinase that is involved in the ERK/MAPK signaling transduction cascade and was present in multiple signaling pathways identified from the kinome array data from 6 h and 24 h p.i., inhibited MERS-CoV by 52%. This also supported the findings from the analysis of the kinome data in regard to the modulation of ERK/MAPK signaling during MERS-CoV infection.

Inhibition of PKC prior to viral infection also resulted in inhibition of MERS-CoV (Fig. 3A). The PKC inhibitors PKC-412, GF109203X, and Ro 31-8220 inhibited MERS-CoV infection by 37%, 54%, and 74%, respectively, suggesting that PKC also plays an important role during infection. Inhibition of MERS-CoV infection by Ro 31-8220 and GF109203X was significantly greater than that by PKC-412 ($P < 0.1$). To examine the role for NF- κ B signaling in MERS-CoV infection, cells were also pretreated with Bay 11-7082, an inhibitor of NF- κ B DNA binding and tumor necrosis factor alpha (TNF- α)-induced I κ B α phosphorylation that inhibited MERS-CoV infection by 28%. MERS-CoV was largely insensitive ($<25\%$ inhibition) to pretreatment of cells with inhibitors for Src (PP2), epidermal growth factor receptor (AG490), or NOS2 (L-NAME) (Fig. 4A).

To further assess the role for these kinases or signaling pathways in MERS-CoV infection, we selected inhibitors from our

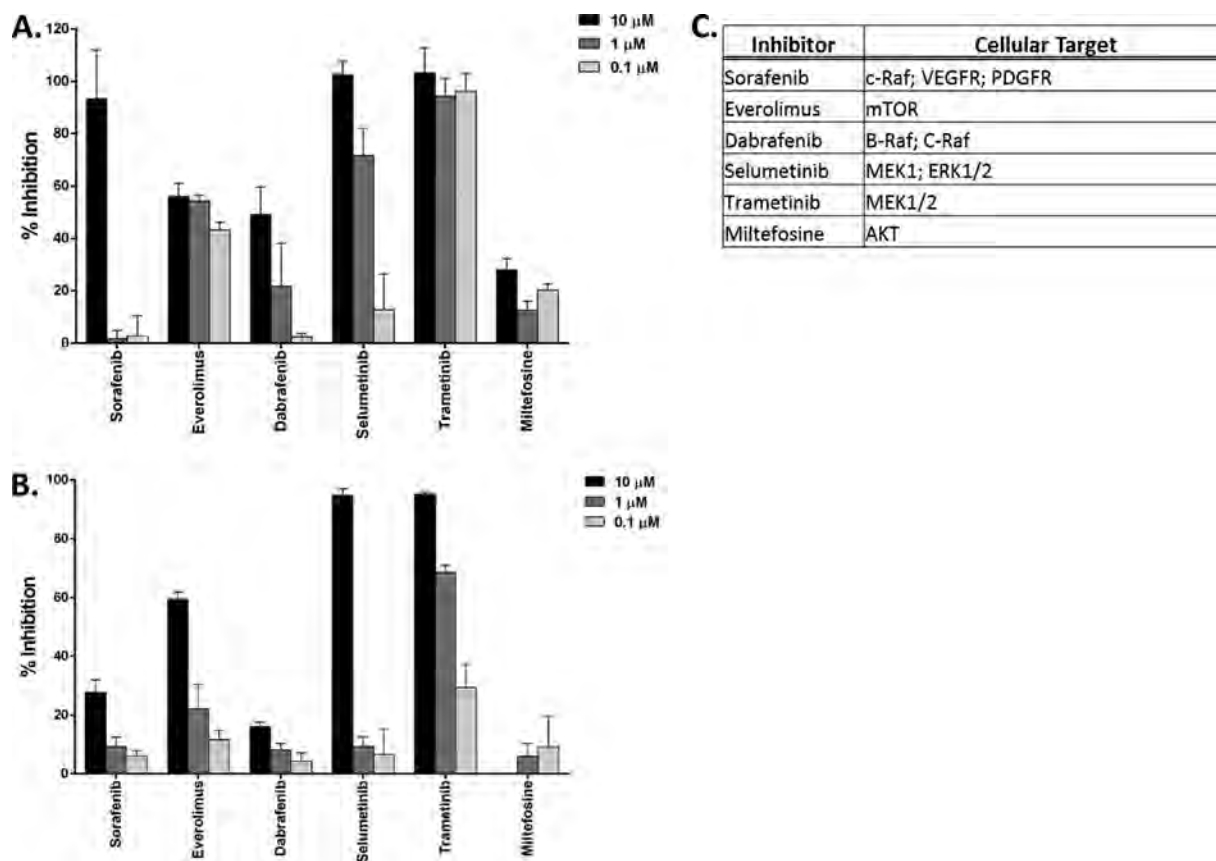

FIG 5 Inhibitory activity of FDA-licensed kinase inhibitors targeting ERK/MAPK or PI3K/AKT signaling added before or after MERS-CoV infection. Kinase inhibitors were added before (-1 h) or after ($+2$ h) MERS-CoV infection at the concentrations listed. Results are presented as the mean \pm SD. (A) Preinfection addition of kinase inhibitors targeting signaling pathways/kinases identified from bioinformatics analysis of temporal kinome data. (B) Postinfection addition of kinase inhibitors. The cytotoxicities for all compounds tested were $<10\%$. (C) Kinase inhibitor targets from this analysis. The results represent those from three experimental repeats (mean \pm SD, $n = 3$), with two technological repeats performed in each experiment. For the pretreatment experiments, trametinib was significantly more inhibitory than selumetinib at $0.1 \mu\text{M}$ ($P < 0.05$). For the postaddition experiments, trametinib was significantly more inhibitory than selumetinib at $1 \mu\text{M}$ ($P < 0.005$). VEGFR, vascular endothelial growth factor receptor; PDGFR, platelet-derived growth factor receptor.

pretreatment experiments with inhibitory activities of $\geq 40\%$ to examine the retention of these activities when added to the cells at 2 h p.i. Inhibitors that fit into this classification included inhibitors of PI3K (wortmannin), mTOR (rapamycin), MEK1/2 (U0126), PKC (Ro 31-8220, GF109203X), and c-Raf1 (GW5074). Addition of inhibitors from this subset to the cells at 2 h p.i. largely resulted in decreased inhibitory activity against MERS-CoV infection compared to that obtained with preinfection treatments. Postinfection treatment of cells with rapamycin (mTOR; 57%) had a significantly stronger inhibitory effect on infection than postinfection treatment of cells with wortmannin (PI3K; 25%), suggesting a more central role for mTOR than for PI3K during MERS-CoV infection ($P < 0.05$). Postinfection treatment of infected cells with Ro 31-8220 resulted in a modest conservation of inhibitory activity (46%) which was similar to that achieved with GF109203X (56%) and rapamycin (Fig. 3B).

As these analyses provided further support for the role of the ERK/MAPK and PI3K/AKT/mTOR signaling pathways initially identified from our kinome analysis, we postulated that licensed therapeutics targeting the same pathways would also have inhibitory activity against MERS-CoV infections. Here, we selected inhibitors targeting AKT (miltefosine), mTOR (everolimus),

ERK/MAPK (selumetinib, trametinib), and Raf (dabrafenib, sorafenib). Cells were treated with inhibitors prior to (1 h) or following (2 h) MERS-CoV infection. For kinase inhibitors targeting the ERK/MAPK signal pathway, selumetinib (MEK1, ERK1/2) and trametinib (MEK1/2) had the strongest inhibitory activities of all the inhibitors tested ($\geq 95\%$), including non-ERK/MAPK inhibitors, whether they were added prior to (-1 h; Fig. 5A) or following ($+2$ h; Fig. 5B) infection. Interestingly, trametinib demonstrated significantly stronger inhibitory activity against MERS-CoV than selumetinib at the lowest concentration tested when the inhibitors were added prior to infection ($P < 0.05$) or when a postinfection treatment concentration of $10 \mu\text{M}$ was used ($P < 0.05$). This suggests that these specific nodes of the ERK/MAPK signaling pathway (MEK1/2 and ERK1/2) may represent critical nodes of the biological responses of the host during MERS-CoV infection and may be the most logical targets for therapeutic intervention. We also examined inhibitors of Raf, a MAP3K found downstream of the Ras family of membrane GTPases, as Raf was found to be an intermediate in upregulated signaling pathways at all time points in our analysis and treatment of cells with GW5074 inhibited MERS-CoV infection (Fig. 3A). Pretreatment with sorafenib strongly inhibited MERS-CoV infection (93%), provid-

ing further support for a role for the ERK/MAPK signaling pathway during viral infection. The inhibitory activity was reduced when sorafenib was added to cells at 2 h following infection (<30% inhibition at the highest concentration tested), suggesting that the role for Raf may be related primarily to processes early in the viral life cycle (viral entry, uptake or uncoating of virions) rather than viral replication processes. Dabrafenib, an inhibitor that also targets Raf, had reduced inhibitory activity against MERS-CoV compared to the activity of sorafenib (45%) when added to cells prior to MERS-CoV infection. As with sorafenib, the inhibitory activity of dabrafenib against MERS-CoV was largely negated when added to cells postinfection (Fig. 5B), providing further mechanistic evidence for a role for Raf primarily in early viral entry or postentry events.

From the perspective of PI3K/AKT/mTOR signaling, we also investigated licensed inhibitors that targeted AKT or mTOR. Everolimus, an inhibitor of mTOR, largely retained inhibitory activity against MERS-CoV whether it was added pre- or postinfection (56% and 59% inhibition, respectively, at 10 μ M) (Fig. 5A). These results were very similar to those for rapamycin (sirolimus; Fig. 3A and B) and provide strong evidence for a critical role for mTOR in MERS-CoV infection. In contrast, miltefosine, an inhibitor of AKT approved for use for the treatment of leishmanial infection (33), had minimal inhibitory activity against MERS-CoV (28%) at the highest concentration tested when added preinfection. The activity was completely abrogated when added postinfection (Fig. 4B). As the inhibitory activity of everolimus was significantly greater than that of miltefosine at all concentrations tested ($P < 0.05$), this provided further support for a critical role for mTOR within the PI3K/AKT/mTOR signaling pathway in the exacerbation of MERS-CoV infection. The results for selumetinib, trametinib, and everolimus were also confirmed by traditional plaque reduction assays. Huh7 cells were pretreated for 1 h with each of the three inhibitors (10 μ M) and then infected at an MOI of 0.05, as in the initial kinome experiments. Following infection, cells were washed and then medium alone was added (see Fig. S2A in the supplemental material) or medium plus the inhibitor at the same concentration used in the preinfection treatments was added (see Fig. S2B in the supplemental material). A single preinfection addition of either selumetinib or trametinib resulted in a significant decrease in viral titers, and the readministration of inhibitor following infection (similar to the conditions for the cell-based ELISAs) resulted in significant inhibition of viral replication for all three inhibitors.

DISCUSSION

Concerns regarding the potential global implications of MERS-CoV as an emerging pathogen have been raised. As a result of this, there has been great interest in both increasing our understanding of the molecular pathogenesis associated with MERS-CoV infections and identifying potential therapeutic treatment options. Further, there is great interest in characterizing the molecular events that underlie host responses to MERS-CoV and the relation of these to disease pathogenesis and severity.

We and others have demonstrated the utility of kinome analysis for characterizing the molecular host response to viral infection through the identification of cell signaling networks or individual kinases that are uniquely modulated during these events (22, 34). Kinases are of critical importance to many biological processes and form an important mechanism for the regulation of

these processes independent of changes in transcription or translation. As the dysregulation of cellular kinases has been implicated in numerous human malignancies (35), kinases have become an important target for the design and development of novel therapeutics (25, 26). There are currently 26 kinase inhibitors with FDA licensure and a continually increasing number at various stages of clinical development. It should also be appreciated that the escalating costs of moving a new drug from bench to bedside (estimated at more than \$1 billion) have prompted calls for the investigation and potential repurposing of licensed therapeutics for alternative uses. Thus, kinome analysis provides a unique opportunity to characterize the molecular host response in the investigation of viral infections, including those caused by high-consequence pathogens. Here, we employed systems kinome analysis with peptide arrays to characterize the host response to MERS-CoV infection in Huh7 cells, a human hepatoma cell line that is highly permissive to MERS-CoV infection (27).

Our kinome analysis and subsequent pathway and functional network analyses demonstrated that MERS-CoV infection resulted in the selective modulation of the ERK/MAPK and PI3K/AKT/mTOR signaling responses throughout the course of infection. Recently, Josset et al. used an inverse genomic signature approach in their transcriptome analysis of MERS-CoV infection *in vitro* for the identification of potential drug targets (20). Our results complement those recently reported by Josset et al. in regard to the potential of kinase inhibitors to be novel treatments for MERS-CoV infection (20). The transcriptome analysis performed by the authors resulted in the prediction of two kinase inhibitors, LY294002 (PI3K) and SB203580 (p38 MAPK), to be potential modulators of MERS-CoV infection. Here, we have employed kinome analysis to provide critical data regarding the functional response of the host to viral infection through the analysis of the activation states of host kinases and cell signaling networks. Further, we have utilized this information for the logical prediction of host kinases that may serve as novel therapeutic targets for MERS-CoV infection. However, our analysis has expanded on these observations by providing functional evidence for the temporal roles of these signaling pathways in the host response during MERS-CoV infection (20).

We have demonstrated through systems-level analysis of our kinome data that multiple ERK/MAPK and PI3K/AKT/mTOR family members formed central components of functional networks and signaling pathways throughout the course of our investigation. In addition, ERK/MAPK and PI3K/AKT/mTOR signaling responses, including the functional network derived from the kinases that were conserved across all of the time points examined in our investigation, were overrepresented in our pathway and network analyses (see Fig. S1 in the supplemental material). The ERK/MAPK and PI3K/AKT/mTOR signaling networks are critical regulatory pathways for many cell regulatory responses, including cell proliferation and apoptosis, and have been demonstrated to be targeted by a broad range of viral pathogens (36–38). This would suggest that both ERK/MAPK and PI3K/AKT/mTOR signaling responses play important roles in the host response to MERS-CoV infection. Our kinome data and data from subsequent pathway and functional network analyses were corroborated by the phosphorylation patterns of specific members of these pathways obtained by Western blot array analysis. Further, the activation of mTOR-regulated intracellular kinases, including S6RP and p70S6K, lends further credence to our pathway and

functional network data. In addition to these findings, our analyses also suggested that PKC-mediated signaling also formed important components of the host response to MERS-CoV infection, as PKC formed components of both the functional and signaling pathway networks found in our investigation and the inhibition of PKC-mediated signaling responses resulted in decreased MERS-CoV infection whether it was added pre- or postinfection. As PKC can activate ERK/MAPK signaling (39), these results may provide additional information regarding the mechanism whereby MERS-CoV modulates ERK/MAPK signaling. A prior analysis of MERS-CoV infection also suggested that IFN responses and, in particular, those of IFN- β play important roles during the course of infection (17). Our analysis demonstrated that IFN-related signaling responses related to IFN signaling were found within the functional networks found at the 1-h-p.i. time point and, as well, were found in the downregulated signaling pathways at the 24-h-p.i. time point. These observations lend further credence to the growing evidence for a specific attenuation of IFN responses during MERS-CoV infection (17, 18, 40).

There has been considerable analysis of the therapeutic potential for host-targeted immunomodulatory agents in viral infections (20, 41, 42). Previous work has demonstrated that viruses modulate host cell signaling networks, including those involving PI3K/AKT/mTOR and ERK/MAPK. Human papillomavirus (HPV) is able to maintain an activated AKT, resulting in activated mTORC1, and it has been postulated that this may be required for the initiation of viral replication (43). A similar requirement for activated PI3K/AKT/mTOR signaling in viral replication has also been demonstrated for myxoma virus (44). Qin et al. have also demonstrated that herpes simplex virus 1 infection stimulated both the PI3K/AKT and ERK/MAPK signaling pathways (45), and the role of ERK/MAPK signaling modulation in viral infection has also been noted for reovirus (46), rabies virus (47), and hepatitis B virus (48), among others. We demonstrated that multiple licensed kinase inhibitors targeting the ERK/MAPK or PI3K/AKT/mTOR signaling pathway inhibited MERS-CoV infection *in vitro* when added prior to or following viral infection. Inhibitors of MEK1/2 (trametinib) and/or ERK1/2 (selumetinib) had the strongest and most conserved inhibitory activities, suggesting that MEK1/2 and ERK1/2 may have unique capabilities as stand-alone or combinatorial therapies for MERS-CoV infections. Further, across all time points, both ERK/MAPK intermediates were represented in signaling pathways or functional networks that were derived from our kinome analysis. These analyses also suggested that mTOR was highly overrepresented within our kinome data. Inhibitors of mTOR (rapamycin and everolimus) had reduced inhibitory activities against MERS-CoV compared to the activities of trametinib and selumetinib. However, the conservation of these activities following treatment pre- or postinfection also suggests that mTOR plays a critical role in MERS-CoV infections beyond viral entry. Although our kinome data suggested that PI3K could be an attractive therapeutic target for MERS-CoV and treatment of cells with wortmannin, a selective PI3K inhibitor, inhibited MERS-CoV infection, the administration of miltefosine (an AKT inhibitor licensed for use as an antileishmanial agent [33]) had minimal inhibitory activity in our analysis. These results suggest that in addition to ERK/MAPK intermediates, as targeted by trametinib and selumetinib, mTOR may also be a logical therapeutic target for MERS-CoV infections. These results were further validated by the significant reduction in viral titers demonstrated by a plaque

reduction assay when cells were treated for only 1 h prior to infection (trametinib and selumetinib) or when inhibitors were replenished following infection (trametinib, selumetinib, and everolimus). The specific mechanism(s) of inhibition for these inhibitors remains to be determined. Though it is postulated that this inhibitory effect is mitigated through the direct inactivation of the primary targets of these inhibitors, it is appreciated that many licensed kinase inhibitors have off-site targets that could contribute to the overall antiviral activities reported here. Specific inhibition of intermediates from the ERK/MAPK and PI3K/AKT/mTOR signaling pathways through approaches that use, for example, small interfering RNA knockdown or gene knockout will help shed light on this question. Although it is tempting to speculate that these compounds may have the potential to be used for the treatment of MERS-CoV infections in the future, their use will require additional investigations of their associated pharmacokinetics and the correlation of these with the levels required for antiviral activity *in vivo*. Future investigations will expand on these findings to determine the precise mechanism of action for these inhibitors in the MERS-CoV viral life cycle (i.e., inhibition of viral replication, viral assembly, or viral egress).

Using kinome analysis, we have demonstrated that MERS-CoV infection resulted in the selective modulation of the ERK/MAPK and PI3K/AKT/mTOR signaling responses in the host and confirmed this through biological validation experiments with kinase inhibitors. Further, we have also demonstrated the utility of temporal kinome analysis for characterizing host responses to infection and for the subsequent selection of therapeutics that may provide resolution of the infection. Taken together, we provide critical information regarding the molecular host response to MERS-CoV infection and evidence for the potential of kinase inhibitor therapeutics with preexisting licensure to be novel strategies for the treatment of MERS-CoV infections.

Systems Kinomics Demonstrates Congo Basin Monkeypox Virus Infection Selectively Modulates Host Cell Signaling Responses as Compared to West African Monkeypox Virus*[§]

Jason Kindrachuk^{‡§§}, Ryan Arsenault^{§¶}, Anthony Kusalik^{||}, Kristen N. Kindrachuk^{**}, Brett Trost^{||}, Scott Napper^{§¶}, Peter B. Jahrling^{‡‡}, and Joseph E. Blaney[‡]

Monkeypox virus (MPXV) is comprised of two clades: Congo Basin MPXV, with an associated case fatality rate of 10%, and Western African MPXV, which is associated with less severe infection and minimal lethality. We thus postulated that Congo Basin and West African MPXV would differentially modulate host cell responses and, as many host responses are regulated through phosphorylation independent of transcription or translation, we employed systems kinomics with peptide arrays to investigate these functional host responses. Using this approach we have demonstrated that Congo Basin MPXV infection selectively down-regulates host responses as compared with West African MPXV, including growth factor- and apoptosis-related responses. These results were confirmed using fluorescence-activated cell sorting analysis demonstrating that West African MPXV infection resulted in a significant increase in apoptosis in human monocytes as compared with Congo Basin MPXV. Further, differentially phosphorylated kinases were identified through comparison of our MPXV data sets and validated as potential targets for pharmacological inhibition of Congo Basin MPXV infection, including increased Akt S473 phosphorylation and decreased p53 S15 phosphorylation. Inhibition of Akt S473 phosphorylation resulted in a significant decrease in Congo Basin MPXV virus yield (261-fold) but did not affect West African MPXV. In addition, treatment with staurosporine, an apoptosis acti-

vator resulted in a 49-fold greater decrease in Congo Basin MPXV yields as compared with West African MPXV. Thus, using a systems kinomics approach, our investigation demonstrates that West African and Congo Basin MPXV differentially modulate host cell responses and has identified potential host targets of therapeutic interest. *Molecular & Cellular Proteomics* 11: 10.1074/mcp.M111.015701, 1–12, 2012.

Monkeypox virus (MPXV)¹ is a member of the genus *Orthopoxvirus*, which also includes vaccinia virus (VACV), ectromelia virus, cowpox virus (CPXV), and variola virus (VARV), the causative agent of smallpox. MPXV causes zoonotic disease that manifests similarly to smallpox with associated case fatality rates of ~10% (1). Although MPXV was first isolated from cynomolgus macaques in 1958 in Denmark (2) there was limited scientific interest in the virus until it was demonstrated in the 1970s that MPXV could cause lethal infection in humans (3). Following the cessation of smallpox vaccination there has been a dramatic increase in MPXV incidence in the Democratic Republic of the Congo over the past 30 years (4) and it is estimated that ~50% of the general population is not protected against MPXV or VARV (4). These concerns have been compounded by the first reported incidence of MPXV outside of the African continent following the accidental introduction of MPXV in the Midwestern United States in 2003 (5). Further concerns have also been raised regarding the potential use of MPXV as a bioterrorism agent thus resulting in its classification as a Class C Select Agent (1, 6).

Monkeypox virus is comprised of two distinct clades that are genetically, clinically, and geographically distinct. Congo Basin MPXV, also known as Central African MPXV, has associated case fatality rates of ~10% in non-vaccinated individ-

uals as compared with the minimal lethality associated with the less-virulent West African MPXV clade (7). Lending further support, comparative infection models in non-human primates (8), mice (9, 10), prairie dogs (11, 12) and ground squirrels (13) have all demonstrated greater lethality or morbidity associated with Congo Basin MPXV infection when compared with West African MPXV. Additionally, an outbreak of West African MPXV in the U.S. in 2003 following importation of MPXV-infected rodents from Ghana resulted in 69 diagnosed MPXV cases; however, disease severity was relatively mild with no fatalities (5). Although these reports have demonstrated a definitive difference in virulence between the two MPXV clades, there is a paucity of information regarding the virus or host factors that mediate the divergent pathogenesis. Recently, investigations of the global gene expression programs of both the host and virus during Congo Basin MPXV infection have provided insight into the underlying mechanisms of MPXV disease pathogenesis. In particular, independent investigations of host responses to Congo Basin MPXV infection by Rubins *et al.* (14) and Alkhalil *et al.* (15) have demonstrated global suppression of host gene expression programs following viral infection. Interestingly, these included the modulation of such diverse host responses as the regulation of histone expression, cytoskeletal rearrangement, cell cycle progression, and interferon-associated gene expression (14, 15). This is perhaps unsurprising as it was demonstrated that the host response modifier genes of Congo Basin MPXV are transcribed at steady-state levels throughout the course of infection (16). Corresponding investigations for West African MPXV have not been reported.

Although studies of global gene expression have been informative, it is increasingly appreciated that many cellular processes are regulated independently of changes in transcription or translation through post-translational modifications of host proteins. For example, phosphorylation is one of the most pivotal biological mechanisms for regulation of cellular processes with 518 annotated human kinase genes and ~100,000 human phosphorylation sites identified to date (17, 18). As virtually all cell signaling processes are regulated by phosphotransfer reactions, and aberrant kinase activity has been implicated in a variety of diseases, kinases are an attractive target for therapeutic intervention (19, 20). The priority that has been placed on the development of kinase inhibitors for the treatment of a variety of human diseases such as cancer has resulted in the development of tremendous libraries of potential inhibitors that may have other applications for treatment of infectious diseases.

Kinome profiling through global analysis of kinase abundance, activity, phosphorylation status, and substrate specificity provides a novel mechanism for investigating disease pathogenesis through the activation or repression of host cell signal transduction pathways (20). For example, a recent investigation by Bowick *et al.* utilized kinome peptide arrays to identify host cell signaling nodes of interest that were differ-

entially modulated by two variants of Pichinde virus producing either lethal or self-limiting disease (21). In addition, numerous pathogens, including poxviruses, have been shown to target host cellular processes as a part of their pathogenic mechanism through host protein mimicry (22, 23), including through production of eukaryotic-like kinases (24–26). Such pathogen-encoded effectors may be equally attractive therapeutic targets as their host-encoded counterparts. Thus, systems kinomics with kinome peptide arrays represents a novel methodology for investigating host responses to clinically relevant infectious diseases and identification of potential therapeutic targets.

As direct comparison of the genomes of West African and Congo Basin MPXV demonstrate significant variability in the regions coding for host response modifier proteins, we postulated that the differential virulence of the two MPXV clades is related to the differential modulation of host cell signaling pathways following infection (27, 28). Thus, we sought to investigate host signaling pathway responses to West African and Congo Basin MPXV insult with peptide arrays comprised of human kinase targets for cell growth and differentiation, stress responses, and innate immunity. Host kinome responses to CPXV and VACV were also included for comparison of host response conservation across the *orthopoxvirus* genus. In the hierarchical clustering analysis Congo Basin MPXV demonstrated similar target phosphorylation patterns to CPXV and moderately to VACV; however, there was limited similarity between West African and Congo Basin MPXV-induced phosphorylation patterns. Congo Basin MPXV infection resulted in a significant down-regulation of host cell responses as compared with infection with West African MPXV as demonstrated through pathway over-representation analysis (ORA) with InnateDB. The down-regulated pathways were related primarily to growth and proliferation, apoptosis, and immune surveillance. The biological relevance of the differential pathways identified was demonstrated through flow cytometry and cell proliferation assays as West African MPXV-infected monocytes had significantly increased apoptotic and cell proliferative responses. Further, pharmacological inhibition of selected host targets differentially phosphorylated following infection by the two MPXV clades validated our systems kinomics results. Thus, we have employed systems kinomics for the investigation of host responses to MPXV infection, and demonstrate for the first time that West African and Congo Basin MPXV induce significantly different host cell signaling pathway activities following viral infection.

MATERIALS AND METHODS

Cell and Virus Conditions—MPXV Zaire 79 and MPXV Sierra Leone 70 strains were propagated in BSC-1 cells at a MOI of 0.1 for 4 days. BSC-1 cells were maintained in MEM supplemented with 10% fetal calf serum and 1% penicillin and streptomycin. Virus stocks were prepared by disruption of BSC-1 cells by successive freeze thaw followed by purification using sucrose gradients. Virus was quantified in a standard plaque assay on either Vero E6 or BSC-1 cells as

described previously (19). VACV Western Reserve and CPXV Brighton Red were generated in a similar fashion. Human THP-1 monocytes (ATCC TIB-202R) were maintained in RPMI 1640 medium supplemented with 10% (v/v) heat inactivated fetal bovine serum, 2 mM L-glutamine and 1 mM sodium pyruvate. All cultures were maintained at 37 °C in a humidified 5% (v/v) CO₂ incubator.

Viral Infection—Cells were plated in six-well plates and rested for 24 h prior to infection. Cells were infected with either Congo Basin MPXV or West African MPXV at a MOI of 3 or mock infected with an equivalent fraction of culture medium free of any virus. All viral infections were performed at the National Institutes of Health at Biosafety Level 3 in accordance with NIH/CDC Biosafety in Microbiological and Biomedical Laboratories guidelines, as well as in accordance with CDC Select Agent regulations. Virus was incubated with host cells for 1 h at 37 °C with periodic rocking. Following incubation, monocytes were washed twice with phosphate-buffered saline (PBS), resuspended with fresh RPMI 1640 media with 2% (v/v) fetal bovine serum and incubated for 24 h.

Kinome Analysis—Design, construction and application of the peptide arrays were based upon a previously reported protocol with the following modifications (56). Virus-infected and mock-infected THP-1 monocytes were pelleted following incubation and cell lysate was prepared and incubated with human kinome arrays (JPT Technologies, Berlin, Germany). Briefly, cell pellets were lysed with 100 µl of lysis buffer (20 mM Tris-HCl, pH 7.5, 150 mM NaCl, 1 mM ethylenediamine tetraacetic acid, 1 mM ethylene glycol tetraacetic acid, 1% Triton-X100, 2.5 mM sodium pyrophosphate, 1 mM Na₃VO₄, 1 mM NaF, 1 µg/ml leupeptin, 1 µg/ml aprotinin, 1 mM phenylmethylsulfonyl fluoride) and incubated on ice for 10 min. Following incubation, cell lysates were filtered through Amicon 100K filters (Millipore) for 15 min at 4 °C to remove intact viral particles. Subsequent peptide array processing was performed under BSL2 conditions. A 70 µl aliquot of the supernatant was mixed with 10 µl of the activation mix (50% glycerol, 50 µM ATP, 60 mM MgCl₂, 0.05% Brij-35 and 0.25 mg/ml bovine serum albumin) and incubated on a peptide array for 2 h at 37 °C. Arrays were subsequently washed once with PBS containing 1% Triton X-100 and submerged in PRO-Q Diamond Phosphoprotein Stain (Invitrogen, Carlsbad, CA) with gentle agitation in the dark for 1 h. Following staining, arrays were washed in destain [20% acetonitrile, 50 mM sodium acetate, pH 4.0 (Sigma)] 3X for 10 min/wash with the addition of fresh destain each time. A final wash was performed with dH₂O and placed in 50 ml conical tubes and air-dried for 20 min. Remaining moisture on the arrays was removed by centrifugation of the arrays at 300 × g for 3 min. Array images were acquired using an Axon 4000B microarray scanner at 532–560 nm with a 580 nm filter to detect dye fluorescence. Images were collected using the GenePix 6.0 software (MDS, Foster City, CA). Signal intensity values were collected using the GenePix 6.0 Software (MDS) with the following settings: scanner saturation level 65535, background calculation done using local feature background, signal mean and background mean intensity values used for analysis, local background features excludes 2 pixels, and width of background set to 3 feature diameters. Intensity values for the spots and background were collected for each array.

Kinome Data Preprocessing—The specific responses of each peptide were calculated by subtracting background intensity from foreground intensity. The resulting data were transformed using the variance stabilization model (57), previously trained by a larger MAP kinome data set, to bring all the transformed data onto the same scale while alleviating variance-mean-dependence. In addition, for each of the 300 peptides in a single treatment, the intensities induced by the treatments were subtracted by the intensities from the biological control (i.e. THP-1 + control media) and test statistics calculated. Average intensities were then taken over the three transformed rep-

licate intensities and these values subjected to hierarchical clustering analysis. The R package variance stabilization was used for the transformation (58).

Treatment-Treatment Variability Analysis—Peptide phosphorylations were subjected to paired t-tests to compare their signal intensities under a treatment condition with those under the control condition. Four tests were done for each peptide. Specifically, the tests were Congo Basin MPXV versus THP-1, West African MPXV versus THP-1, CPXV BR versus THP-1, and VACV WR versus THP-1. The *p* value cutoff was chosen to be 0.20. Formally, the test statistic (TS) was calculated as:

$$TS = \frac{D}{S_D \sqrt{n}}$$

where *D* is the mean of the differences between responses for the same peptides induced by two different treatments, *S_D* the standard deviation of the differences, and *n* is the number of replicates for that peptide in each treatment (i.e. 3 in our data set). Finally, the *p* values for the phosphorylation and dephosphorylation events were calculated as $P[TS > t^{(n-1)}]$ and $P[TS < t^{(n-1)}]$, respectively (i.e. one-sided *t* test). Peptides with significant (*p* < 0.20) changes in phosphorylation were selected using PERL and BASH scripts. The paired *t* test was done using R built-in function *t.test* with *paired* = *True*.

Hierarchical Clustering Analysis—The preprocessed data was subjected to hierarchical clustering and principle component analysis (PCA) to cluster treatments based on their kinome profiles. Specifically, for hierarchical clustering, McQuitty + (1 - Pearson Correlation) was used. Briefly, each treatment vector was considered as a singleton (i.e. a cluster with a single element) at the initial stage of the clustering. This method uses (1 - Pearson correlation) to calculate the distances between any two vectors of treatment, say *X* and *Y*. Formally, the Pearson correlation is computed as:

$$V_{xy} = \frac{300}{300} \frac{\sum_{i=1}^{300} x_i - x(y_i - y)}{\sum_{i=1}^{300} (x_i - x) \sum_{j=1}^{300} (y_j - y)}$$

and,

$$\text{dist}(\mathbf{X}, \mathbf{Y}) = 1 - v_{xy}$$

In addition, the McQuitty method updates the distance between the two clusters in such a way that upon merging cluster *C_x* and cluster *C_y* into a new cluster *C_{xy}*, the distance between *C_{xy}* and each of the remaining clusters, say *C_R*, is calculated in concern with the sizes of *C_x* and *C_y*. Mathematically, let the size of *C_x* be *nX* and size of *C_y* be *nY*, then:

$$D(C_{xy}, C_R) = \frac{nX \times D(C_x, C_R) + nY \times D(C_y, C_R)}{nX + nY}$$

The hierarchical clustering was augmented by a heatmap which is also generated using the R function *heatmap.2*. The function converts the intensity values to statistical z-scores, and then the z-scores are encoded as color (green/red) intensities. Green usually means a value lower than the mean; red a value higher.

Pathway Analysis of Differentially Phosphorylated Peptides—InnateDb (www.innatedb.com) is a publicly available resource which, based on levels of either differential expression or phosphorylation, predicts biological pathways based on experiment fold change datasets. Pathways are assigned a probability value (*p*) based on the number of proteins present for a particular pathway as well as the degree to which they are differentially expressed or modified relative

to a control condition. For our investigation input data was limited to peptides which showed consistent responses across the biological replicates ($p < 0.05$) as well as statistically significant changes from the control condition ($p < 0.10$).

WST-1 Cell Proliferation Assay—Cell proliferation in the MPXV-infected and mock-infected THP-1 monocytes was performed using the WST-1 proliferation assay (Millipore). Briefly, THP-1s (2×10^4 cells) were plated and rested overnight followed by 24 h MPXV infection as described above. WST-1/ECS solution was then added at a ratio of 1:10 and incubated at 37 °C for 2 h. Absorbance readings were acquired on a plate reader at a wavelength of 450 nm. Independent experiments were done in duplicate or triplicate and were repeated at least three times.

Apoptosis Assays—Induction of apoptosis in MPXV-infected THP-1 monocytes was determined using the ApoAlert Annexin V assay (Clontech) according to the manufacturer's instructions. Briefly, THP-1 monocytes were infected as described above. Following 24 h infection, cells were rinsed and resuspended with 1X binding buffer followed by the addition of 500 ng of Annexin V-FITC and Propidium iodide and incubated at room temperature in the dark for 10 min. Cells were subsequently washed with 1X binding buffer, incubated in fixative solution for 1 h at room temperature (PBS, 4% formaldehyde, 1% pluronic acid), and finally washed and resuspended in 1X binding buffer. Percentage of apoptotic cells was determined by BD[®] FACS analysis. Independent experiments were done in duplicate or triplicate and were repeated at least three times.

Caspase-3 activity was assessed using the EnzChek Caspase-3 Assay Kit (Invitrogen) according to the manufacturer's instructions. Briefly, MPXV-infected and mock-infected THP-1 monocytes were harvested by centrifugation 24 h postinfection and washed with PBS. Cell pellets were resuspended in 1X cell lysis buffer for 30 min on ice and centrifuged to remove cellular debris. Z-DEVD-AMC substrate was subsequently added and samples were incubated at room temperature for 30 min and fluorescence was measured at 441 nm on a standard plate reader.

Met PhosphoELISAS—THP-1 monocytes were infected or mock-infected as described above. At 24 h post-infection cells were harvested by centrifugation, washed with PBS, and lysed on ice for 10 min with 1X lysis buffer (20 mM Tris-HCl, pH 7.5, 150 mM NaCl, 1 mM ethylenediamine tetraacetic acid, 1 mM ethylene glycol tetraacetic acid, 1% Triton-X100, 2.5 mM sodium pyrophosphate, 1 mM Na_3VO_4 , 1 mM NaF, 1 $\mu\text{g}/\text{ml}$ leupeptin, 1 $\mu\text{g}/\text{ml}$ aprotinin, 1 mM phenylmethylsulfonyl fluoride). Phosphorylated c-Met was measured using the PathScan Phospho-Met (Tyr1234/1235) enzyme-linked immunosorbent assay (ELISA) Assay Kit (Cell Signaling) following the manufacturer's instructions. Experiments were done in duplicate were repeated independently at least three times.

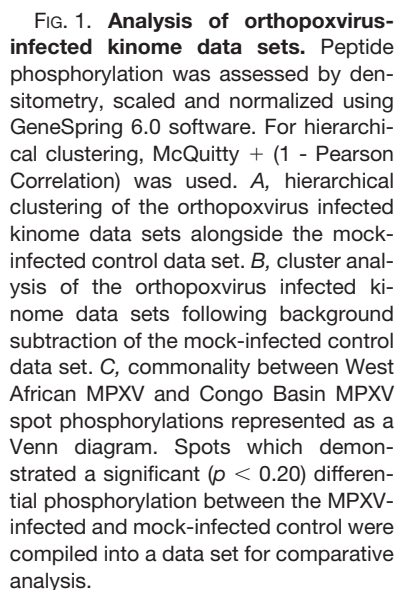

Pathway Inhibitor Assays—For the inhibitor studies THP-1 monocytes were pretreated for 30 min with LY29002 (20 μM ; Sigma Aldrich), Akt-X (15 μM ; EMD Biosciences, San Diego, CA) nutlin 3 (10 μM ; Sigma Aldrich), Met Kinase Inhibitor (1 μM or 10 μM ; Santa Cruz Biotechnology, Santa Cruz, CA), staurosporine (10 μM ; Enzo Lifesciences, Farmingdale, NY), SB-202190 (10 μM ; Enzo Lifesciences) or BML-257 (10 μM ; Enzo Lifesciences). Control cells were also employed in the absence of inhibitors. Cells were subsequently infected as described above in the continued presence or absence of inhibitor and harvested by centrifugation at 24 h post-infection followed by washing with cold PBS. Cells were subsequently disrupted by freezing and thawing and virus was collected from the supernatant of centrifuged cells and assayed for infectivity as described previously (19). Each experiment was run in duplicate and the results are reported as average values. The data was confirmed by at least three independent experiments with identical results.

RESULTS

West African and Congo Basin MPXV Induce Differential Host Target Phosphorylation—We postulated that the virulence differences associated with West African and Congo Basin MPXV may be attributed to the differential modulation of host cell signaling pathways following infection. Thus, we employed systems kinomics (20, 29, 30) with high-throughput human kinome peptide arrays to study the global activation state of host kinases, the kinome, following West African or Congo Basin MPXV infection. The resultant kinome data sets were subjected to hierarchical cluster analysis for comparative analysis and visualization of changes to host cell phosphorylation following infection. Conserved patterns of host kinome responses across the orthopoxvirus genus were also compared by the incorporation of CPXV BR and VACV WR. Interestingly, West African and Congo Basin MPXV demonstrated weak patterns of clustering independent of subtraction of the mock infected control (Figs. 1A, 1B). Further, Congo Basin MPXV-induced host phosphorylations clustered strongly with those induced by CPXV BR and VACV WR. Pairwise comparison of the MPXV data sets using Student's *t* test revealed a number of differential phosphorylations between either of the MPXV clades and the mock-infected condition or between the two MPXV clades directly. The commonality of peptide phosphorylations between West African and Congo Basin MPXV is presented in Fig. 1C. Of the peptide phosphorylations that displayed high technical reproducibility (as described in the materials and methods), 129 and 130 peptides were differentially phosphorylated relative to the mock-infected control for Congo Basin and West African MPXV, respectively. Approximately one-third of the differentially phosphorylated peptides were conserved in both identity and direction of phosphorylation changes (Fig. 1C). This is not unanticipated as the limited amino acid sequence variability between the MPXV clades (27) would suggest some degree of conserved interaction with the host. The remaining peptide phosphorylation differences represented phosphorylation events specific to a particular MPXV clade and represent differential trends in responses (increased *versus* decreased phosphorylation).

Congo Basin MPXV Selectively Down-regulates Host Signaling Pathways As Compared With West African MPXV—To gain insight into the relation between our kinome data and differential mechanisms of host response modulation employed by either West African or Congo Basin MPXV, we employed pathway ORA with the online software InnateDB (31). Input data for the analysis was limited to significant differences in peptide target phosphorylations ($p < 0.10$) relative to the mock-infected controls to ensure that identified pathways represented conserved biological responses.

For our initial pathway analysis we focused on protein phosphorylations that were common only to Congo Basin or West African MPXV infection (Fig. 1C). Pathway ORA of protein phosphorylations common to the Congo Basin MPXV

phosphorylations common to West African MPXV infection resulted in a broader subset of pathways identified by our ORA (Table II). Up-regulated pathways were primarily related to immune activation, including interleukin 2 (IL-2) and IL-6 signaling pathways (33), and growth factor responses, including fibroblast growth factor (FGF) (34), epidermal growth factor (EGFR) (35, 36), and platelet derived growth factor beta (PDGF β). In contrast, down-regulated pathways were found to be primarily related to transforming growth factor beta (TGF β) signaling responses (Table II).

Although these comparisons suggested that Congo Basin and West African MPXV differentially modulate host cell response following infection, the limited information from our initial pathway ORA compelled us to investigate this phenomenon further through direct comparison of the complete Congo Basin and West African MPXV kinome array data sets. We hypothesized that this comparison would provide a more detailed comparison by including protein phosphorylations that were common to both MPXV infection groups as well as those that were uncommon. As predicted, the direct comparison of the complete data sets yielded a much broader range of pathways differentially modulated by the two MPXV clades (Table III). Interestingly, Congo Basin MPXV infection resulted in the global down-regulation of host cellular responses as compared with West African MPXV following direct comparison of the two kinome data sets. As found in our initial comparative the down-regulated pathways were primarily related to growth factor signaling: including fibroblast growth factor (FGF) signaling (34), BCR-ABL-mediated signaling (17), and growth hormone signaling pathway (18)). However, pathways related to subversion of apoptotic responses were also identified, including the FAS signaling pathway (32), direct p53 effectors (37), regulation of bad phosphorylation (38), and phosphatase and tensin homolog (PTEN) dependent cell cycle arrest and apoptosis (16). Thus, our pathway ORA suggest that the Congo Basin MPXV selectively down-regulated host cell responses primarily related to growth factor signaling and apoptotic responses as compared with the less virulent West African MPXV clade.

Biological Validation of Signaling Responses Identified Through Kinome Analysis—Following the demonstration that Congo Basin MPXV infection down-regulated pathways related to growth factor signaling/cell proliferation and apoptosis as compared with West African MPXV, we sought to biologically validate these results. Importantly, we first demonstrated that the growth kinetics and level of virus replication of the two MPXV clades were similar throughout the course of our infection studies (supplemental Fig. S1).

First, our pathway ORA data for the direct comparison of Congo Basin and West African MPXV suggested that Congo Basin MPXV down-regulated cell proliferative responses as compared with West African MPXV (Table III). Thus, we monitored cell proliferation responses to the two MPXV viruses through a WST-1 assay as this assay is routinely used to investigate cell proliferation, cell viability and cytotoxicity. Our data demonstrate that Congo Basin MPXV infection resulted in a moderate but significant reduction in THP-1 cell proliferation as compared with West African MPXV (Fig. 2; data presented relative to mock-infected cells). This is consistent with the differential host responses identified through our pathway ORA.

The direct comparison of the kinome array data sets for Congo Basin and West African MPXV also suggested that West African MPXV selectively down-regulated apoptotic responses in host cells (Table I). Using fluorescence-activated cell sorting (FACS) analysis of AnnexinV staining we demonstrated a significant increase in host cell apoptosis following West African MPXV infection as compared with Congo Basin

TABLE III

Differential host cell signaling responses to Congo Basin MPXV-infected monocytes as compared to West African MPXV-infected monocytes. InnateDB is a publically available pathway analysis tool. Based on levels of differential expression or phosphorylation InnateDB is able to predict pathways that are consistent with the experimental data. Pathways are assigned a probability value (*p*) based on the number of proteins present for a particular pathway. It also provides the number of uploaded pathways associated with a particular pathway as well as the subset of individual proteins that are differentially phosphorylated. For this investigation fold change cutoffs were set at 80% confidence of the difference between the infected and mock-infected treatment

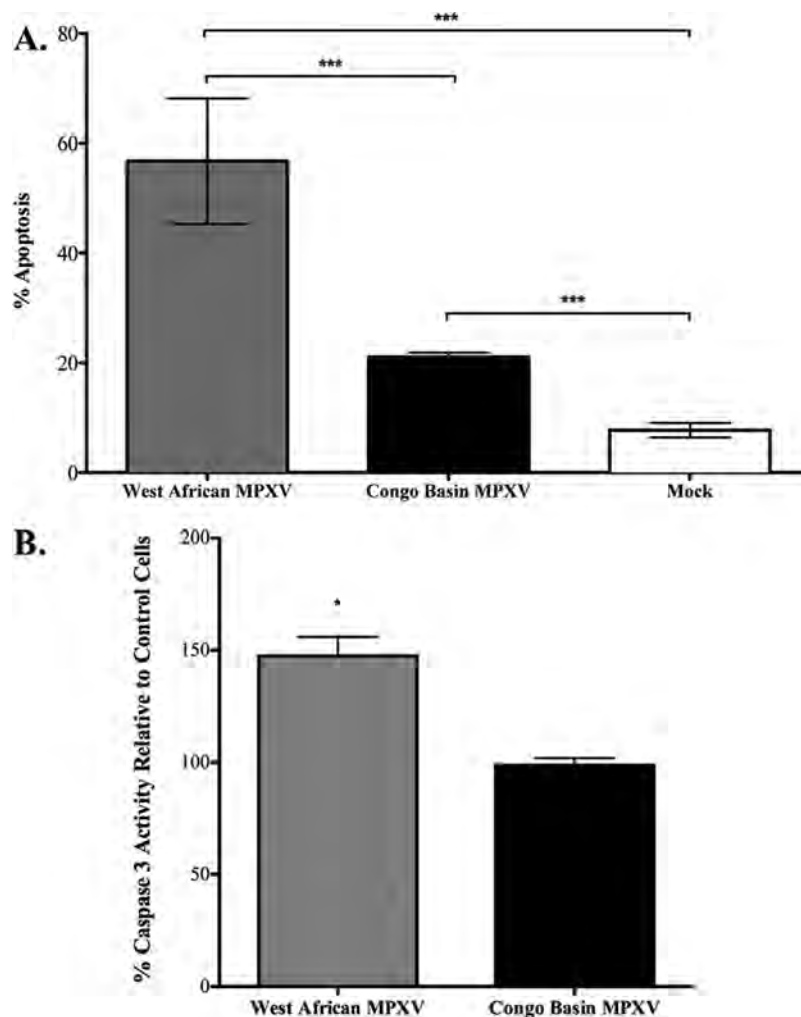

FIG. 2. Comparison of the effect of West African MPXV or Congo Basin MPXV on cell proliferation. Human THP-1 monocytes were seeded in a 96-well plate at 1×10^5 cell/well with 100 μ l of culture medium and infected at an MOI of 3 with West African or Congo Basin MPXV for 24 h. Cell proliferation was assessed through the addition of WST-1 reagent 30 min at the 24 h time point and absorbance was measured at 450 nm in a multiwell plate reader. Data is presented as the mean of three independent experiments \pm S.D. *, $p < 0.1$. A Student's *t* test was used for the comparison.

MPXV (Fig. 3A). This was further corroborated through a caspase 3 activity assay demonstrating a significant increase in caspase 3 activity in West African MPXV-infected cells relative to Congo Basin MPXV-infected cells (Fig. 3B; data presented relative to mock-infected control cells).

To further validate our kinome array data we selected a target that was common in all iterations of the pathway ORA, c-Met. c-Met-related signaling pathways were found to be repressed by Congo Basin MPXV in both Table I and Table III. We investigated the phosphorylation status of c-Met in response to both Congo Basin and West African MPXV directly through phosphospecific ELISA. Our array data demonstrated that c-Met Y1234 phosphorylation was significantly repressed (~ 1.4 -fold) in Congo Basin MPXV infected monocytes as compared with West African MPXV. Using a c-Met Y1234 phosphospecific ELISA we demonstrated that Congo Basin MPXV-infected cell lysates had a significant reduction (~ 1.4 -fold) in c-Met Y1234 phosphorylation as compared with lysates from West African MPXV-infected monocytes (Fig. 4A). Further, pharmacological inhibition of c-Met phosphorylation with 1 μ M or 10 μ M of Met Kinase Inhibitor 30 min prior to infection with the two MPXV clades (multiplicity of infection (MOI) = 3) resulted in a concentration-dependent increase in Congo Basin MPXV viral titers as compared with untreated Congo Basin MPXV-infected cells and no significant effect on West African MPXV infection (Fig. 4B). Taken together, the results of our biological validation functionally confirmed our kinome array data demonstrating the reliability and power of this approach.

FIG. 3. West African MPXV infection results in increased apoptosis as compared with Congo Basin MPXV.

Human THP-1 monocytes (1×10^6 cells) were infected at an MOI of 3 and seeded in a six-well plate with 3 ml of culture medium and incubated for 24 h. **A**, FACS analysis of THP-1 monocyte apoptosis 24 h postinfection by the two MPXV clades. Data is presented as the mean of three independent experiments \pm S.D. **B**, Caspase 3 activity of West African or Congo Basin MPXV-infected THP-1 monocyte lysates relative to the mock-infected THP-1 cells. Data is presented as the mean of three independent experiments with identical results \pm S.D. *, $p < 0.1$; ***, $p < 0.001$. A Student's *t* test was used for the comparison.

Disruption of Akt S473 and p38 α Phosphorylation, or Activation of Apoptosis, Significantly Inhibits Congo Basin MPXV Replication as Compared with West African MPXV—In addition to increasing our understanding of mechanisms of viral pathogenesis, our kinome data and pathway ORA provided the identities of specific host pathways and kinases that were differentially modulated by Congo Basin and West African MPXV. Previously, it has been demonstrated that poxviruses can selectively modulate host responses mediated by the PBK/Akt pathway for regulation of viral replication (39, 40). Soares *et al.* demonstrated that the selective pharmacological inhibition of Akt S473 phosphorylation with Akt-X or T308 phosphorylation with LY294002 reduced CPXV and VACV virus yields by 80–90% (40). Our kinome array data suggested that phosphorylation of Akt S473 was significantly increased (1.8 fold) following Congo Basin MPXV but was unaffected following West African MPXV infection. Akt T308 phosphorylation was comparably increased in both West African and Congo Basin MPXV infected cells as compared with the mock-infected controls (supplemental Table S5). Thus, we sought to investigate the effects of pharmacological inhibition

of Akt phosphorylation on West African and Congo Basin MPXV viral replication. We performed one-step viral growth curves for both MPXV clades in the presence or absence of LY294002 (20 μ M) or Akt-X (15 μ M). This concentration of inhibitors had no significant effect on cell viability (data not shown). Cells were left untreated or were pretreated with inhibitors for 30 min prior to infection at an MOI of 3 in the continued presence of inhibitors. At 24 h post-infection virus was collected and assayed for infectivity. Inhibition of Akt S308 by LY294002 had no significant inhibitory effect on virus production in monocytes infected with either MPXV clade (Fig. 5). However, inhibition of Akt S473 phosphorylation with Akt-X selectively inhibited Congo Basin MPXV virus replication (261-fold reduction in virus yield), whereas there was no significant inhibition West African MPXV infection as compared with the untreated infected controls (Fig. 5). Interestingly, pharmacological inhibition of Akt translocation with BML-257 demonstrated a similar inhibitory effect (~3.5-fold difference) on the two MPXV clades suggesting a central role for Akt in the life cycles of both MPXV clades.

FIG. 4. West African MPXV infection increases Met phosphorylation as compared with Congo Basin MPXV. Human THP-1 monocytes (1×10^6 cells) were infected at an MOI of 3 and seeded in a six-well plate with 3 ml of culture medium and incubated for 24 h. **A**, Met PhosphoELISA analysis of West African or Congo Basin MPXV-infected THP-1 monocytes relative to the mock-infected THP-1 cells. Phosphorylated Met (Tyr1234/1235) was determined by phospho-ELISA assay as described in Methods. **B**, Effect Met phosphorylation inhibition on West African and Congo Basin MPXV virus yields. Human THP-1 monocytes were either left untreated or treated for 30 min with Met Kinase Inhibitor (1 μ M or 10 μ M) prior to virus infection. Cells were subsequently infected with West African MPXV or Congo Basin MPXV at an MOI of 3 in the absence or continued presence of inhibitor for 24 h. Viruses were then collected and viral titers were determined. Data is presented as the means of three independent experiments \pm S.D. *, $p < 0.1$. A Student's t test was used for the comparison and p values were based on comparison to the control infected conditions.

Recently, Zachos *et al.* have demonstrated that herpes simplex virus type 1 (HSV-1)-enhanced infection through stimulation of p38 MAPK signaling (41). Analysis of our kinome data sets also suggested that Congo Basin MPXV infection resulted in increased p38 phosphorylation (p38 α and p38 δ) as compared with West African MPXV (1.5-fold and 2.4 fold, respectively). We had also found that pre-treatment of HEK293 cells with SB-202190, a p38 α inhibitor, resulted in a significant inhibition of a GFP expressing Congo Basin MPXV (Data not shown) suggesting a central role for p38 in Congo Basin MPXV infection. Pretreatment of cells with SB-202190 resulted in decreased West African and Congo Basin MPXV virus yields; however, addition of the inhibitor had a 9.5-fold

FIG. 5. Inhibitors of Akt or p38 alpha phosphorylation, or activation of apoptosis, decrease Congo Basin MPXV viral replication as compared with West African MPXV. Human THP-1 monocytes were either left untreated or treated for 30 min with LY294002 (20 μ M), Akt-X (15 μ M), nutlin 3 (10 μ M), staurosporine (10 μ M), SB-202190 (10 μ M), or BML-257 (10 μ M) prior to virus infection. Cells were subsequently infected with West African MPXV or Congo Basin MPXV at an MOI of 3 in the absence or continued presence of the pharmacological agents for 24 h. Viruses were then collected and viral titers were determined. Data are representative of three independent experiments \pm S.D. *, $p < 0.1$; **, $p < 0.01$; ***, $p < 0.001$. A Student's t test was used for the comparison and p values were based on comparison to the control infected conditions.

greater inhibitory effect on Congo Basin MPXV virus production. SB-202190 was not cytotoxic to cells at the concentration tested.

As Congo Basin MPXV selectively repressed apoptosis in infected monocytes as compared with West African MPXV, and this correlated with reduced phosphorylation of p53 in our kinome array comparison (~ 1.6 -fold), we investigated the effect of chemical antagonism of apoptosis on MPXV virus yields. We postulated that increased apoptosis in Congo Basin MPXV-infected monocytes would result in reduced virus yields as compared with West African MPXV. Cells were pre-treated with staurosporine (10 μ M) and were subsequently infected with MPXV as above. Cells treated with staurosporine were $>94\%$ viable after 24 h. Activation of apoptosis resulted in significantly reduced viral yields in both Congo Basin MPXV-infected cells (495-fold decrease) and West African MPXV-infected cells (10-fold decrease) (Fig. 5). However, the ~ 50 -fold greater inhibition of Congo Basin MPXV suggests a much stronger effect of apoptosis activation on Congo Basin MPXV virus replication. These data indicate the rapid translation of kinomic data into rational strategies for antiviral target discovery.

DISCUSSION

Although global eradication of smallpox was announced in 1980 there is a paucity of information regarding the molecular mechanisms underlying VARV disease pathogenesis. The critical importance of understanding the molecular mechanisms of poxvirus disease is further underscored by the increasing incidence of MPXV, a surrogate for VARV studies, and the accidental introduction of MPXV into the United States in

2003. Through a combination of systems kinomics and biological and functional validation assays we have demonstrated that West African and Congo Basin MPXV differentially modulate host cell responses and in particular those related to cell proliferation, cell survival and apoptosis.

Our investigation demonstrated that Congo Basin MPXV selectively downregulated pathways largely related to apoptotic events, including p53- and Fas-mediated cell signaling events, and cell proliferation, and enhanced cell survival as compared with West African MPXV. Indeed, the ability of poxviruses to subvert pro-apoptotic host cell responses, in particular through gene-encoded apoptosis inhibitors, is well documented (40, 42–45). Analysis of our kinome data sets suggested that the anti-apoptotic activities associated with Congo Basin MPXV were largely related to p53-mediated signaling apoptosis pathways and supported by FACS analysis and caspase 3 activity assays. Proteomic analysis of West African and Congo Basin MPXV has demonstrated >99% amino acid sequence conservation between the two MPXV clades; however, differences within the two sequences were sequestered to host response modifier proteins at the terminal ends of the genome (28). Interestingly, BR-203, an ortholog of myxoma virus M-T4 believed to have a role in subversion of host apoptotic responses (32, 46), is predicted to be severely truncated in West African MPXV though the full-length gene appears in Congo Basin MPXV (42). Thus, it is enticing to speculate that BR-203 plays a central role in the virulence associated with Congo Basin MPXV and may be a novel target for therapeutic investigations. Further, there is an increasing appreciation for subversion of host apoptotic responses as a means of facilitating viral replication (47). As apoptosis is an important function of innate immunity for limiting pathogen dissemination it is unsurprising that viruses have evolved diverse mechanisms for subverting host apoptotic responses.

To gain further insight into the mechanisms of MPXV-mediated host response modulation we directly compared the kinome data sets from the two MPXV clades. Pathway ORA suggested that Congo Basin MPXV-infection represses host signaling pathways largely related to growth factor signaling and cell proliferative responses as compared with the less virulent West African MPXV clade. Although it may seem counter-intuitive for a more virulent virus to reduce cell proliferative responses, investigations of vFGF, a baculovirus FGF mimic, have demonstrated that vFGF increases virus dissemination and reduces the time to death for the host (48). The ability of vFGF to bind and activate the host FGF receptor results in virus-mediated host cell proliferation. Signaling events mediated by the hepatocyte growth factor receptor c-Met were identified through pathway ORA in both the phosphorylation events common to Congo Basin MPXV and following direct comparison to the West African MPXV kinome data sets. This coupled with our phosphoELISA data and Met Kinase Inhibitor data suggested that c-Met occupied a central

role in Congo Basin MPXV infection of monocytes. This suggests that Congo Basin MPXV selectively modulates c-Met-mediated signaling pathways, and perhaps other growth factor-mediated signaling events, during infection. Indeed, the repression of monocyte cell proliferation by Congo Basin MPXV may highlight a secondary mechanism for the virus to subvert potential host cell apoptosis following enhanced, and potentially uncontrolled, cell proliferation. Recent evidence from Ryan and colleagues suggests that chronic hepatitis C infection may impede host immune responses by disabling dendritic cells as a mechanism to reduce pathogen recognition and initiation of the innate immune response (49). Moreover, pathway ORA of phosphorylation events common to Congo Basin MPXV infection suggested that the FoxO signaling pathways were distinct to infection by this MPXV clade. FoxO signaling pathways have been implicated in the delicate balance between cell survival and cell death (50). As FoxO activation can block cell proliferation and promote quiescence in many cell types it is enticing to speculate that this may reflect a vital role for the activation of FoxO signaling pathways in subversion of host immunity by Congo Basin MPXV. Thus, our data suggests that the increased virulence associated with Congo Basin MPXV as compared with West African MPXV may be a consequence of both the precise modulation of programmed cell death, cell cycle progression and promotion of cell survival. Further investigations focusing on the selective modulation of the pathways identified in our comparison of the two MPXV clade data sets may identify previously unknown roles of these pathways in viral infection.

A recent investigation by Soares *et al.* highlighted the central role of Akt phosphorylation in orthopoxvirus infection (40). Our kinome analysis demonstrated that West African and Congo Basin MPXV differentially modulate Akt S473 phosphorylation. Importantly, pharmacological inhibition of S473 phosphorylation with Akt-X significantly inhibited viral replication in Congo Basin MPXV-infected cells; however, no reduction was demonstrated for West African MPXV-infected cells. Thus, our data suggest that the two MPXV clades may utilize different host cell signaling pathways for viral replication and the precise mechanisms underlying these differences require further exploration. Interestingly, pretreatment with BML-257, an Akt translocation inhibitor, had similar inhibitory effects on West African and Congo Basin MPXV. This indicates that the modulation of Akt-mediated signaling by Congo Basin MPXV is likely related to the phosphorylation state of Akt rather than its cellular localization. Our investigation also suggests a central role for p38 α , and potentially p38-MAPK signaling, in Congo Basin MPXV infections. Our kinome data demonstrated that Congo Basin MPXV infection results in increased phosphorylation of the p38 α and treatment with the p38 α inhibitor SB-202190 resulted in a 9.5-fold greater decrease in Congo Basin MPXV virus yields as compared with West African MPXV. Although the activation of p38 MAPK signaling is classically related to stress responses and activation of cell

death (51), there is increasing evidence that under certain circumstances p38 MAPK can enhance cell survival. Indeed, p38 MAPK activation has been demonstrated to enhance cell survival responses to DNA damage (52, 53). Further, Zachos *et al.* have demonstrated that herpes simplex virus type 1 (HSV-1)-mediated stimulation of p38 MAPK resulted in enhanced viral transcription and increased virus yields (41).

Although systems kinomics has been employed extensively in cancer research (20) there has been limited application to the investigation of viral infections. Thus, molecular investigations of poxvirus disease pathogenesis have relied on gene expression studies. Rubins *et al.* demonstrated that MPXV genes related to immunomodulation were expressed throughout the course of infection (54). Alkhalil *et al.* and Rubins *et al.* recently demonstrated that Congo Basin MPXV infection down-regulated a broad range of host responses (15). More recently, Brown *et al.* demonstrated that MPXV insult resulted in reductions to host protein expression levels, most notably those participating in structural or metabolic processes (55). Although these investigations have provided important information regarding modulation of host immunity by Congo Basin MPXV, the integration of systems kinomics has provided pertinent functional information regarding the differential host response to Congo Basin MPXV and the less-virulent West African MPXV clade and identified potential host targets for therapeutic intervention.

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Vertical transmission of coronavirus disease 2019: a systematic review and meta-analysis

Alexander M. Kotlyar, MD; Olga Grechukhina, MD; Alice Chen, BS; Shota Popkhadze, MD; Alyssa Grimshaw, MSLIS; Oded Tal, PhD; Hugh S. Taylor, MD; Reshef Tal, MD, PhD

Introduction

The coronavirus disease 2019 (COVID-19) has spread from isolated cases of pneumonia in Wuhan, Hubei province, China, to become a worldwide pandemic as declared by the World Health Organization on March 11, 2020.¹ As of June 1, 2020, there have been more than 6,300,000 confirmed cases and more than 370,000 deaths worldwide. Coronaviruses are single-stranded RNA viruses. Although there are many coronaviruses, the particular coronavirus that is responsible for this pandemic is the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2).² After 2 to 7 days of incubation, most symptomatic patients typically experience fever, cough, or loss of taste or smell, with some cases developing into life-threatening pneumonia and acute respiratory distress syndrome.^{3,4} Case fatality rates range from 1% to 2%, which is substantially less than the case fatality rates for other coronavirus infections including the severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS) (10% and 35%, respectively).⁵

OBJECTIVE: This study aimed to conduct a systematic review of the current literature to determine estimates of vertical transmission of coronavirus disease 2019 based on early RNA detection of severe acute respiratory syndrome coronavirus 2 after birth from various neonatal or fetal sources and neonatal serology.

DATA SOURCES: Eligible studies published until May 28, 2020, were retrieved from PubMed, EMBASE, medRxiv, and bioRxiv collection databases.

STUDY ELIGIBILITY CRITERIA: This systematic review included cohort studies, case series, and case reports of pregnant women who received a coronavirus disease 2019 diagnosis using severe acute respiratory syndrome coronavirus 2 viral RNA test and had reported data regarding the testing of neonates or fetuses for severe acute respiratory syndrome coronavirus 2 immediately after birth and within 48 hours of birth. A total of 30 eligible case reports describing 43 tested neonates and 38 cohort or case series studies describing 936 tested neonates were included.

STUDY APPRAISAL AND SYNTHESIS METHODS: The methodological quality of all included studies was evaluated by a modified version of the Newcastle-Ottawa scale. Quantitative synthesis was performed on cohort or case series studies according to the neonatal biological specimen site to reach pooled proportions of vertical transmission.

RESULTS: Our quantitative synthesis revealed that of 936 neonates from mothers with coronavirus disease 2019, 27 neonates had a positive result for severe acute respiratory syndrome coronavirus 2 viral RNA test using nasopharyngeal swab, indicating a pooled proportion of 3.2% (95% confidence interval, 2.2–4.3) for vertical transmission. Of note, the pooled proportion of severe acute respiratory syndrome coronavirus 2 positivity in neonates by nasopharyngeal swab in studies from China was 2.0% (8/397), which was similar to the pooled proportion of 2.7% (14/517) in studies from outside of China. Severe acute respiratory syndrome coronavirus 2 viral RNA testing in neonatal cord blood was positive in 2.9% of samples (1/34), 7.7% of placenta samples (2/26), 0% of amniotic fluid (0/51), 0% of urine samples (0/17), and 9.7% of fecal or rectal swabs (3/31). Neonatal serology was positive in 3 of 82 samples (3.7%) (based on the presence of immunoglobulin M).

CONCLUSION: Vertical transmission of severe acute respiratory syndrome coronavirus 2 is possible and seems to occur in a minority of cases of maternal coronavirus disease 2019 infection in the third trimester. The rates of infection are similar to those of other pathogens that cause congenital infections. However, given the paucity of early trimester data, no assessment can yet be made regarding the rates of vertical transmission in early pregnancy and potential risk for consequent fetal morbidity and mortality.

Key words: COVID-19, SARS-CoV-2, transplacental transmission, vertical transmission

The presence of COVID-19 infection in a pregnant patient raises concerns given that infections with other coronaviruses such as SARS and MERS have been associated with severe maternal and neonatal morbidity and mortality and adverse pregnancy outcomes including miscarriage, preterm birth, and

stillbirth.⁶ However, the effects of COVID-19 on pregnancy and the fetus are still largely unknown because of the recent nature of the outbreak. Pregnant patients are a potentially vulnerable group to COVID-19 infection. The first and third trimesters of pregnancy can be considered periods of increased

AJOG at a Glance

Why was this study conducted?

Coronavirus disease 2019 (COVID-19) is a pandemic that has and will continue to affect many pregnant women. Knowledge regarding the possible risk of vertical transmission is very limited but is crucial for guiding patient counseling regarding COVID-19—related pregnancy risks and obstetrical care for women with COVID-19.

Key findings

The vertical transmission of COVID-19 in the third trimester is approximately 3.2% (22/936) by infant nasopharyngeal swab testing, with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) RNA positivity in other test sites ranging from 0% (0/51) in amniotic fluid and urine (0/17), 3.6% (1/28) in the cord blood, 7.7% (2/26) by placental sample analysis, 9.7% (3/31) by rectal or anal swab, and 3.7% (3/81) by serology.

What does this add to what is known?

There is evidence of SARS-CoV-2 vertical transmission when the infection occurs in the third trimester of pregnancy.

inflammatory activity, whereas the second trimester is a period of overall decreased immune activity.^{7,8} Although initial reports of pregnant women infected with COVID-19 in the third trimester raised a concern for an increased risk for premature delivery,^{9,10} recent larger cohorts of 116 women in China and 427 women in the United Kingdom suggest that pregnant women are not at an increased risk of spontaneous abortion or spontaneous preterm birth but have higher rates of cesarean delivery (CD).^{11,12}

Vertical transmission is defined as the transmission of the infectious pathogen from the mother to the fetus during the antepartum and intrapartum periods, or to the neonate during the postpartum period via the placenta in utero, body fluid contact during childbirth, or through direct contact owing to breastfeeding after birth. Although multiple infectious vectors have been shown to be capable of vertical transmission, the possibility of vertical transmission of SARS-CoV-2 from the infected mother to the fetus or neonate has been a point of a recent debate with previous systematic reviews, albeit with a limited number of studies, concluding that there is no evidence of vertical transmission.^{13–16} No known cases of vertical transmission have been noted

with similar coronaviruses such as SARS and MERS, although the number of cases has been limited.^{17,18} COVID-19 shares 50% and 79% sequence homology with SARS and MERS, respectively; despite this homology, a similar lack of vertical transmission cannot be assumed.⁶

A concern over vertical transmission in the case of COVID-19 exists for several reasons. First is the known tissue tropism of COVID-19. The main receptor that COVID-19 binds to enter a cell is the angiotensin-converting enzyme 2 (ACE2) receptor. ACE2 is expressed in the placenta¹⁹ and is found in the syncytiotrophoblast, cytotrophoblast, endothelium, and vascular smooth muscle from both primary and secondary villi.²⁰ A recent systematic review also found evidence that ACE2 is expressed in gynecologic organs such as the ovary, uterus, and vagina.²¹ Overall, ACE2 expression is seen in numerous tissues that are in direct communication with a developing pregnancy. These data were further bolstered by a recent single-cell RNA sequencing analysis that found ACE2 expression in stromal, perivascular, placental, and decidual cells at the maternal-fetal interface.²² However, a single-cell RNA sequencing analysis looking at the coexpression of ACE2 and the transmembrane serine protein for

virus spike (S) protein priming, transmembrane serine protease 2 (TMPRSS2), showed that only a minimal number of placental cells express both proteins in any trimester. Furthermore, this group showed that chorionic membranes from the third trimester exhibit minimal coexpression of both proteins. Nonetheless, the authors suggested that viral entry into placenta cells may still occur using a combination of ACE2 and a noncanonical cell-entry mediator.²³ In addition, animal data indicated that oronasal inoculation of pregnant mice with mouse hepatitis virus (MHV), which is part of the Coronaviridae family, led to the dissemination of the virus to the fetus in each trimester. However, the dissemination was dependent on the strain of MHV and the strain of mice, with BALB/cByJ mice being the most susceptible.²⁴ In addition to this biological plausibility, there are several lines of clinical evidence concerning vertical transmission. Initial reports from China have documented immunoglobulin M (IgM) antibodies in neonates born to mothers who had positive results for COVID-19,^{25,26} raising concerns for in utero transmission because IgM cannot cross the placenta. Moreover, several recent case reports provided evidence that COVID-19 can infect the placenta as confirmed by the presence of SARS-CoV-2 viral RNA and protein in the placenta and evidence of virions found within the syncytiotrophoblast.^{27–30}

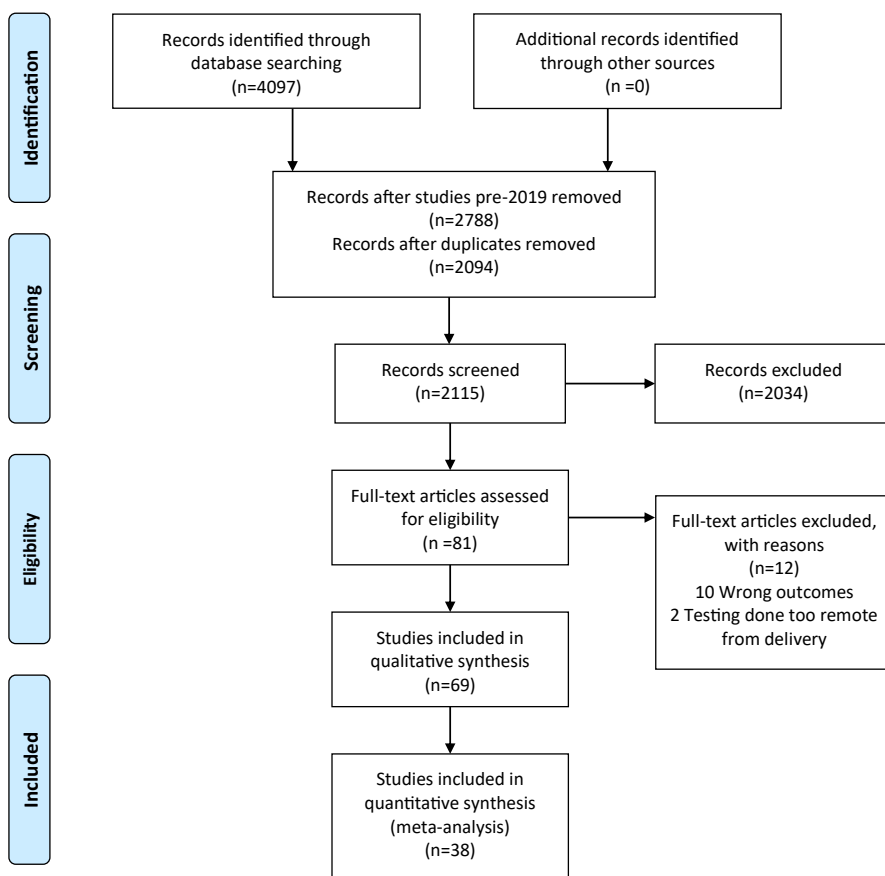

Answering the question of vertical transmission is crucial for guiding patient counseling regarding COVID-19—related risks before and during pregnancy and obstetrical care for women infected with COVID-19. Therefore, we conducted this systematic review to summarize the available evidence regarding the risk of vertical transmission.

Methods**Search strategy, study selection, and data extraction**

A medical librarian conducted a systematic search of the literature from Cochrane Library, DisasterLit, Ovid Embase, Ovid Medline, Google Scholar, LitCovid, MedRxiv, Pubmed, Scopus,

and Web of Science Core Collection databases to find relevant articles published from inception of the database to May 28, 2020, to identify cohort studies, case series, and case reports of pregnant women with COVID-19 that include information regarding fetal or neonatal COVID-19 testing. The study was conducted according to the Preferred Reporting Items for Systematic Reviews and Meta-analyses guidelines for the reporting of systematic reviews and meta-analyses and was registered in the International Prospective Register of Systematic Reviews (CRD42020190885). The databases were searched using a combination of controlled vocabulary and free-text terms for SARS-CoV-2, COVID-19, coronavirus, Coronaviridae, pregnancy, fetus, infant, mother-to-child, mother-to-infant, maternal-fetal, virus transmission, disease transmission, and vertical transmission (the full search strategy is provided in the [Supplemental Figure](#)). The search results were limited to English-language abstracts. Foreign-language articles were included only if a translation was available given the time-sensitive nature of this review. Bibliographies were cross-referenced to identify additional relevant studies. Studies were included if they were English-language articles that focused on the development of COVID-19 infection in fetuses and neonates. Citations from all databases were imported into an EndNote X9 library. Duplicates were removed from the EndNote, reducing the initial list of 4907 citations to 2904 citations. The database of 2904 citations was entered into Covidence, which is a screening and data extraction tool. Two independent screeners (A.K. and O.G.) performed a title abstract review and resolved conflicts by consensus between the 2 screeners. The screeners selected a total of 81 records for full-text review and included 68 studies that fulfilled the eligibility criteria in the qualitative synthesis ([Figure 1](#)). Cohort studies and case series (defined as having 5 or more patients) were selected for quantitative synthesis. Case series were defined as having 5 or more patients, consistent with the recommendations according to the study by Abu-Zidan et al³¹ showing that case reports have a

FIGURE 1
PRISMA flowchart outlining study selection

PRISMA, Preferred Reporting Items for Systematic Reviews and Meta-analyses.

Kothiyar. Vertical transmission of COVID-19: a systematic review and meta-analysis. *Am J Obstet Gynecol* 2021.

median number of 4 patients. Data were extracted from the article texts and tables and organized into tables in a systematic manner. The following information was extracted: author name; country; publication date; number of pregnant women; number of eligible neonates; gestational age (at onset of testing); mode of delivery; neonatal SARS-CoV-2 reverse transcription–polymerase chain reaction (RT-PCR) testing results from nasopharyngeal (NP) swab, placenta, cord blood, amniotic fluid, and any other fetal or neonatal sources; placental histology; and neonatal serology.

Eligibility criteria

Studies were included in this systematic review if they met the following criteria: (1) the study population included

women who had COVID-19 infection during pregnancy confirmed by positive viral SARS-CoV-2 RNA testing; (2) the study described results of viral RNA testing for SARS-CoV-2 infection in fetuses or neonates; (3) testing for SARS-CoV-2 infection was performed within 48 hours of delivery; and (4) any study design (cohort, case series, case report). Articles that focused on the transmission of COVID-19 outside of the perinatal period were excluded given that this was deemed out of scope for this article.

Methodological quality assessment

Each cohort or case series study selected for final inclusion in the quantitative synthesis was scored by the researchers (A.C. and R.T.) using the modified Newcastle-Ottawa scale, as previously

described (Supplemental Table).³² Items that relate to comparability and adjustment are not relevant and were removed, whereas items that focused on the selection and representativeness of cases and ascertainment of outcome and exposure were maintained. This resulted in 5 items regarding the study quality characteristics: (1) representativeness of the exposed cohort, (2) exposure assessment, (3) outcome assessment, (4) adequacy of the length of time before follow-up, and (5) adequacy of the follow-up of cohorts. We considered the quality of the report good (low risk of bias) when all 5 criteria were fulfilled, moderate when 4 were fulfilled, and poor (high risk of bias) when 3 or fewer were fulfilled.

Statistical analysis

We evaluated the positive rates of each of the explored SARS-CoV-2 testing outcomes (RT-PCR of NP swab, placenta, cord blood, rectal or anal, urine, amniotic fluid, and IgM serology). Pooled proportions of these categorical variables were calculated with percentages and 95% confidence intervals (CIs). Calculations were performed using the MedCalc Statistical Software version 19.3.1 (MedCalc Software Ltd, Ostend, Belgium; <https://www.medcalc.org; 2020>). The Cochran Q test was used to determine whether to use the fixed effects model or the random effects model ($P < .1$: random effects model). A Freeman-Tukey transformation (arcsine square root transformation)³³ was used to calculate the weighted summary proportion under the fixed and random effects models.³⁴ The random effects model was preferred because it is more conservative.

Results

Search results

A total of 81 records were selected for full-text review, and 69 studies fulfilled the eligibility criteria and were included in the qualitative synthesis. There were 30 case reports. Their characteristics and test findings are summarized in Table 1. A total of 39 additional studies were cohort studies or case series (defined as having 5 or more patients) and were

selected for quantitative synthesis. The characteristics and test findings of these cohort or case series studies are summarized in Tables 2 and 3. These were divided into reports from China (Table 2) and reports from the rest of the world (Table 3) because evidence indicates that earlier Asian viral samples were completely dominated by the original Wuhan D614 form through mid-March, and subsequently, in countries outside of China and across the globe, a different form (G614) was expanding and dominating.⁹¹ The flow diagram of the study selection strategy is presented in Figure 1. The methodological quality assessment of the cohort or case series studies included in the quantitative synthesis showed that 13 studies were of high quality, 16 studies were of moderate quality, and 10 studies were of low quality (Supplemental Figure).

Systematic review

This systematic review included 30 eligible case reports describing a total of 44 SARS-CoV-2–positive pregnant women with outcomes available for 43 neonates (Table 1) and 39 cohort or case series studies describing a total of 936 tested neonates born to SARS-CoV-2–positive pregnant women (Tables 2 and 3). Data in this review were limited to pregnant women who had laboratory-confirmed SARS-CoV-2 infection diagnosed by RT-PCR in an NP swab specimen, which is considered the gold standard for the diagnosis of COVID-19.

Because of the recent onset of the pandemic, the vast majority of data came from pregnant women in their third trimester, whereas the greatest paucity of reports involved patients in the earlier stages of pregnancy. Of the 30 case reports, 29 reports described neonatal outcomes of women in their third trimester, whereas only 2 case reports described outcomes of women in their second trimester.^{13,18,25,27–30,}

^{35–50,51–58,66} To date, no reports are available describing the assessment for the presence of SARS-CoV-2 in products of conception of a first-trimester pregnancy. Most women in case report studies (32/44) underwent CD with a

resultant CD rate of 73%. Similarly, 73% of women (659/901) in cohort or case series studies delivered via CD.

This systematic review identified 2 case reports of second-trimester fetal SARS-CoV-2 testing. Baud et al²⁸ reported a case of a patient at 19 weeks' gestation with a positive result from a SARS-CoV-2 NP swab who had a miscarriage delivering a stillborn infant. Fetal axillary, oral, meconium, and blood samples all tested negative for SARS-CoV-2 RNA. However, placental swabs from the fetal side taken immediately after expulsion were positive for SARS-CoV-2 by RT-PCR. In another case report by Hosier et al,²⁷ a COVID-19–positive patient delivered at 22 weeks' gestation because of early-onset preeclampsia with severe features. Quantitative RT-PCR tests of placental and umbilical cord samples were positive for SARS-CoV-2 RNA, and viral capsids were found within the trophoblast cells by electron microscopy, confirming infection of the fetal side of the placenta by this novel coronavirus. Although these cases do not provide evidence that placental COVID-19 infection was the cause of these adverse pregnancy outcomes, they lend support to the possibility of in utero maternal-to-fetal transmission.

Overall, the majority of COVID-19 cases of pregnant women with fetal or neonatal outcomes reported thus far involved patients in their third trimester of pregnancy. Given the plethora of studies of patients in the third trimester, we analyzed them according to the study type (case report vs cohort or case series study) and site of SARS-CoV-2 testing. Because selection bias is more likely in case reports than in cohort or case series studies, we focused our quantitative synthesis on the case series and cohort studies to reach pooled proportions regarding various parameters indicative of vertical transmission.

Severe acute respiratory syndrome coronavirus 2 reverse transcription–polymerase chain reaction testing of nasopharyngeal swab. In our review, 38 of 39 cohort or case series studies of pregnant women with COVID-19 infection had information on

neonatal NP swab testing results. There were 22 studies from China (Table 2) and 17 studies from countries outside of China (Italy, Spain, United Kingdom, and United States of America) (Table 3). In total, of 397 neonates born to mothers with COVID-19 infection in China, there were 8 who had a positive result for SARS-CoV-2 by NP swab resulting in a pooled proportion of 2.0% for vertical transmission.^{8–11,26,56,59–71,72–75} The largest cohort study from China was by Yan et al,¹¹ in which 116 COVID-19–positive pregnant patients delivered 100 infants, of whom 86 underwent testing for SARS-CoV-2. None of the 86 infants had a positive result for COVID-19 via NP swab. Among studies from outside of China, the largest cohort study thus far came from the United Kingdom involving 427 pregnant women with COVID-19 including 244 neonates tested by NP swab, 12 of whom were positive for SARS-CoV-2 (12/244).¹² An analysis of 68 women from a hospital in New York City showed that of the 55 neonates born, 48 were tested at day 0 of life with none having a positive result for COVID-19 (0/48).⁸² One Italian study that assessed 42 infants born via vaginal delivery and CD found 3 infants (3/42) who had positive results for SARS-CoV-2 via NP swabs within 48 hours after birth.⁷⁸ Pooling studies from outside of China revealed that 19 of 539 neonates born to mothers with COVID-19 infection had positive results for SARS-CoV-2 by NP swab, yielding a pooled proportion of 3.5%.^{12,18,76–90} Combining all 38 cohort or case series studies in a meta-analysis, of all 936 neonates tested, 27 had positive results for SARS-CoV-2 RNA by NP swab either immediately after birth or within 48 hours of birth, yielding a pooled proportion of 3.2% (95% CI, 2.2–4.3) (Figures 2 and 3).

Placental analysis. In our review, we identified 8 cohort or case series studies that reported on the assessment of placentas for SARS-CoV-2 by RT-PCR, 2 from China and 6 from outside of China. The placental analysis yielded the second highest pooled rate of possible vertical transmission with 7.7% (2/26) of all

tested placentas of COVID-19–infected mothers having positive results for SARS-CoV-2 RNA (Figure 2). Among the case reports, 4 of 20 placentas tested for SARS-CoV-2 RNA had positive results. In 1 case, the placenta from a 19-week fetal demise had a positive result for SARS-CoV-2 RNA via PCR.²⁸ In another case mentioned earlier, a patient was diagnosed as having severe preterm preeclampsia complicated by placental abruption in the setting of COVID-19 at 22 weeks' gestation and underwent dilation and evacuation. Placental and fetal tissues were examined for the evidence of SARS-CoV-2 infection. Placenta and umbilical cord were positive for SARS-CoV-2 RNA tested by RT-PCR, whereas the fetal heart, lungs, and kidneys were negative. The sequencing of the virus isolated from the placenta confirmed it to be identical to the typical locally isolated SARS-CoV-2. Immunohistochemistry for the SARS-CoV-2 S protein and electron microscopy confirmed viral localization predominantly in the syncytiotrophoblast cells of the placenta.²⁷ The presence of SARS-CoV-2 virions in the fetal side of the placenta was similarly confirmed using electron microscopy in another case report of a woman who presented at 28 weeks' gestation and delivered by CD because of rapid maternal deterioration.⁵⁷ In this case, single virions were visible invading a syncytiotrophoblast, a single virion was also visualized in a microvillus, and virions were also noted in the mesenchymal core of terminal villus in the processes of the fibroblasts, but there was no evidence of fetal infection. In another case of a woman with a COVID-19 infection who delivered at 35 weeks' gestation by CD, placental viral testing had a positive result, which also correlated to the positive SARS-CoV-2 PCR testing of the newborn in NP, plasma, and stool samples, highly suggestive of in utero vertical transmission.²⁹ Another case of SARS-CoV-2 being detected in the placenta, which provides a particularly strong evidence for vertical transmission, was in a patient who delivered at 35 weeks and 5 days' gestation. In this case report, immunostaining of the perivillous

Kotlyar. Vertical transmission of COVID-19: a systematic review and meta-analysis. *Am J Obstet Gynecol* 2021.

trophoblastic cells showed positivity for SARS-CoV-2 N-protein. Viral RNA was also detected in placental, amniotic fluid, and neonatal blood samples taken at birth, which is indicative of transplacental transmission of SARS-CoV-2.⁵⁸

Placental histologic assessment from COVID-19–infected mothers was described in 6 cohort or case series studies showing various abnormalities that seem to have some common pathologic themes including vascular malperfusion, fibrin deposition, and chronic villitis or intervillitis. In a pathologic study of placentas from COVID-19–infected mothers, 12 of 15 placentas showed evidence of maternal vascular malperfusion, with 4 placentas demonstrating central and peripheral villous infarctions.⁸⁸ In addition, another series demonstrated the presence of placental vascular malperfusion in 10 of 20 placentas, with some showing intramural fibrin deposition (3/20) and chronic

villitis (4/20).⁸⁴ In both of these studies, there was no evidence of neonatal SARS-CoV-2 infection by NP swab, and direct assessment of SARS-CoV-2 in the placenta was not performed. In another series of 5 COVID-19–positive mothers, all 5 placentas were negative for SARS-CoV-2 RNA but similarly exhibited fetal vascular malperfusion (5/5) and fibrin and complement deposition (4/5).⁸³ In a cohort of 8 COVID-19–positive patients who delivered, 1 still-born fetus delivered at 38.7 weeks' gestation did not show any SARS-CoV-2 RNA in the placenta or in fetal tissues tested at autopsy, but the placenta demonstrated evidence of severe chronic villitis.⁸¹ In another cohort study of 22 women with COVID-19, 2 neonates who were positive for SARS-CoV-2 by NP swab had placental histologic assessment revealing chronic intervillitis.³⁰ A similar evidence of chronic histiocytic intervillitis with intervillous inflammatory infiltrate consisting of mostly

CD68+ macrophages and some T cells was also seen in other reports.^{27,29,58}

Additional testing sites for severe acute respiratory syndrome coronavirus 2 by reverse transcription–polymerase chain reaction. Other neonatal sites have been tested for SARS-CoV-2 RNA. A total of 8 cohort or case series studies included in this systematic review had SARS-CoV-2 testing of the amniotic fluid (6 from China, 1 from the United Kingdom, and 1 from Italy). There were no positive cases among the 51 total amniotic fluid specimens tested (0/51) (Figure 2). However, we identified 2 case reports of positive amniotic fluid testing (Table 1). In the first case report, sterilely collected amniotic fluid (via syringe before rupturing the membranes) during a CD performed on a critically ill mother at 34 weeks' gestation was subjected to RT-PCR and had a positive result for SARS-CoV-2 RNA. The infant was immediately separated

from the mother, and initial testing was negative for SARS-CoV-2 RNA in the NP samples; however, the second neonatal NP swab was positive at 24 hours of life. Repeat throat swab from the neonate at 1 week of life remained positive.⁴⁷

Six cohort or case series studies (5 from China and 1 from Italy) reported cord blood testing in 34 neonates with 1 positive test result resulting in a pooled vertical transmission rate of 2.9% (Figure 2).⁸⁵ In the aforementioned case report by Vivanti et al,⁵⁸ SARS-CoV-2 RNA was also detected in the amniotic fluid and NP swab of the neonate. Furthermore, SARS-CoV-2 RNA was also detected in bronchoalveolar lavage specimens and neonatal blood, showing the presence of neonatal viremia after

transplacental transmission. Numerous case reports also assessed the cord blood for SARS-CoV-2 RNA. Of 16 case reports that tested the cord blood, none reported any positive cases (Table 1).

In adults, there has been evidence of the presence of SARS-CoV-2 in the gastrointestinal (GI) tract and persistent viral RNA identification in fecal specimens.^{92,93} In our review, among 6 cohort or case series studies (5 from China, 1 from Italy), 9.7% of neonates (3/31) had positive results for SARS-CoV-2 in the GI tract through RT-PCR testing in anal or rectal swabs and feces (Figure 2). One case report demonstrated a positive stool sample 7 days after birth.²⁹ In another study, 3 neonates of mothers with COVID-19 had positive results for SARS-CoV-2 RNA on anal swabs at day 2

of life.⁶⁷ There have been only 2 cohort or case series studies from China describing results of SARS-CoV-2 RT-PCR testing of urine samples in neonates born to women with COVID-19 infection. Of a total of 17 neonates tested, the detection rate for SARS-CoV-2 was 0% (0/17) (Figure 2).

In addition, we reviewed the articles for the presence of SARS-CoV-2 RNA in maternal body fluids that may be responsible for vertical transmission before and after delivery. There were 2 studies from China that reported on SARS-CoV-2 RT-PCR testing in vaginal swabs, demonstrating a detection rate of 0% (0/19). Our review included 6 cohort or case series studies from China that assessed for the presence of SARS-CoV-2 in breast milk by RT-PCR, revealing a

positive rate of 4.2% (2/47) in the breast milk specimens tested.^{29,72,85}

Serologic assessment. Serologic assessment was performed on neonates born to COVID-19–infected mothers in 4 cohort or case series studies from China and 1 from Italy.^{26,71,75,85} Among the total number of neonates tested in those cohort or case series studies, 3.7% of tested infants (3/82) were positive for anti–SARS-CoV-2 IgM antibodies (Figure 2). In a case report, an otherwise healthy infant was born via CD to a 29-year-old woman with an RT-PCR–confirmed COVID-19 infection. This infant was immediately placed in isolation, and a blood sample at 2 hours of age was noted to show an elevated SARS-CoV-2 immunoglobulin G (IgG) and IgM. Although the IgG can be secondary to transplacental transfer, the infant's positivity for SARS-CoV-2 IgM cannot be explained by transplacental transfer.²⁵ Furthermore, IgM antibodies usually do not appear until 3 to 7 days after infection. Paradoxically, all 5 RT-PCR tests on the infant were negative for COVID-19.²⁵ Nonetheless, the antibody profile of this infant is suggestive of fetal exposure to COVID-19 in utero. A follow-up study conducted on 6 infants born to COVID-19–positive mothers showed positive IgM antibodies in 2 infants. However, all throat swabs and blood samples from the neonates similarly tested negative for the virus.²⁶ In one of the largest studies looking at neonatal serology, Liu et al⁷¹ tested 51 infants for COVID-19 antibodies with none having a positive result for IgM and IgG. Yang et al⁷⁵ assessed 23 infants for COVID-19 infection; although none of them had positive NP swabs, 1 premature infant was found to have a positive result for anti–SARS-CoV-2 IgM within 2 hours after birth. Overall, the presence of IgM in these neonates immediately after birth is highly suggestive of in utero vertical transmission.

Comment

Main findings

In this systematic review, we aimed to summarize initial data regarding the risk of vertical transmission of COVID-19 to

help inform counseling and care of women who are pregnant or contemplating pregnancy at this time. It included 39 cohort or case series studies in the quantitative synthesis summarizing data from a total of 936 SARS-CoV-2–tested neonates to pregnant women with COVID-19 infection, spanning the initial 6 months since the disease manifested (end of December 2019). Regarding the most common method of testing for SARS-CoV-2, that is, NP swab RT-PCR testing, we determined that maternal-to-fetal transmission of the virus may occur in approximately 3.2% of infected mothers in the third trimester. Interestingly, there is a striking similarity in NP swab SARS-CoV-2 pooled positivity rates between studies from China (2%) and studies outside of China (3.5%). This rate of SARS-CoV-2 RNA positivity was also in the same range as for placental (7.7%) and cord blood samples (2.9%). The fact that IgM serology was also in the same range (3.7%) provides further support to the notion that vertical transmission is occurring in the third trimester, albeit in a minority of pregnant women. Nonetheless, these are all indirect measures of possible vertical transmission. The best evidence to date for transplacental transmission of SARS-CoV-2 was seen in the case report by Vivanti et al⁵⁸ showing not only viral RNA and protein in the placenta but also viral RNA in the amniotic fluid and neonatal blood sampled at birth. Although these studies further strengthen the case for vertical transmission occurring in utero, fetal infection could only be conclusively determined by the direct demonstration of the presence of SARS-CoV-2 in fetal tissues.

Clinical implications

Because of the teratogenicity and fetal morbidity associated with other viral infections such as Zika and Rubella, vertical transmission remains a concern with COVID-19. Compared with other known viruses leading to congenital infections, the vertical transmission rates reported in this review are consistent with those for numerous pathogens. The transmission rates for these pathogens

range from as low as 0.2% to 0.4% for cytomegalovirus and varicella zoster virus to as high as 17% to 33% for parvovirus B19.⁹⁴ Although the vast majority of infants delivered in these reports did not experience significant morbidity and mortality, nearly all of them were born in the third trimester.⁹⁴ For the aforementioned pathogens, the transplacental passage of infectious pathogens tends to occur with increasing frequency as gestational age increases, whereas detrimental effects on the fetus increase with decreasing gestational age. Therefore, we should assume that COVID-19 may also have similar detrimental effects when maternal infection occurs early in gestation.

In addition to direct fetal infection and subsequent teratogenicity, indirect fetal effects are also a major concern with the COVID-19 infection. It has recently been proposed that COVID-19 results in systemic endothelial damage that, in adults, predisposes to the development of or exacerbation of already existing hypertension and other cardiovascular diseases and results in a severe COVID-19 course.^{95,96} In particular, COVID-19 frequently induces hypercoagulability with both microangiopathy and local thrombus formation.⁹⁷ Pregnant women present an especially vulnerable population given their hypercoagulable state, with associated unique conditions. Hypertensive disorders of pregnancy are a group of conditions, the pathogenesis of which is not well understood; however, systemic endothelial dysfunction, vascular malperfusion, and a systemic proinflammatory state have been implied as potential etiologies or components of the disease pathophysiology, especially in cases of preexisting hypertension, obesity, or diabetes.⁹⁸ Of note, our systematic review found several cohort studies and case reports describing an association between maternal COVID-19 infection and placental evidence of maternal vascular malperfusion, particularly maternal vessel injury and intervillous thrombi. One may speculate that COVID-19 may result in the activation of endothelial damage pathways predisposing to the development of hypertensive disorders

of pregnancy with associated adverse maternal and neonatal outcomes (ie, prematurity, growth restriction) over the long term. This is one of the many issues that remain open for study.

Research implications

The standard for detecting COVID-19 infection is via detection of viral RNA using RT-PCR. However, this diagnostic method does exhibit variable performance. In a study assessing the performance capability of RT-PCR test in patients with COVID-19 using numerous sources for viral RNA including nasal, bronchoalveolar lavage, feces, blood, and urine specimens, sensitivities for COVID-19 detection were 63%, 93%, 29%, 1%, and 0%, respectively.⁹⁹ In our systematic review, blood similarly had one of the lowest rates of SARS-CoV-2 detection (2.9%), along with urine (0%) and amniotic fluid (0%). The lack of detection of SARS-CoV-2 in the amniotic fluid is not surprising because its source of production is fetal urine. Nevertheless, such substantial variation in SARS-CoV-2 positivity as a factor of testing site argues for specimen testing from multiple sites to increase sensitivity and reduce false-negative rates and preferably the use of complementary testing methods such as serology. In this systematic review, the rate of IgM positivity in tested neonates was 3.6%, which is quite similar to the positive rates by RT-PCR NP testing (3.2%). Patients typically develop IgG antibodies approximately 2 weeks after the onset of symptoms. Although developing fetuses can produce immunoglobulins early in gestation, the protective IgG antibodies in their circulation come from transplacental antibody transfer of maternal IgG.¹⁰⁰ Because IgM antibodies are too large to cross the placenta, the presence of IgM in a neonate during the perinatal period is suggestive of fetal production after in utero infection. The reported performance of perinatal IgM antibody testing indicates a sensitivity of 70.2% to 88.2% and specificity of 96.2% to 99%, although experience with IgM assays suggests that they are inherently limited by false-positive results in other

congenital infections.¹⁰¹ Further testing and validation of serologic assays are ongoing.

Strengths and limitations

We acknowledge that there are significant limitations to our study. Our current knowledge as reflected in this systematic review is limited to a few cohort studies and mostly case series and case reports. In addition, significant heterogeneity exists in the quality of included studies and in what data were reported. Although almost all studies reported results of SARS-CoV-2 NP testing of neonates, there was a significant variation in the performance of SARS-CoV-2 testing of other specimen sites across studies and of neonates within each study, making it challenging to aggregate the data. Moreover, because most of the included cohort or case series studies comprised pregnant patients who underwent selective testing for COVID-19 owing to symptoms, it is likely that patients with asymptomatic infections are underrepresented. Whether the risk of vertical transmission of SARS-CoV-2 may be related to symptom or disease severity is unknown, and as such, pooled rates of vertical transmission risk in this systematic review should be interpreted with caution.

Our study also has several strengths. The quantitative synthesis of this review, which was the basis for the pooled proportion results, was limited to cohort and case series studies as defined by at least 5 pregnant patients with COVID-19 infection. This significantly reduced the chance of publication bias of rare positive outcomes inherent to case reports. A second strength is that the studies included in this review were restricted to laboratory-confirmed cases of SARS-CoV-2 infection, which included both symptomatic and asymptomatic women. Diagnosis was made by RT-PCR of NP swab, which is currently the gold standard for diagnosis, thus avoiding reliance on uncertain COVID-19 diagnostic tests. Moreover, the review included only studies in which SARS-CoV-2 RT-PCR testing was performed on the fetus or neonate within 48 hours of delivery, substantially decreasing the

likelihood of a positive result arising from postpartum horizontal transmission. Another strength is that this review includes reports from multiple countries including China, the United States, the United Kingdom, Italy, and Spain, making the results more generalizable.

Conclusion and implications

Given the accumulating evidence from studies noting the presence of COVID-19 viral RNA in numerous fetal or neonatal sources and positive serology, vertical transmission of COVID-19 is indeed highly likely. This systematic review suggests that maternal COVID-19 infection in the third trimester appears to be associated with low rates of vertical transmission (approximately 3.2%) without significant consequence to the newborns. This low rate is consistent with recent transcriptomic data showing that placental cells coexpressing ACE2 and TMPRSS2 proteins, required for SARS-CoV-2 viral cell entry, are rare.²³ However, numerous questions remain to be addressed concerning vertical transmission of this novel coronavirus. These include whether the virus can cross the placenta in utero and cause an infection in fetal tissues. Furthermore, it is necessary to understand whether susceptibility varies by gestational age and whether there is a gestational age at which the virus is more likely to infect and cross the placenta. An even more crucial set of questions center around fetal development and morbidity. For example, if placental infection occurs in the first trimester, can the virus have teratogenic effects and what would those be? In addition, it would be essential to determine whether there are any non-teratogenic fetal effects that can result from viral effects on the uterine vasculature and placental tissue (ie, growth restriction; placental abruption, infarction, or stillbirth; hypertensive disorders of pregnancy). Finally, if in utero transmission indeed occurs, does the rate of transmission depend on the severity of the maternal disease and does a positive test at birth correlate with the clinical course of COVID-19 in newborns? To answer these questions, further larger-

scale studies are needed ideally across numerous countries. A cooperative system of monitoring COVID-19—positive pregnant women throughout gestation would help to answer these remaining questions to help guide patients, physicians, and policy makers. ■

Questions:

1. Did the patients represent the whole cases of the medical center? Cases included represented the general population of COVID-19 pregnant women.
 2. Was the diagnosis correctly made? COVID-19 was diagnosed by viral PCR.
 3. Was the outcome correctly ascertained? Clear description of adequate methodology of testing for COVID-19 in fetus or neonate was provided.
 4. Was follow-up long enough for outcomes to occur? Adequate follow-up time was reported.
 5. Were all important data cited in the report? Testing was repeated at least 2 times on 2 separate occasions.
- Methodological quality: high=5 stars, moderate=4 stars, low=3 or fewer stars.

CORRESPONDENCE

Antibody Responses in Seropositive Persons after a Single Dose of SARS-CoV-2 mRNA Vaccine

TO THE EDITOR: The efficacy of two injections of the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) spike messenger RNA (mRNA) vaccines (BNT162b2 [Pfizer] and mRNA-1273 [Moderna])¹ in preventing symptomatic SARS-CoV-2 infection in persons without previous coronavirus disease 2019 (Covid-19) has been shown to be high.^{2,3} We wondered what the response would be to the first vaccine dose in persons with previous Covid-19.

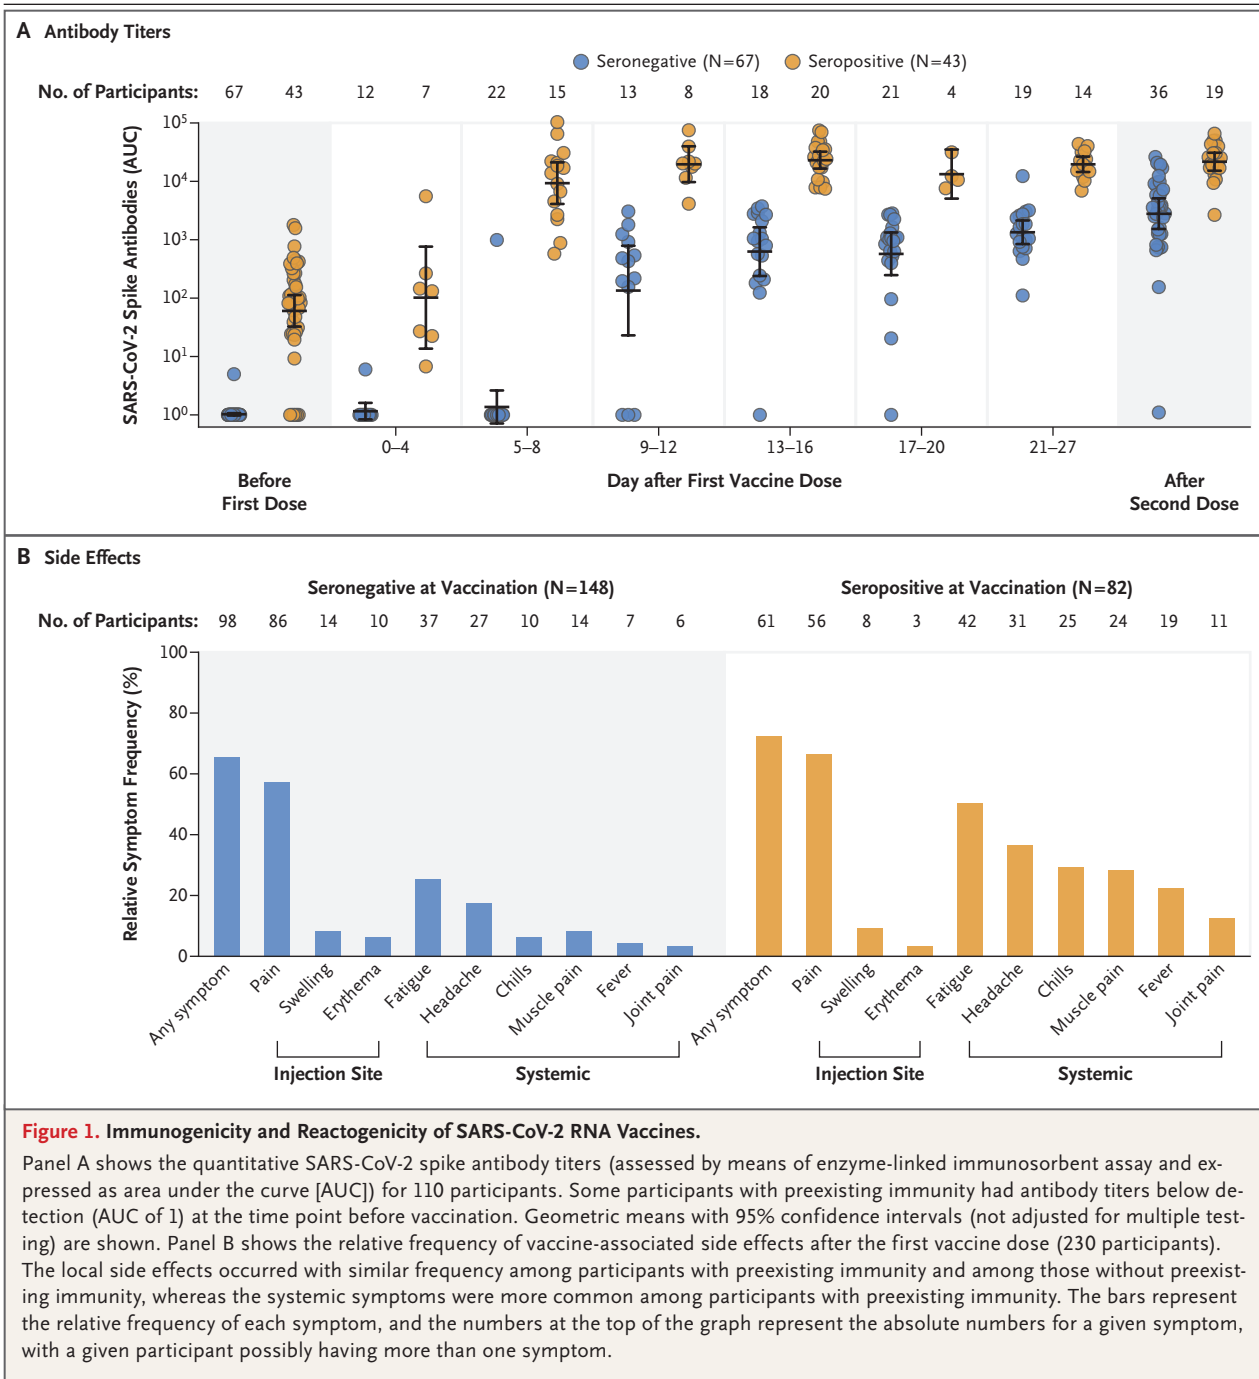

We took advantage of our ongoing institutional review board–approved, longitudinal PARIS (Protection Associated with Rapid Immunity to SARS-CoV-2) study to provide a limited snapshot of the antibody responses in 110 study participants with or without documented preexisting SARS-CoV-2 immunity (mean age overall, 40.0 years [range, 24 to 68; ≥60 years, 8%]; 67 seronegative participants [64% female] with a mean age of 41.3 years and 43 seropositive participants [59% female] with a mean age of 41.4 years) (Table S1 in the Supplementary Appendix, available with the full text of this letter at NEJM.org) who received their first spike mRNA vaccine dose in 2020 (88 received the Pfizer vaccine and 22 the Moderna vaccine). SARS-CoV-2 spike IgG was measured with the use of a previously described two-step enzyme-linked immunosorbent assay and expressed as area under the curve (AUC).^{4,5}

Repeated sampling after the first dose indicates that the majority of seronegative participants had variable and relatively low SARS-CoV-2 IgG responses within 9 to 12 days after vaccination (median AUC before vaccination, 1 [67 participants]; at 0 to 4 days, 1 [12 participants]; at 5 to 8 days, 1 [22 participants]; at 9 to 12 days, 439 [13 participants]; at 13 to 16 days, 1016 [18 participants]; at 17 to 20 days, 1037 [21 participants]; at 21 to 27 days, 1293 [19 participants]; and after the second dose, 3316 [36 participants]) (Fig. 1A). In contrast, participants with SARS-CoV-2 antibodies at baseline before the first vac-

cine injection rapidly developed uniform, high antibody titers within days after vaccination (median AUC before vaccination, 90 [43 participants]; at 0 to 4 days, 133 [7 participants]; at 5 to 8 days, 14,208 [15 participants]; at 9 to 12 days, 20,783 [8 participants]; at 13 to 16 days, 25,927 [20 participants]; at 17 to 20 days, 11,755 [4 participants]; at 21 to 27 days, 19,534 [14 participants]; and after the second dose, 22,509 [19 participants]) (Fig. 1A).

The antibody titers of vaccinees with preexisting immunity were 10 to 45 times as high as those of vaccinees without preexisting immunity at the same time points after the first vaccine dose (e.g., 25 times as high at 13 to 16 days) and also exceeded the median antibody titers measured in participants without preexisting immunity after the second vaccine dose by more than a factor of 6. Although the antibody titers of the vaccinees without preexisting immunity increased by a factor of 3 after the second vaccine dose, no increase in antibody titers was observed in the Covid-19 survivors who received the second vaccine dose. No substantial difference was noted in the dynamics of antibody responses elicited by the Pfizer and Moderna vaccines after the first dose (Fig. S1). The current analysis represents a convenience sample in which not all participants were able to provide biospecimens for antibody analysis at all the additional time intervals. Ongoing follow-up studies will show whether these early differences in immune responses are maintained over a prolonged time period.

In addition, we compared the frequency of local, injection-site-related as well as systemic reactions after the first dose of vaccine in 230 participants (mean age, 39.2 years [range, 22 to 70; ≥60 years, 8%]; 148 seronegative participants [70% female] and 82 seropositive participants [64% female]) (Fig. 1B). Overall, both vaccines (156 participants received the Pfizer vaccine and 74 the Moderna vaccine) had no side effects that

resulted in hospitalization. A total of 159 of the 230 participants (69%) who completed the PARIS study survey reported having some side effects after the first vaccine dose (46% of the seronegative survey respondents and 89% of the seropositive survey respondents). Most common were localized injection-site symptoms (pain, swelling,

and erythema), which occurred with equal frequency independently of the serostatus at the time of vaccination and resolved spontaneously within days after vaccination. Vaccine recipients with preexisting immunity had systemic side effects at higher frequencies than those without preexisting immunity (fatigue, headache, chills,

muscle pain, fever, and joint pain, in order of decreasing frequency) (Fig. 1B). Because a convenience sample was used and only participants with available data were studied, caution is needed until the full data set, including side effects occurring after the first as well as the second vaccine dose, can be assessed.

We found that a single dose of mRNA vaccine elicited rapid immune responses in seropositive participants, with postvaccination antibody titers that were similar to or exceeded titers found in seronegative participants who received two vaccinations. Whether a single dose of mRNA vaccine provides effective protection in seropositive persons requires investigation.

Summary

On March 11, 2020, the World Health Organization declared COVID-19 a pandemic¹. The outbreak containment strategies in China based on non-pharmaceutical interventions (NPIs) appear to be effective², but quantitative research is still needed to assess the efficacy of NPIs and their timings³. Using epidemiological and anonymised human movement data^{4,5}, here we develop

a modelling framework that uses daily travel networks to simulate different outbreak and intervention scenarios across China. We estimated that there were a total of 114,325 COVID-19 cases (interquartile range 76,776 -164,576) in mainland China as of February 29, 2020. Without NPIs, the COVID-19 cases would likely have shown a 67-fold increase (interquartile range 44 - 94) by February 29, 2020, with the effectiveness of different interventions varying. The early detection and isolation of cases was estimated to have prevented more infections than travel restrictions and contact reductions, but combined NPIs achieved the strongest and most rapid effect. The lifting of travel restrictions since February 17, 2020 does not appear to lead to an increase in cases across China if the social distancing interventions can be maintained, even at a limited level of 25% reduction on average through late April. Our findings contribute to an improved understanding of NPIs on COVID-19 and to inform response efforts across the World.

Introduction

As of March 30, 2020 the COVID-19 outbreak has resulted in 693,282 confirmed cases and 33,106 deaths across the World⁶. As an emerging disease, effective pharmaceutical interventions are not expected to be available for months⁷, and healthcare resources will be limited for treating all cases. Nonpharmaceutical interventions (NPIs) are therefore essential components of the public health response to outbreaks^{6,8–10}. These include isolating ill persons, contact tracing, quarantine of exposed persons, travel restrictions, school and workplace closures, cancellation of mass gatherings, and hand washing, among others^{8–10}. These measures aim to reduce transmission, thereby delaying the timing and reducing the size of the epidemic peak, buying time for preparations in the healthcare system, and enabling the potential for vaccines and drugs to be used later on⁸.

Three major groups of NPIs have been implemented to contain the spread and reduce the outbreak size of COVID-19 across China¹¹. First, inter-city travel restrictions were used to prevent further seeding of the virus during the Chinese new year (CNY) holiday. A cordon sanitaire of Wuhan and surrounding cities in Hubei Province was put in place two days before CNY's day on January 25, 2020. Since CNY's day, travel restrictions in other provinces were also put in place across the country. Early identification and isolation of cases comprised the second group of NPIs, including improving the screening, identification, diagnosis, isolation, reporting, and contact tracing of suspected ill persons and confirmed cases¹¹. Along these lines, local governments across China encouraged and supported routine screening and quarantine of travellers from Hubei Province in an attempt to detect COVID-19 infections as early as possible. Highlighting how these efforts improved detection and diagnosis, the average interval from symptom onset to laboratory confirmation dropped from 12 days in the early stages of the outbreak to 3 days in early February^{3,12}. Third, contact restrictions and social distancing measures, together with personal preventive actions, such as hand washing, were implemented to reduce the community-level exposure risk. As part of these social distancing policies, the Chinese government encouraged people to stay at home as much as possible, cancelled or postponed large public events and mass gatherings, and closed libraries, museums, and workplaces^{13,14}. Additionally, school holidays were also extended, with the CNY holiday end date changed from January 30 to March 10 for Hubei province, and February 9 for many other provinces^{15,16}.

The implementation of these NPIs coincided with a rapid decline in the number of new cases across China, albeit at high economic and social costs^{3,12}. Previous studies have preliminarily explored the lockdown of Wuhan^{17,18}, travel restrictions¹⁹, airport screening²⁰, and the isolation of cases and contact tracing for containing virus transmission²¹. However, a comprehensive and quantitative comparison of the effectiveness of different NPIs in China and their timings for containing the COVID-19 outbreak is lacking. Based on epidemiological data on COVID-19 and historical and near-real time anonymised human movement data, we developed a travel network-based stochastic susceptible-exposed-infectious-removed (SEIR) modelling framework to simulate the COVID-19 spread across 340 prefecture-level cities in mainland China. Within each city, numbers of susceptible, exposed, infectious, and recovered/removed people were estimated per day since December 1, 2019. Using this modelling framework, we conducted before-and-after comparable analyses to quantify the relative effect of the three major groups of NPIs in China, including the restriction of inter-city population movement, the identification and isolation of cases, and the reduction of inner-city travel and contact to increase social distance. We also assessed the risk of COVID-19 transmission since the lifting of travel restrictions on February 17, 2020.

Results

Reconstruction of COVID-19 spread

The epidemiological parameters estimated for the early stage of the outbreak in Wuhan were initially used to parameterise the epidemic before widely implementing interventions⁵. The three major groups of NPIs outlined above were derived and measured from inter-city and inner-city population movement data, obtained from smartphone users of Baidu location-based services⁴, and data on delay from illness onset to reporting of cases across the country. Population travel and contact patterns have changed significantly since the implementation of interventions, with the timeliness of case reporting also improving (Fig. 1 and Supplementary Information Files 1 and 2). These indicators were then incorporated into the model (see Methods).

We estimated that there were a total of 114,325 COVID-19 cases (interquartile range [IQR] 76,776 – 164,576) in mainland China as of February 29, 2020, with 85% of these in Hubei Province (Extended Data Table 1). The outbreak increased exponentially prior to CNY, but the peak of epidemics across the country quickly appeared at CNY, following the implementing NPIs. The estimated epidemics and peaks were consistent with patterns of reported data by onset date, with high correlations between daily estimates and reported data found across time and regions (Extended Data Fig. 1). The overall correlation between the number of estimated cases and the reported number by province, as of February 29, 2020, was also significant ($p < 0.001$, $R^2 = 0.86$), with a high sensitivity (91%, 280/308) and specificity (69%, 22/32) in predicting cities with or without COVID-19 cases (Extended Data Fig. 1Sa and 1b).

Quantifying the effect of different NPIs

Without NPIs, as of February 29, the number of COVID-19 cases would increase rapidly across China, with a 51-fold (IQR 33 - 71) increase in Wuhan, a 92-fold (58 - 133) increase in other cities in Hubei, and a 125-fold (77 - 180) increase in other provinces. However, the apparent effectiveness of different interventions varied (Fig. 2). The lockdown of Wuhan might not have prevented the seeding of the virus from the city, as the travel ban was put in place at the latter stages of pre-CNY population movement out of the city (Fig. 1b)²². Nevertheless, if inter-city travel restrictions were not implemented, cities and provinces outside of Wuhan would have received more cases from Wuhan, and the affected geographic range would have expanded to the remote western areas of China (Extended Data Fig. 2c). Generally, the early detection and isolation of cases was estimated to quickly and substantially prevent more infections than contact reduction and social distancing across the country (5-fold versus 2.6-fold). However, without the intervention of contact reductions, in the longer term, the epidemics would increase exponentially across regions (Fig. 2c and 2f). Therefore, combined NPIs would achieve the strongest and most rapid effect on COVID-19 outbreak containment, with about a one-week interval from NPIs to epidemic peak (Extended Data Table 1).

Intervention timings

If interventions in China could have been conducted one week, two weeks, or three weeks earlier, cases could have been dramatically reduced by 66% (IQR 50% - 82%), 86% (81% - 90%), or 95% (93% - 97%), respectively (Fig. 3a). The geographical range of affected areas would also shrink from 308 cities to 192, 130, and 61 cities, respectively (Extended Data Fig. 3). However, if NPIs were conducted one week, two weeks, or three weeks later than they were, cases may have shown a 3-fold (IQR 2 - 4), 7-fold (5 - 10), or 18-fold (11 - 26) increase, respectively (Fig. 3b).

The lifting of travel restrictions

Under interventions implemented as of 17 February, 2020, the epidemics outside of Hubei province likely reached a low level (<10 cases per day, excluding imported cases from other countries) in early March, while Hubei Province might need another four weeks to reach same level as other provinces. However, if population contact resumed to the normal levels seen in previous years, the lifting of travel restrictions since February 17 might cause case numbers to rise again (Fig. 3c). Accordingly, our simulations suggest that maintaining social distancing at even a limited degree (e.g. 25% contact reduction on average) through late April would help ensure control of COVID-19 in epicentres like Wuhan.

Our estimates were sensitive to the basic reproduction number (R_0), with a higher and later peak of epidemics and longer time needed to contain the outbreak under a higher R_0 (Extended Data Fig. 3). Sensitivity analyses also suggested that our model could have robustly measured relative changes in the efficacy of interventions under different epidemiological parameters and transmission scenarios (Extended Data Figs. 4 - 9).

Extending findings

Our findings show that combined NPIs substantially reduced COVID-19 transmission across China. Earlier implementation of NPIs could have significantly reduced the magnitude and geographical range of the outbreak, but equally, a delayed response would have led to a larger outbreak. China's aggressive, multifaceted response is likely to have prevented a far worse situation, which would have accelerated spread globally. The lessons drawn from China provide robust evidence and provide a preparation window and fighting chance for containing the spread and mitigating the effects of COVID-19 in other regions around the World^{3,12}.

Our results suggest three key points. First, they support and validate the idea that population movement and close contact has a major role in the spread of COVID-19 within and beyond China^{22,23}. As the lockdown of Wuhan happened at the latter stages of the pre-CNY movement, travel restrictions did not halt the seeding of the virus from Wuhan, but did prevent cases being exported from Wuhan to a wider area. Secondly, the importance and effects of the three types of NPIs differed. Compared to travel restrictions, improved detection and isolation of cases as well as the social distancing likely had a greater impact on the containment of outbreak. The social distancing intervention reduced contact with people who travelled from the epicentre of the outbreak. This is likely to have been especially helpful in curbing the spread of an emerging pathogen to the wider community, and reduced the spread risk from asymptomatic or mild infections⁸. Third, given travel and work resuming in China, the country should consider at least the partial continuation of NPIs to ensure that the COVID-19 outbreak is sustainably controlled for the first wave of this outbreak. For example, early case identification and isolation should be maintained, which may also help to prevent and delay the arrival of a second wave, considering the increasing numbers of cases imported from other countries and the presence of asymptomatic or subclinical infections found in China²⁴.

The analyses presented here represent the most comprehensive study yet in which the effect of NPIs on COVID-19 transmission has been quantitatively assessed. The model framework accounts for daily interactions of populations, interventions between and within cities, as well as the inherent statistical uncertainty associated with a paucity of epidemiological parameters, before and after the implementation of interventions. The network-based SEIR model is methodologically robust and built on the basic SEIR models previously used to predict COVID-19 transmission in its early stages²³. Considering delays in case reporting, our approach can be used for rapid, ongoing estimation of the effectiveness of various NPIs in different countries for outbreak control decision-making.

Our study has several limitations. First, as our simulations were based on parameters estimated for symptomatic cases found in the early stage of the outbreak in Wuhan, which may not account for asymptomatic and mild infections, we may have underestimated the total number of infections. Second, our findings could be confounded by other factors that changed during the outbreak. Although we have shown that the apparent fall in incidence of COVID-19 since CNY's day in China is likely to be attributed to the interventions taken, we cannot rule out the possibility that the decrease is partially attributable to other unknown

seasonal factors, e.g. temperature and absolute humidity^{25,26}. Third, if the epidemiological parameters of COVID-19 transmission in other cities across China differed with estimates from the outbreak at the early stage where no NPIs were in place in Wuhan, then our estimates of the effectiveness of interventions in reducing COVID-19 transmission could be biased. Fourth, coverage biases in mobile phone and Baidu users likely exist. Though a high percentage (from 46.9% in 2013 to 55.3% in 2018) of the population owns smartphones in China^{27,28}, the mobile user group still does not cover specific subgroups of the population, particularly children. Therefore, our population movement data may provide an incomplete picture, and differences between the characteristics of smartphone owners and non-owners may also bias estimates in this study. Additionally, the magnitude and patterns of movements could change year by year, although previous studies have supported the consistent seasonality of travel patterns across years in China and other countries.²² Lastly, we only examined three main groups of NPIs and other interventions might also have contributed to the outbreak containment. For example, due to the data availability, we did not assess the effect of personal hygiene and protective equipment on containing COVID-19 spread. Other data sources and further investigations are needed to measure and elaborate the efficacy of each intervention.

COVID-19 has caused a substantial burden on health systems and society across many countries. From a public health standpoint, our results highlight that countries should consider proactively planning NPIs and relevant resources for containment and mitigation, given how the earlier implementation of NPIs could have lead to significant reductions in size of the outbreak in China. The results here also provide guidance for countries as to the likely effectiveness of different NPIs at different stages of an outbreak. Suspected and confirmed cases should be identified, diagnosed, isolated and reported as early as possible to control the source of infection, and the implementation of cordon sanitaires or travel restrictions for significantly affected areas may prevent seeding the virus to wider regions. Reducing contact and increasing social distance, together with improved personal hygiene can protect vulnerable populations and mitigate COVID-19 spread at the community level, and these interventions should be promoted throughout the outbreak to avoid resurgence. As called by the World Health Organization, and backed up by our findings for China here, early and integrated NPI strategies should be prepared, deployed and adjusted to maximise benefits of these interventions and minimize health, social and economic impacts around the World³.

Methods

A travel network-based stochastic susceptible-exposed-infectious-removed (SEIR) model was built to simulate the COVID-19 spread between and within all prefecture-level cities in mainland China. This model has been made openly available for further use at <https://github.com/wpgp/BEARmod>. Population movement data across the country were used to estimate the intensity of travel restrictions and contact reductions. Data from illness onset to reporting of the first index case for each county were used to infer the changing timeliness of case identification and isolation across the course of the outbreak. The outputs of the model under NPIs were validated by using daily numbers of new cases reported across all regions

in mainland China. Based on this modelling framework, the efficacy of applying or lifting non-pharmaceutical measures under various scenarios and timings were tested and quantified.

Data sources

Three population movement datasets, obtained from Baidu location-based services providing over 7 billion positioning requests per day^{4,29}, were used in this study to measure travel restrictions and social distancing across time and space. The first is an aggregated and de-identified dataset on near-real time daily relative outbound and inbound flow of smartphone users for each prefecture-level city in 2020 (340 cities in mainland China were included) to understand mobility patterns during the outbreak. The daily outflow from each city since Wuhan's lockdown and travel restrictions that were applied on January 23 were rescaled by the mean daily flow for each city during January 20 – 22 for comparing travel reductions across cities and years (Fig. 1).

The second Baidu dataset is a historical relative movement matrix with daily total number of users at city level from December 26, 2014 to May 26, 2015, aligning with the 2020 CNY holiday period, for which the corresponding period is December 1, 2019 to April 30, 2020. We assumed that the pattern of population movements was the same in years when there were no outbreaks and interventions. Adjusted by the level of travel reductions derived from the 2020 dataset where applicable, the second dataset was used to simulate the COVID-19 spread and predict future transmission via population movements under various scenarios, with or without inter-city travel restrictions. Corresponding city-level population data in 2015 for modelling were obtained from the Chinese Bureau of Statistics³⁰.

The third Baidu dataset measures daily population movements at county level (2862 counties in China) from January 26 through April 30, 2014, as described elsewhere³¹. Based on the assumption that the pattern of population contact was consistent across years when there were no interventions, it was used to estimate inner-city travel and contact reduction under the outbreak and interventions. First, we aggregated data from county to city level and rescaled the daily flows since January 29, 2014 by the mean of the daily flow for the January 26 – 28 period, aligning with the date of Wuhan's lockdown and the 2020 CNY holiday. Then, the rescaled first dataset for 2020 under interventions was compared with the 2014 dataset to derive the percentage of travel decline for each city. The percentages for cities were averaged by day to preliminarily quantify the intensity of contact reduction in China under NPIs (Supplementary Information File 2), as the policies of travel restriction and social distancing measures were implemented and occurred at the same time across the country.

We also collated data of the first case reported by county across mainland China to measure the delay from illness to case report as a reference of the improved timeliness of case identification, isolation and reporting during the outbreak (Supplementary Information File 1). The daily number of COVID-19 cases by date of illness onset in Wuhan City, Hubei Province and other provinces as of February 13, 2020 were used to further validate the epicurves estimated in this study across time. There was an abnormal increase of cases in Wuhan City and Hubei Province on February 1, 2020, based on the date of illness onset.² We interpolated the number on February 1 by using the mean of numbers of cases reported

on January 31 and February 2 in the epicurve. The number of cases reported by city across mainland China as of February 29 were used to define the predictability of our model across space. These case data were collated from the websites of national and local health authorities, news media, and publications (Supplementary Information File 3)^{2,3,32}.

Data analysis

We constructed a travel network-based SEIR modelling framework (BEARmod) for before-and-after comparable analyses on NPI efficacy. This model was extended from a typical SEIR model to specifically incorporate movement between locations that varied with each timestep. In this model, each city was represented in the model as a separate subpopulation, with its own susceptible (S), exposed (E), infected (I), and recovered/removed (R) populations.

Exposure, infection, and recovery—During each timestep, infected people first recovered or were removed at an average rate r , where r was equal to the inverse of the average infectious period, and removal represents self-isolation and effective removal from the population as a potential transmitter of disease. Explicitly, this was incorporated as a *Bernoulli* trial for each infected person with a probability of recovering $1 - \exp(-r)$. We used the median of time lags from illness onset to reported case as a proxy of the average infectious period, indicating the improving case identification and isolation under improved interventions (Supplementary Information File 1). Then, the model converted exposed people to infectious by similarly incorporating a *Bernoulli* trial for each exposed individual, where the daily probability of becoming infectious $1 - r \exp(-e)$, where e was the inverse of the average time spent exposed but not infectious, based on the estimated incubation period (5.2 days, 95% confidence interval [CI] 4.1 - 7.0).⁵ Finally, to end the exposure, infection, and recovery step of the model, newly exposed people were calculated for each city based on the number of infectious people in the city I_i , and the average number of daily contacts that lead to transmission that each infectious person has c . We simulated the number of exposed in a patch on a given day through a random draw from a *Poisson* distribution for each infectious person where the mean number of new infections per person was c , which was then multiplied by the fraction of people in the city that were susceptible. We calculated the daily contact rate c using the basic reproduction rate calculated by other studies (R_0 , 2.2, 95% CI 1.4 - 3.9) divided by the average days (5.8, 95% CI 4.3 - 7.5) from onset to first medical visit and isolation,⁵ weighted by the relative level of daily contact where relevant, based on the Baidu movement data (Supplementary Information File 2). Because simulation runs were not extended beyond five months, we did not include the addition of new susceptibles, or conversion of recovered people back to susceptible.

The infection processes within each patch therefore approximate the following deterministic, continuous-time model, where c and r through time:

$$\begin{aligned}\frac{dS}{dt} &= S - c \frac{SI}{N} \\ \frac{dE}{dt} &= c \frac{SI}{N} - \epsilon E \\ \frac{dI}{dt} &= \epsilon E - rI \\ \frac{dR}{dt} &= rI\end{aligned}$$

Movement—After the model completed the infection-related processes, we moved infectious people between cities. To do this, we moved infected people from their current location to each possible destination (including remaining in the same place) using *Bernoulli* trials for each infected person, and each possible destination city. We parameterized the probability of moving from city i to city j (p_{ij}) was equal to the proportion of smartphone users who went from city j in the corresponding day from the Baidu dataset in 2015, accounting for the travel restrictions in 2020. This included modelling the numbers of people who stayed in the same location using p_{ii} , the proportion of users who did not move to a new location on that day. This allowed us to incorporate variance in the actual composition of travellers (infected vs non-infected), but because movement numbers were generated independently, it was possible for the number of infected stayers and movers in each patch to exceed or be fewer than the number of infected people in the patch. As we only wanted to incorporate variance into relative patterns of movement and not absolute numbers (particularly because the underlying values are proportions of people who moved and therefore cannot influence the total numbers of people infected), in any case where infected movers and stayers differed from the total number of infected people in the origin patch, we rescaled values to the total number of infected people. Rescaling in this way meant the variance introduced by the *Bernoulli* trials could only influence relative movement patterns, and not actual numbers of infected people. Further, because we explicitly model the number of stayers in the same way as movers, rescaling should not introduce any bias in terms of the final relative movement patterns.

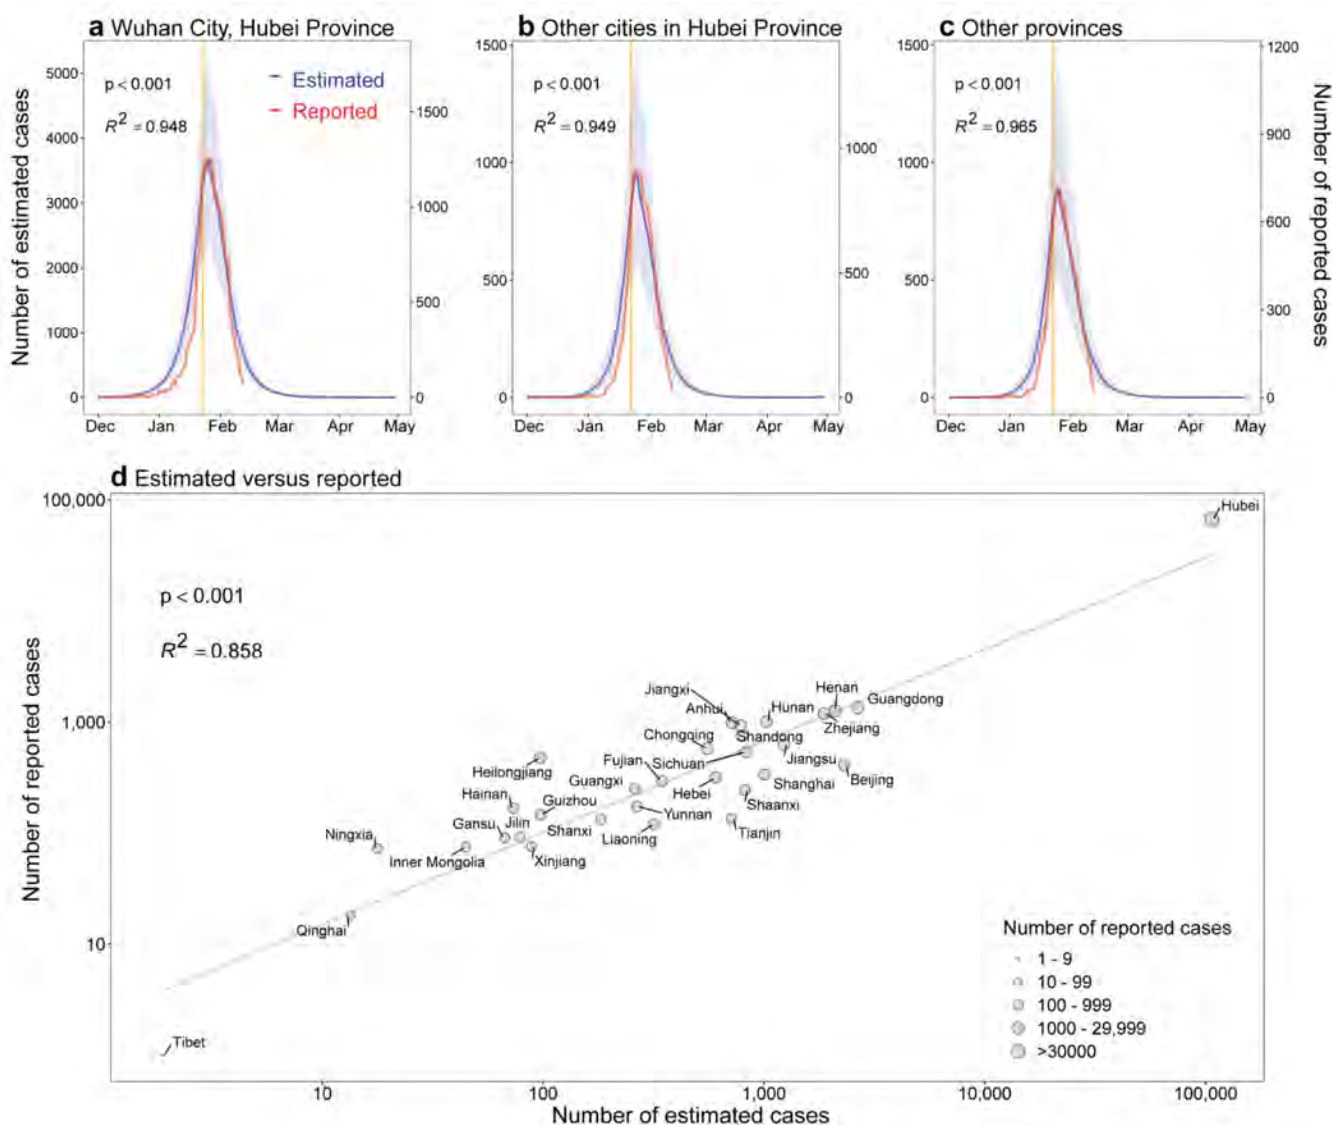

Through this model, stochasticity in the numbers and places where COVID-19 appears between simulation runs in this model through variance in numbers of people becoming exposed, infectious, and removed/recovered, as well as variance in numbers of people moving from one city to another. By modelling the COVID-19 epidemic in this way, we could simulate the incidence of COVID-19 cases, accounting for variance in recovery, infection, and movement across many simulation runs (1000). Additionally, this allowed for us to account for uncertainty in contact rates after NPIs were implemented or lifted.

Simulation runs—Using this model, we quantified how transmission of COVID-19 varied with different intervention scenarios and timings, as well as the potential of further transmission after the lifting of travel restrictions and contact distancing measures on February 17, 2020. As the earliest date of illness onset in cases was December 2, 2020³, considering the underreporting of cases and the delay from infection to onset and identification of this novel virus, we did simulations by initially infected 5 people in Wuhan on December 1, 2019 and propagating the epidemic through time, varying factors including

timing and types of interventions used, assumed contact and recovery rates, and movement. We initially infected 5 people as a minimum number of infected people that prevented stochastic extinction of the epidemic during the initial days of simulation, and found no significant difference after 3 months, over simulation runs that started with 3, 5, and 8 initially infected people (though with 3 people initially infected, 50% of runs led to zero cases over the initial week of simulation). When using data from other years we fixed the simulation dates around Chinese New Year and adjusted the start date of the epidemic accordingly.

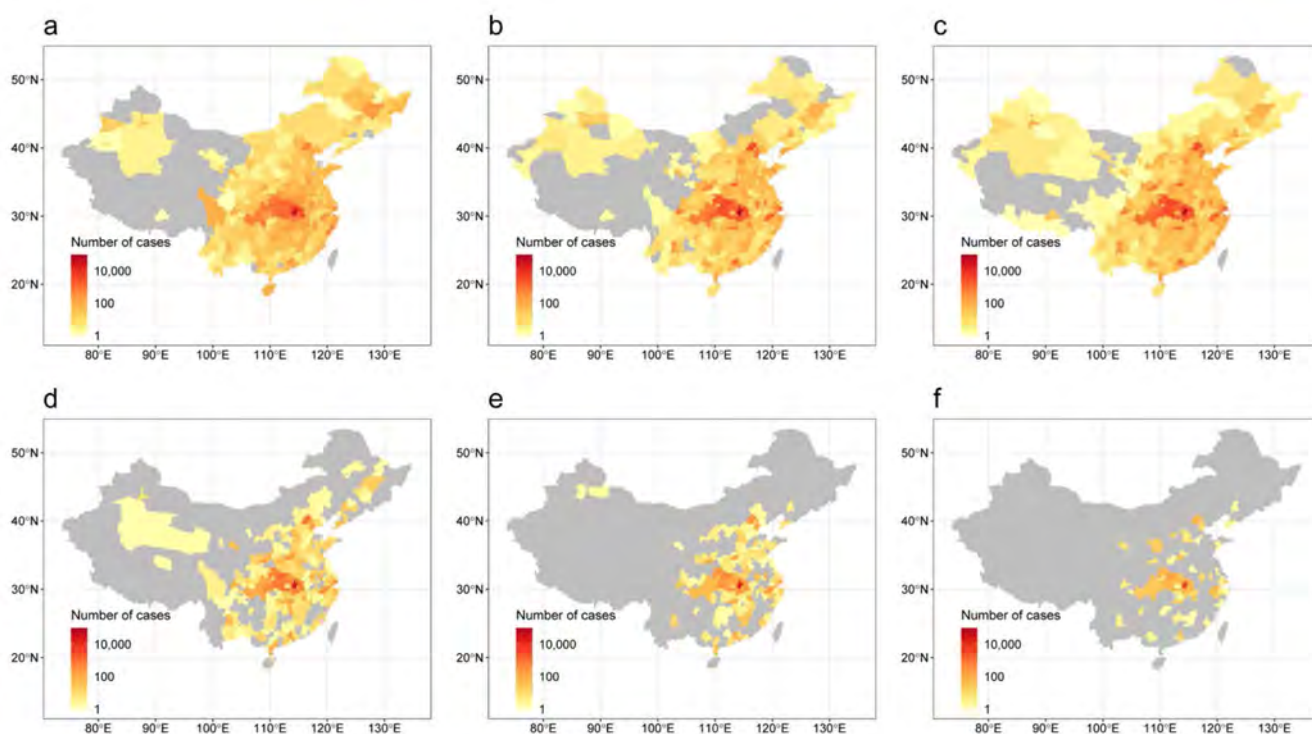

The estimates of the model for the outbreak under current NPIs as the baseline scenario were compared with reported COVID-19 cases across time and space. The sensitivity and specificity were also calculated to examine the performance of the model in predicting the occurrence of COVID-19 cases at city level across China. The relative effect of NPIs were quantitatively assessed by comparing estimates of cases under various NPIs and timings with that of the baseline scenario. We also conducted a series of sensitivity analyses to understand the impact of changing epidemiological parameters on the estimates and uncertainties of intervention efficacy. R version 3.6.1 (R Foundation for Statistical Computing, Vienna, Austria) was used to perform data collation and analyses.

Extended Data

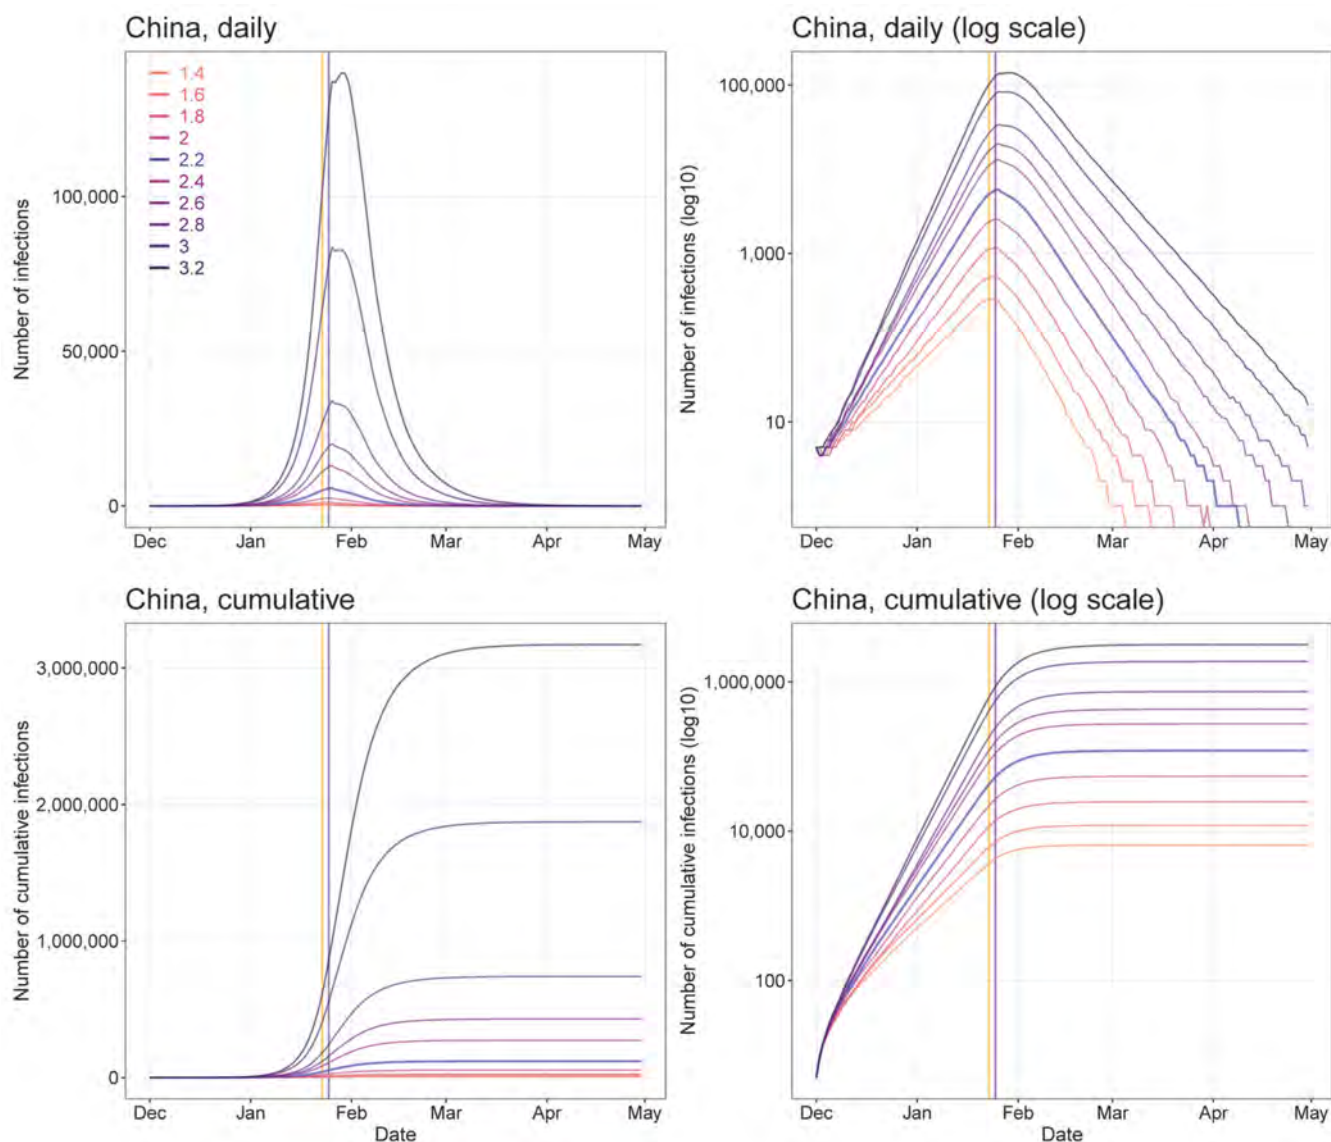

Extended Data Fig. 1. Estimated and reported epicurves of COVID-19 outbreak in mainland China.

(a) Wuhan City in Hubei Province. (b) Other cities in Hubei Province. (c) Other 30 provincial regions in mainland China. The orange vertical lines indicate Wuhan's lockdown on January 23, 2020. The estimated epicurve of COVID-19 cases presents the median (dark blue) and interquartile range (light blue) of estimates (1000 simulations), and the Pearson's correlation between the median of daily estimates and the number of daily reported cases by region as of February 13, 2020 are also presented. (d) The Pearson's correlation between the total number of estimated cases and the total number of reported cases by province as of February 29, 2020. The p values of two-sided t-test are also provided.

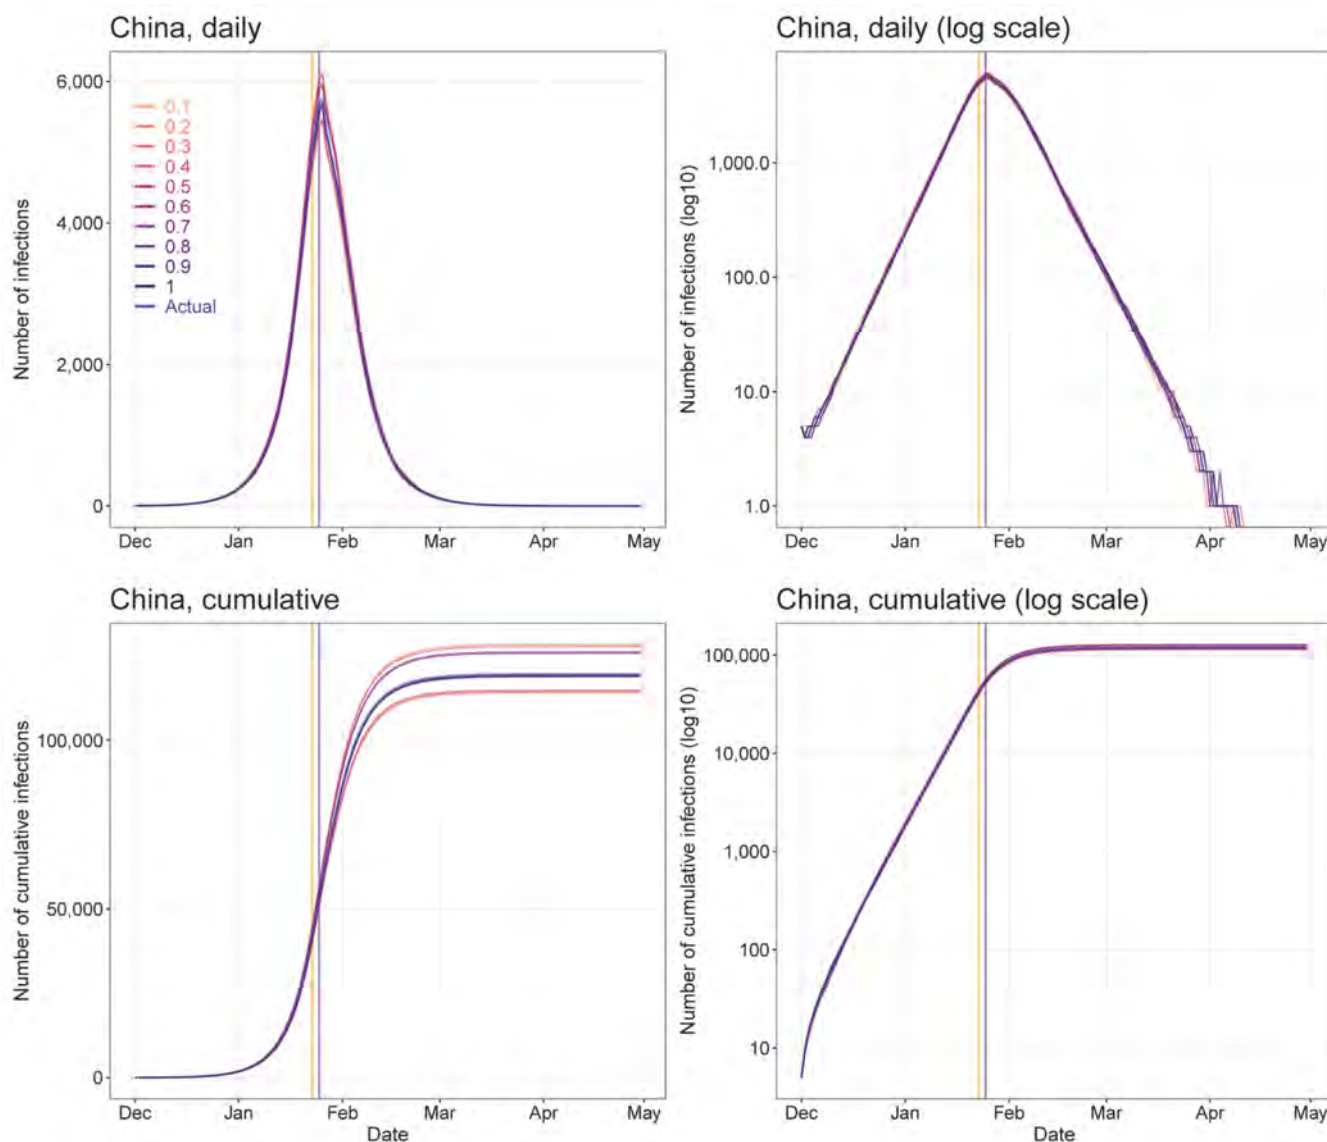

Extended Data Fig. 2. Affected areas of COVID-19 in mainland China under various intervention timings.

(a) A total of 308 cities reported COVID-19 cases, based on the data obtained from national and local health authorities, as of February 29, 2020. (b) Affected areas (298 cities) estimated by models under interventions implemented at actual timing. (c) Estimated affected areas (326 cities) under interventions at actual timing, but without inter-city travel restrictions. (d) Estimated affected areas (192 cities) under interventions at one week earlier than actual timing. (e) Estimated affected areas (130 cities) under interventions implemented at two weeks earlier than actual timing. (f) Estimated affected areas (61 cities) under interventions at three weeks earlier than actual timing. The administrative boundary maps were obtained from the National Platform of Common Geospatial Information Services of China (www.tianditu.gov.cn).

Extended Data Fig. 3. Sensitivity of estimates of COVID-19 epidemics under various values of R_0 .

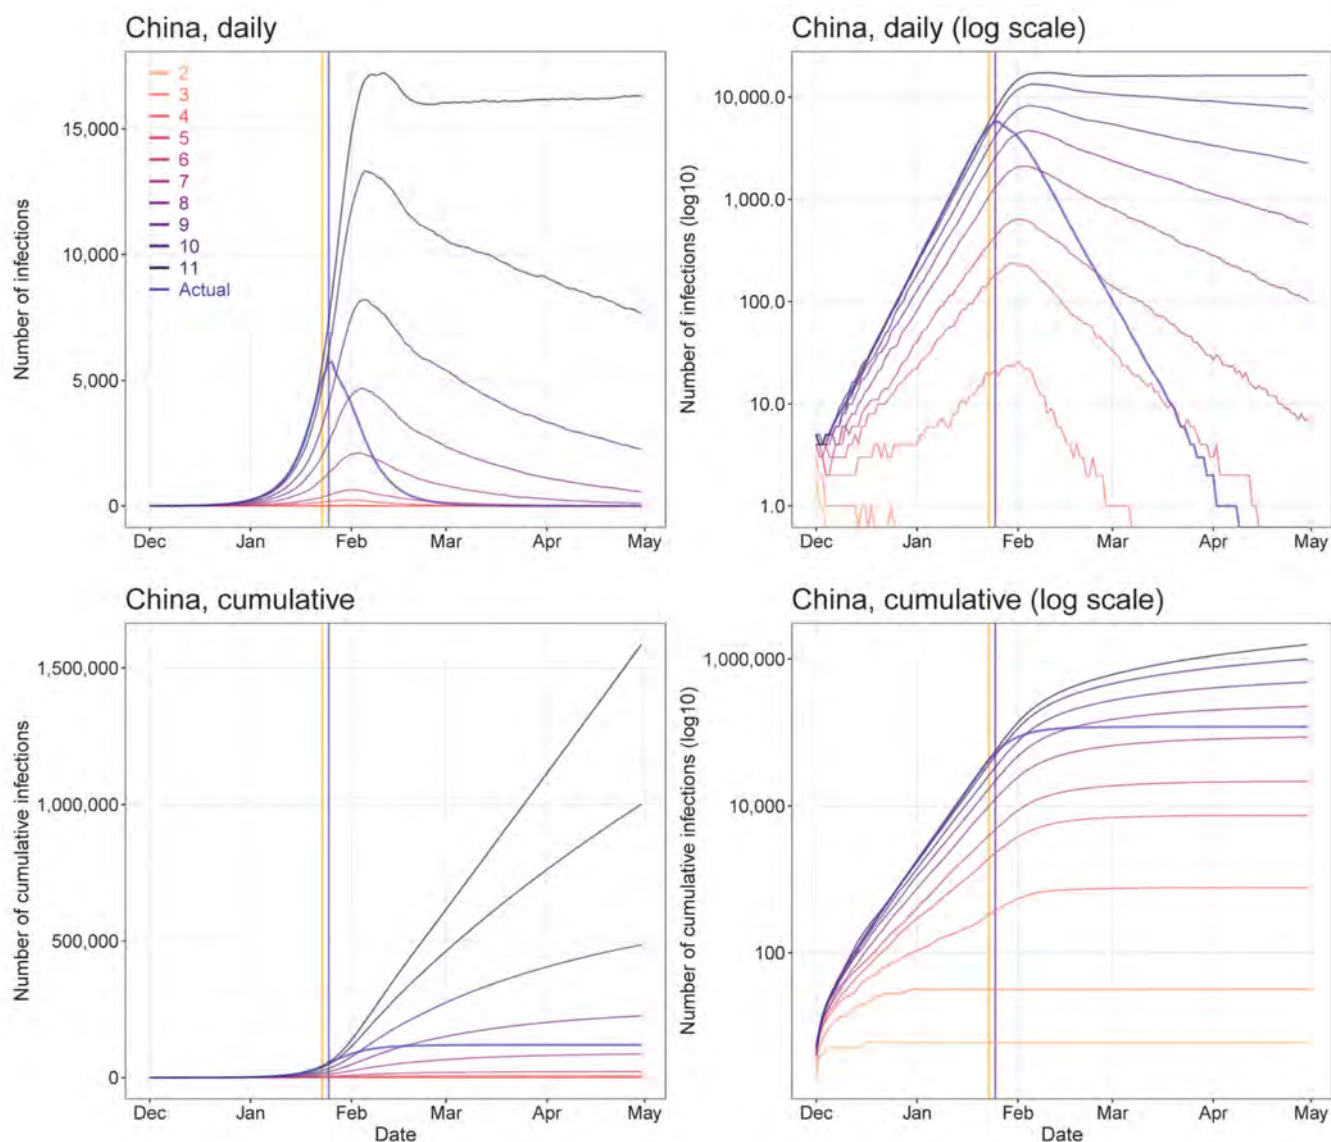

All other parameters, NPIs and input data were the same as the baseline model with $R_0 = 2.2$. Vertical lines: orange – date of Wuhan's lockdown; purple - CNY's day.

Extended Data Fig. 4. Sensitivity of estimates of COVID-19 epidemics under various levels of inter-city travel restrictions since January 23, 2020.

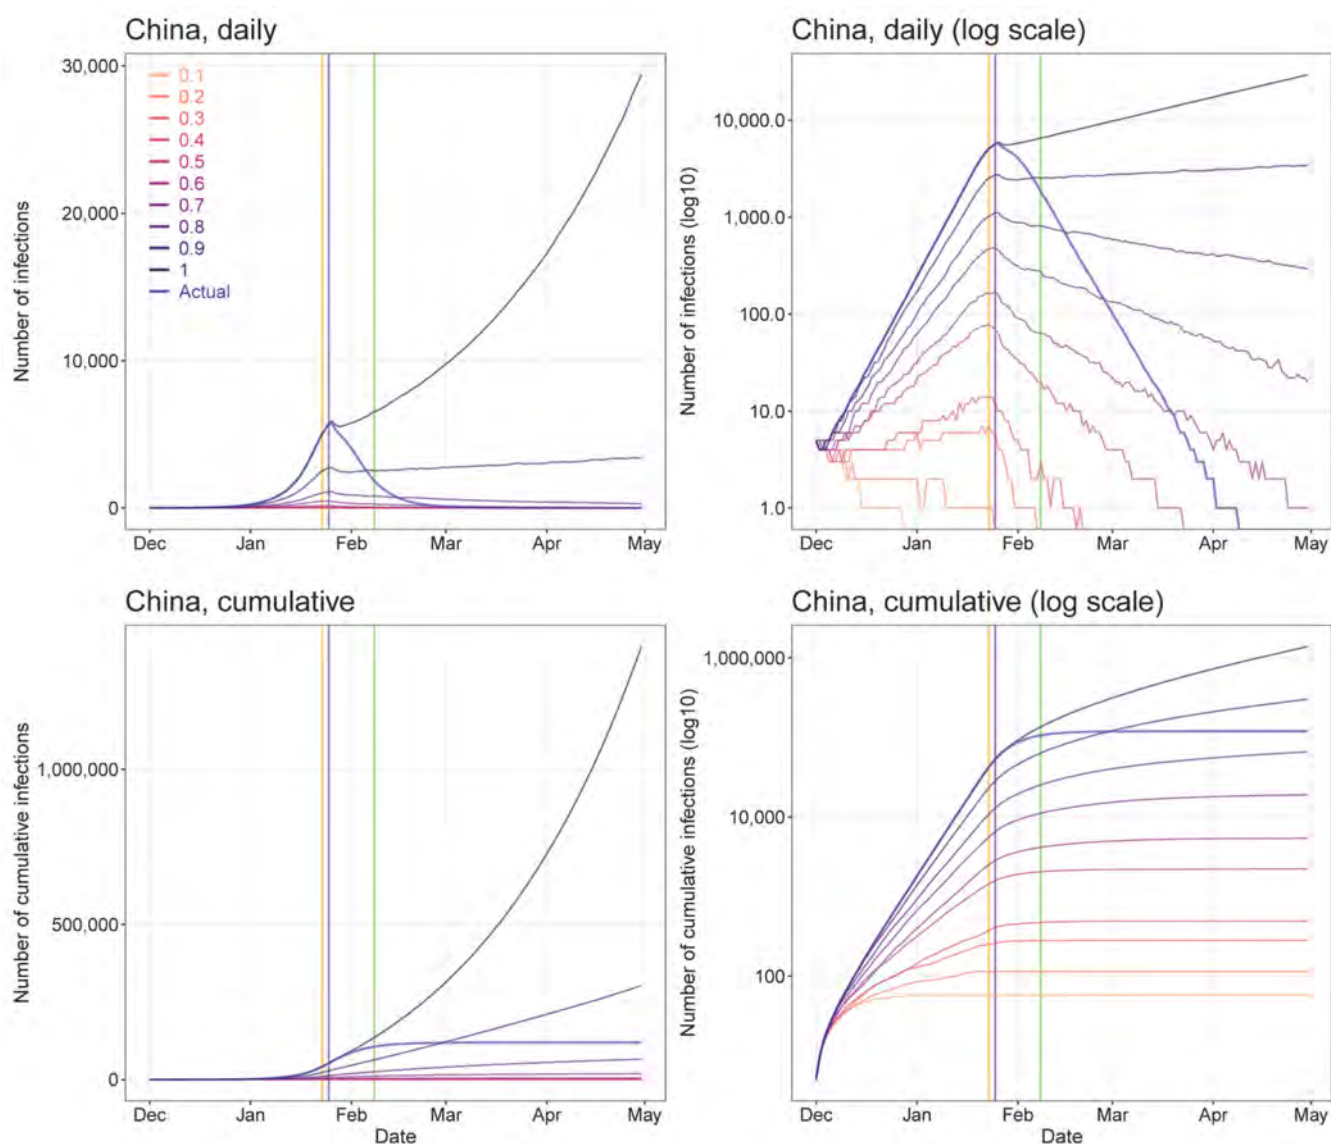

All other parameters, NPIs and input data were the same as the baseline model with $R_0 = 2.2$. The actual percentages of inter-city travel restrictions changed day-by-day across cities in China (0.1 means 90% reduction from normal travel, 1 means no travel restrictions).

Vertical lines: orange – date of Wuhan's lockdown; purple - CNY's day.

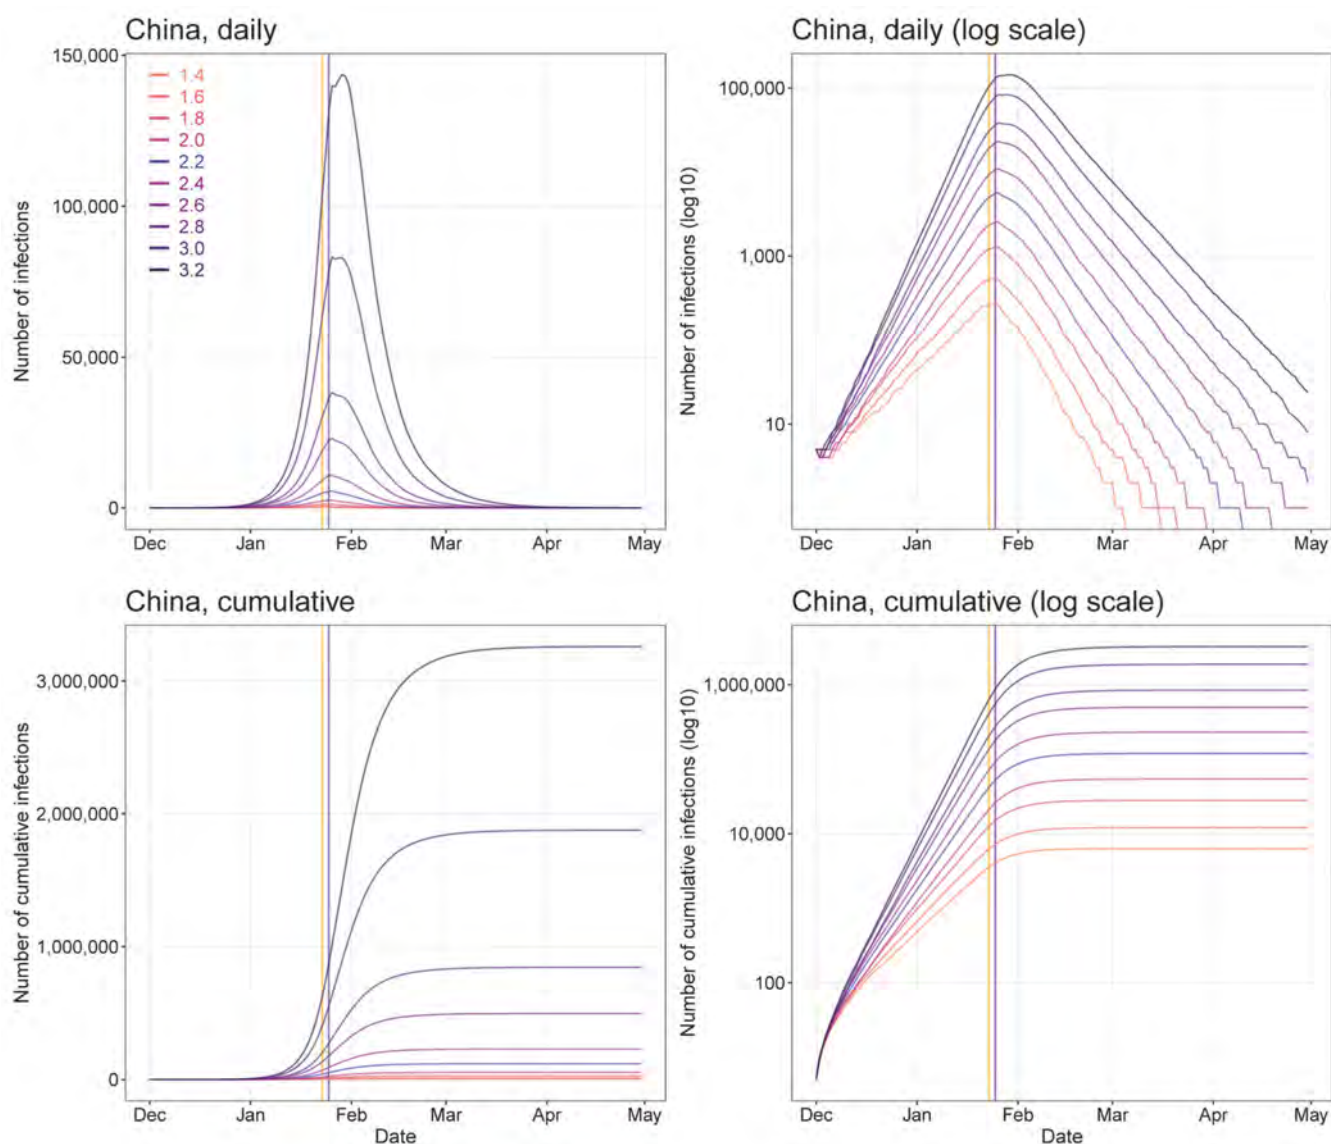

Extended Data Fig. 5. Sensitivity of estimates of COVID-19 epidemics under various numbers of days from illness onset to report/isolation.

All other parameters, NPIs and input data were the same as the baseline model with $R_0 = 2.2$. The actual delays of illness onset to report/isolation changed day-by-day (appendix Table S2). Vertical lines: orange – date of Wuhan's lockdown; purple – CNY's day.

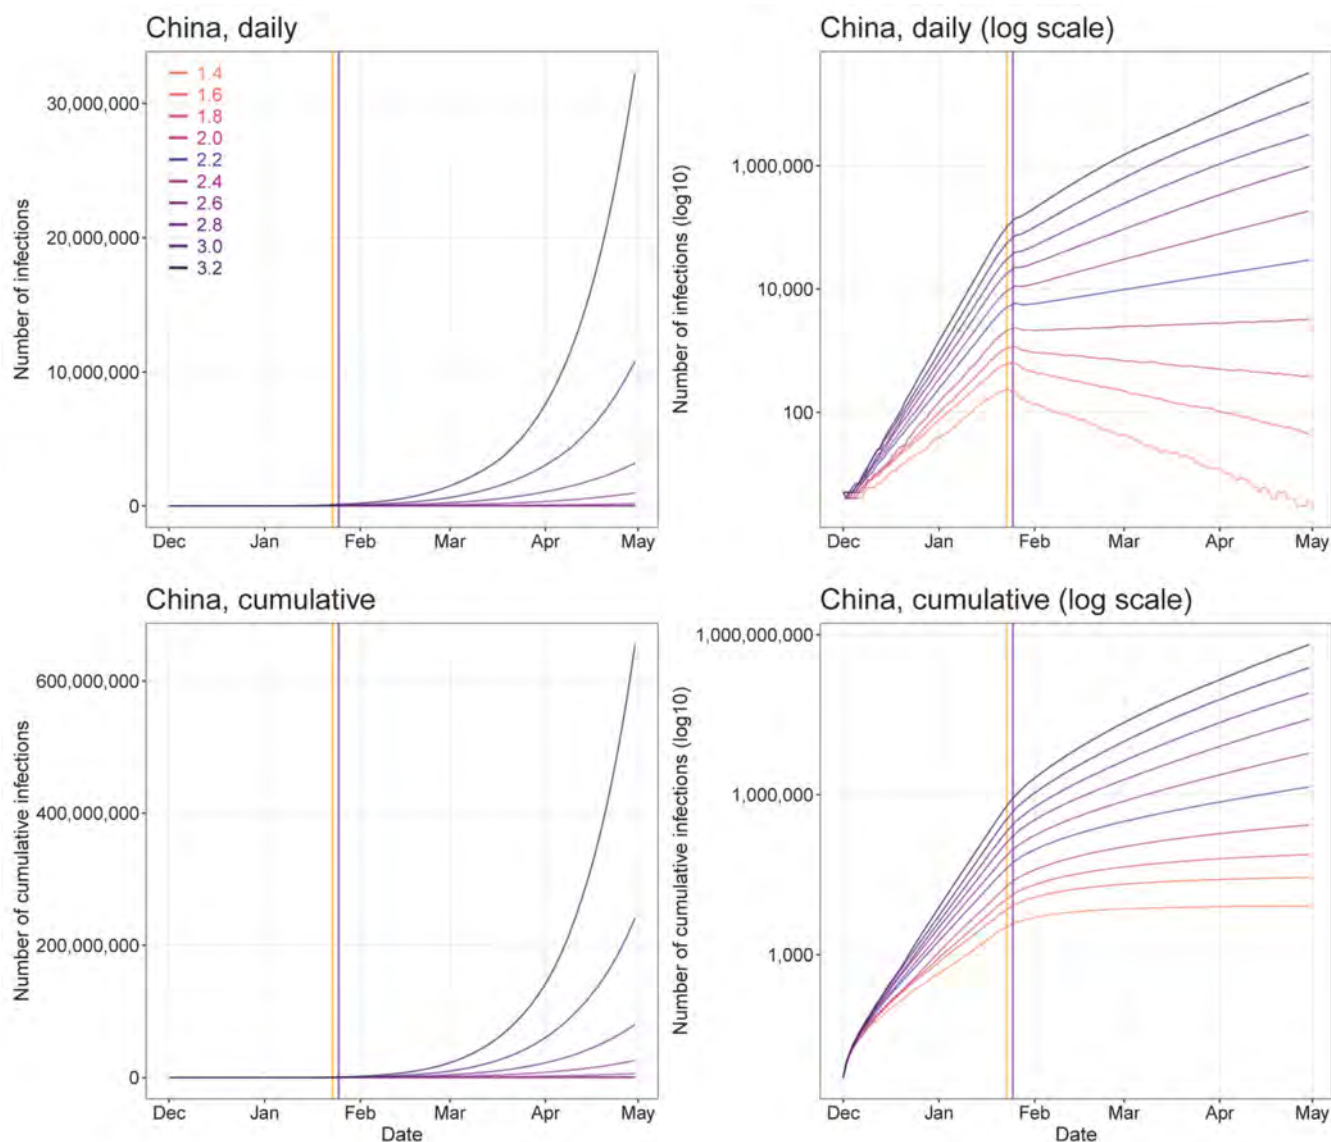

Extended Data Fig. 6. Sensitivity of estimates of COVID-19 epidemics under various contact rate values.

All other parameters, NPIs and input data were the same as the baseline model with $R_0 = 2.2$. The actual percentage of population contact (0.1 means 10% contact as usual, 1 means no contact restrictions) changed day-by-day across the country (appendix Table S1). Vertical lines: orange – date of Wuhan's lockdown; purple - CNY's day.

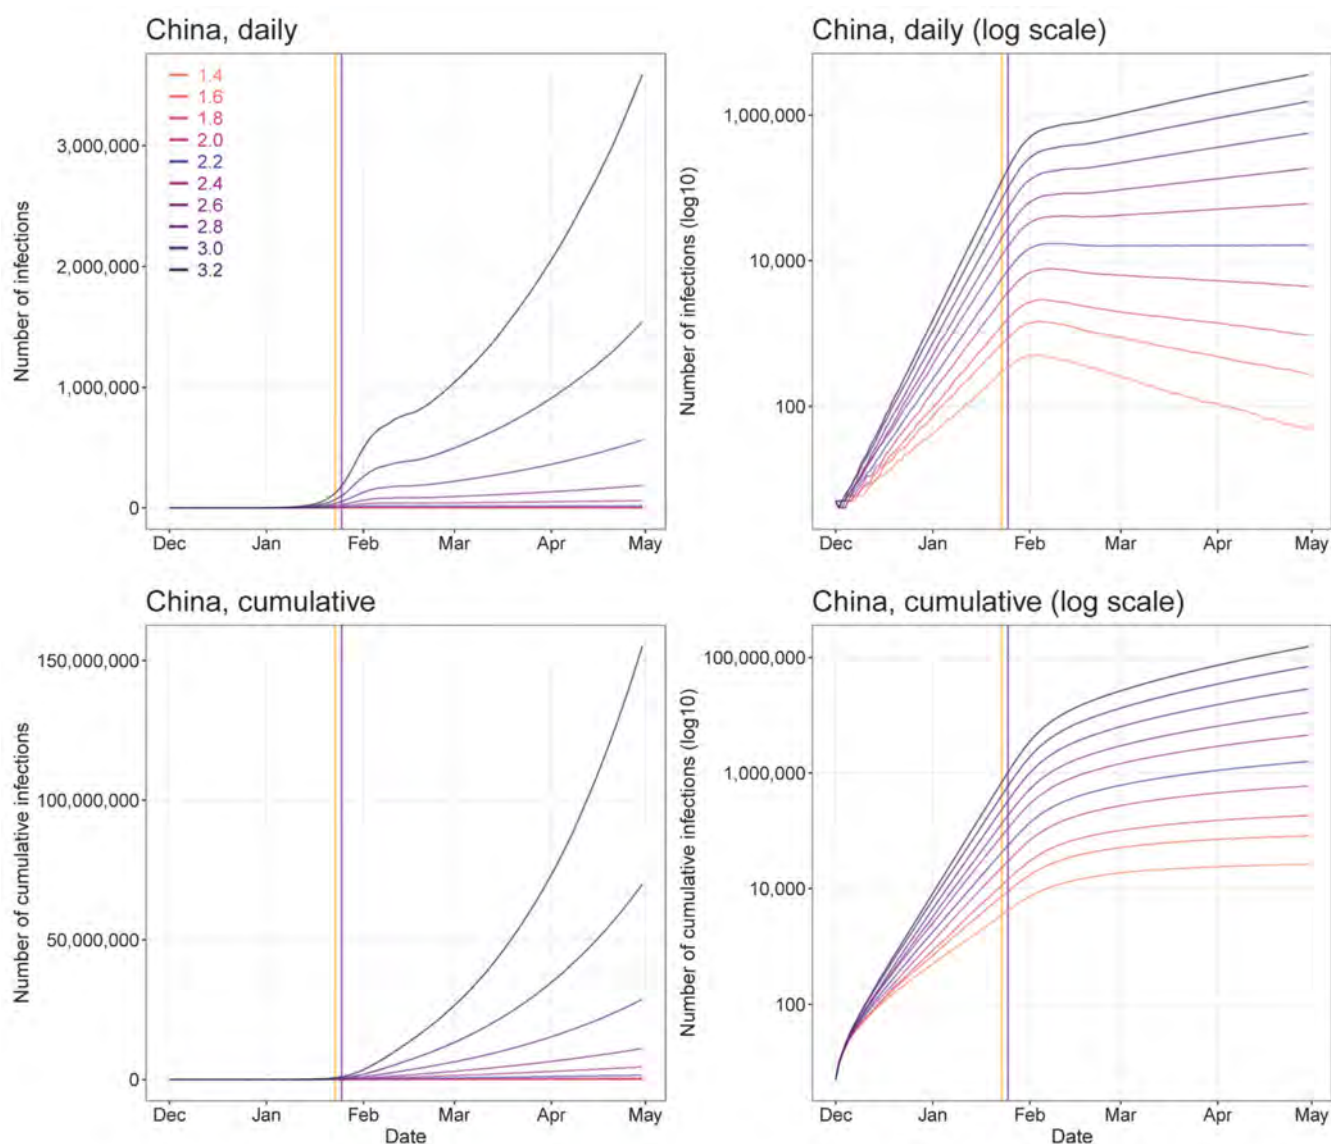

Extended Data Fig. 7. Sensitivity of estimates of COVID-19 epidemics under various values of R_0 and without inter-city travel restrictions.

All other parameters, NPIs and input data were the same as the baseline model with $R_0 = 2.2$. Vertical lines: orange – date of Wuhan's lockdown; purple - CNY's day.

Extended Data Fig. 8. Sensitivity of estimates of COVID-19 epidemics under various values of R_0 but without the intervention of inner-city contact restrictions.

All other parameters, NPIs and input data were the same as the baseline model with $R_0 = 2.2$. Vertical lines: orange – date of Wuhan's lockdown; purple - CNY's day.

Extended Data Fig. 9. Sensitivity of estimates of COVID-19 epidemics under various values of R_0 but without improved timeliness of case detection and isolation.

The delay from illness onset to detection and isolation was set as a constant of 11 days as that on January 16-18, 2020. All other parameters, NPIs and input data were the same as the baseline model with $R_0 = 2.2$. Vertical lines: orange – date of Wuhan's lockdown; purple – CNY's day

Extended Data Table 1
Reports and estimates of the COVID-19 cases in
mainland China, as of February 29, 2020.

Interventions and timing	Wuhan City, Hubei Province	Other cities in Hubei Province	Other provinces	Mainland China
Under current non-pharmaceutical interventions (NPIs)				
No. of cases reported (%) ^a	49,122 (62)	17,785(22)	12,917 (16)	79,824 (100)
Estimates of cases (%)	78,910(69)	18,503(16)	16,912 (15)	114,325(100)
Interquartile range	51,952-111,280	11,029-28,685	9,499-27,033	76,776-164,576
Dates of estimated peak	Jan 25-27	Jan 24-26	Jan 24-26	Jan 25-27
Interval between NPIs and epidemic peak ^b	7 days	6 days	6 days	7 days
Percentage (%) of cases that could have been prevented with earlier interventions				
One week ahead	61 (45-79)	71 (55-86)	78 (62-90)	66 (50-82)
Two weeks ahead	84 (78-89)	90 (82-94)	91 (84-95)	86 (81-90)
Three weeks ahead	94 (92-96)	97 (95-99)	98 (97-99)	95 (93-97)
Estimated relative no. of cases with later interventions^c				
One week delay	2.4 (1.6-3.5)	3.1 (1.8-4.6)	3.3 (2-5.4)	2.6 (1.8-3.8)
Two weeks delay	5.8 (4.0-8.6)	8.6 (5.3-12.8)	9.4 (6.1-14.6)	6.7 (4.6-10.0)
Three weeks delay	15.1 (9-21.1)	22.6 (13.5-33.9)	27.9 (17.5-42.8)	17.6(11.2-25.5)
Estimated relative no. of cases under various NPIs^c				
Without inter-city travel restriction	1.0 (0.6-1.3)	1.1 (0.7-1.7)	1.1 (0.7-1.7)	1.0(0.6-1.4)
Without inner-city contact reduction	2.5 (1.7-3.7)	2.6(1.5-4.2)	2.4(1.2-4.0)	2.6(1.7-3.7)
Without case early detection and isolation	5.0 (3.3-6.9)	5.6 (3.2-8.4)	5.1 (2.5-8.4)	5.0 (3.3-7.1)
Without all interventions above	51.4 (33.2-71.2)	91.6 (57.6-132.5)	124.7 (77.4-180)	67.3 (43.7-93.7)

^aThe reported data on COVID-19 cases were obtained from the Chinese National Health Commission as of February 29, 2020.

^bThe timeliness of case identification and reporting has been improved since January 19, 2020 and the travel restriction and social distancing were implemented from 23 January. We compared the peak dates by region with January 19 to define the interval from NPIs to epidemic peak.

^cReferring to the median of estimates under current interventions and timing. The median and interquartile range of estimates are provided here

OP is supported by funding from the National Science Foundation, USA (No. 1816075).

Role of the funding source

The funder of the study had no role in study design, data collection, data analysis, data interpretation, or writing of the report. The corresponding authors had full access to all the data in the study and had final responsibility for the decision to submit for publication.

Data and code availability

The code for the model built in this study has been made openly available for further use at <https://github.com/wpgp/BEARmod>. The data on COVID-19 cases reported by county, city, and province across China are available from the data sources listed in the Supplementary Information File 3, and the average days from illness onset to report of the first case by each county used in the modelling are detailed in Supplementary Information File 1. The mobile phone datasets analysed during the current study are not publicly available since this would compromise the agreement with the data provider, but the information on the process of requesting access to the data that support the findings of this study are available from Dr Shengjie Lai (Shengjie.Lai@soton.ac.uk), and the data on travel and contact reductions derived from the datasets and used in our model are detailed in Supplementary Information File 2.

Fig. 1. Relative daily volume of outbound travellers from cities (prefecture level) across mainland China, January 23 – April 13, 2020.

(a) All cities (n=340) in mainland China, presented with the median (solid line) and interquartile range (shading) of relative outbound flows. (b) Cities in Hubei province with Wuhan highlighted by using darker colours. Each red line represents the outflow of each city in 2020, standardized by the mean of daily outflows of each city on January 20th – 22nd, 2020. Each blue line represents estimates of normal outflow by city under the scenario of no

travel restrictions, following travel in previous years. The lines of relative volume in **(b)** were smoothed by using locally estimated scatterplot smoothing (LOESS) regression.

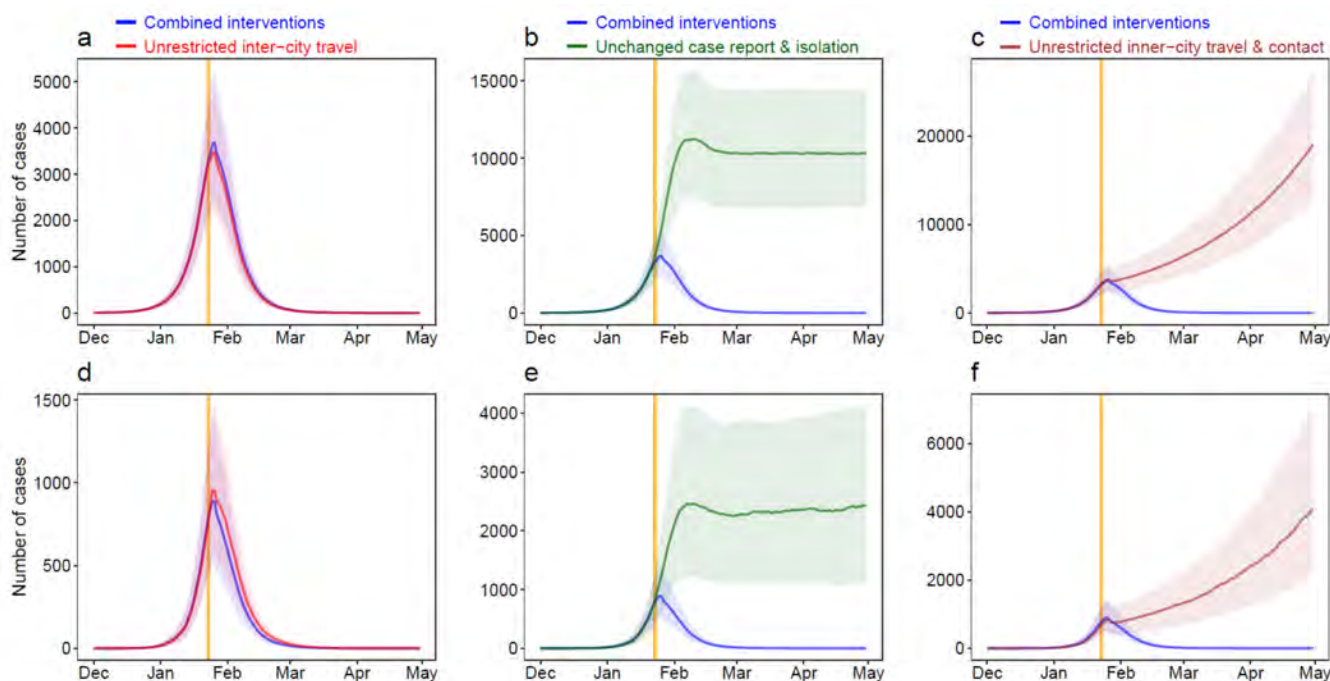

Fig. 2. Estimated epicurves of the COVID-19 outbreak under various scenarios with or without non-pharmaceutical interventions (NPIs) by region.

(a) – (c) Wuhan City. (d) – (f) Provinces outside of Hubei Province in mainland China. The blue lines present estimated transmission under current combined NPIs, and each other line represents the scenario without one type of intervention. The median and interquartile range of estimates (1000 simulations) are presented here. The orange vertical line indicates the date of Wuhan's lockdown on January 23, 2020.

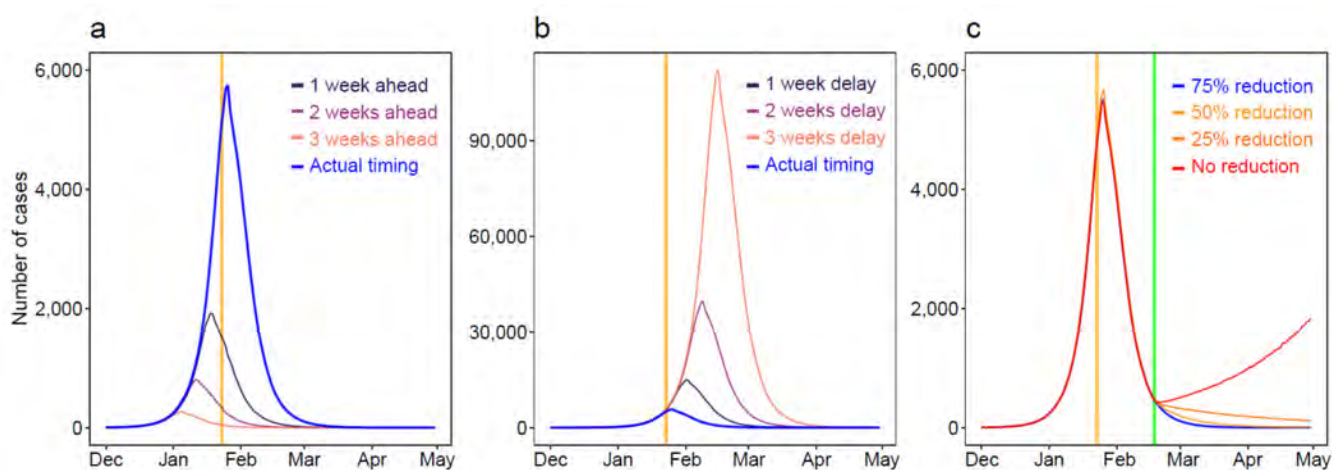

Fig. 3. Estimates of the COVID-19 outbreak under various scenarios of intervention timing and lifting of travel restrictions across China.

(a) Estimated epicurves under interventions implemented earlier than actual timing. **(b)**

Estimated epicurves under interventions implemented later than actual timing. **(c)** Estimated

COVID-19 spread under different population contact rates after lifting intercity travel

restrictions on February 17, 2020. The orange vertical lines indicate the date of Wuhan's

lockdown, and the green line shows the date of travel restrictions being lifted.

Genetic Variants of SARS-CoV-2—What Do They Mean?

Over the course of the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic, the clinical, scientific, and public health communities have had to respond to new viral genetic variants. Each one has triggered a flurry of media attention, a range of reactions from the scientific community, and calls from governments to either “stay calm” or pursue immediate countermeasures. While many scientists were initially skeptical about the significance of the D614G alteration, the emergence of the new “UK variant”—lineage B.1.1.7—has raised widespread concern. Understanding which variants are concerning, and why, requires an appreciation of virus evolution and the genomic epidemiology of SARS-CoV-2.

Mutations, Variants, and Spread

Mutations arise as a natural by-product of viral replication.¹ RNA viruses typically have higher mutation rates than DNA viruses. Coronaviruses, however, make fewer mutations than most RNA viruses because they encode an enzyme that corrects some of the errors made during replication. In most cases, the fate of a newly arising mutation is determined by natural selection. Those that confer a competitive advantage with

speaking, a variant is a *strain* when it has a demonstrably different phenotype (eg, a difference in antigenicity, transmissibility, or virulence).

Evaluation of a new SARS-CoV-2 variant should include assessment of the following questions: Did the variant achieve prominence through natural selection or chance events? If the evidence suggests natural selection, which mutation(s) are being selected? What is the adaptive benefit of these mutations? What effect do these mutations have on transmissibility and spread, antigenicity, or virulence?

Spike D614G

The D614G mutation in the spike glycoprotein of SARS-CoV-2 was first detected at a significant level in early March 2020 and spread to global dominance over the next month.² The mutation initially appeared to arise independently and simultaneously sweep across multiple geographic regions. This apparent convergent evolution was suggestive of natural selection and an adaptive benefit of D614G. However, subsequent sequencing efforts identified the D614G mutation in viruses in several Chinese provinces in late January. This raised the possibility that global dispersal of this mutation could have resulted from chance founder events, in which viruses harboring 614G just happened to initiate the majority of early transmission events in multiple locations.

This plausible null hypothesis led many in the evolution community to doubt that the D614G mutation was adaptive, despite in vitro data showing

Understanding which variants are concerning, and why, requires an appreciation of virus evolution and the genomic epidemiology of SARS-CoV-2.

respect to viral replication, transmission, or escape from immunity will increase in frequency, and those that reduce viral fitness tend to be culled from the population of circulating viruses. However, mutations can also increase and decrease in frequency due to chance events. For example, a “founder effect” occurs when a limited number of individual viruses establish a new population during transmission. The mutations present in the genomes of these viral ancestors will dominate the population regardless of their effects on viral fitness. This same interplay of natural selection and chance events shapes virus evolution within hosts, in communities, and across countries.

Although the terms *mutation*, *variant*, and *strain* are often used interchangeably in describing the epidemiology of SARS-CoV-2, the distinctions are important. *Mutation* refers to the actual change in sequence: D614G is an aspartic acid-to-glycine substitution at position 614 of the spike glycoprotein. Genomes that differ in sequence are often called *variants*. This term is somewhat less precise because 2 variants can differ by 1 mutation or many. Strictly

its effects on receptor binding. A recent population genetic and phylodynamic analysis of more than 25 000 sequences from the UK found that viruses bearing 614G did appear to spread faster and seed larger phylogenetic clusters than viruses with 614D.³ The effect size was modest, and the varying models did not always achieve statistical significance. More recently, complementary work in animal models indicates that 614G viruses transmit more efficiently.^{4,5}

Spike Y453F and Mink

Concerning outbreaks of SARS-CoV-2 began to emerge on mink farms in the Netherlands and Denmark in late spring and early summer 2020.⁶ Genomic and epidemiologic investigation of an early outbreak in the Netherlands demonstrated human to mink, mink to mink, and mink to human transmission.⁷ In early November 2020 Danish authorities reported 214 cases of human coronavirus disease 2019 (COVID-19) associated with mink farms. Many SARS-CoV-2 sequences from the Netherlands and Danish outbreaks had a Y453F mutation in the receptor binding domain of

Figure. Spread of a New SARS-CoV-2 Variant

A, Phylogenetic tree showing the relationship of lineage B.1.1.7 (20B/501Y.V1, orange branch and tips) to other circulating lineages. The long branch length for this lineage reflects the fact that it accumulated a significant number of

mutations prior to being discovered. B, Frequencies of circulating lineages over time. Lineages are colored as in the tree, with lineage B.1.1.7 (20B/501Y.V1) shown in orange.

spike, which might mediate increased binding affinity for mink ACE2 (angiotensin-converting enzyme 2). Eleven individuals from the Danish outbreak had a variant termed cluster 5, which had 3 additional mutations in spike (del69_70, I692V, and M1229I). An initial investigation of 9 human convalescent serum samples suggested a modest and variably statistically significant reduction in neutralization activity against cluster 5 viruses (mean, 3.58 fold; range, 0-13.5). The apparent adaptation of SARS-CoV-2 to mink was nevertheless concerning because continued evolution of the virus in an animal reservoir could potentially lead to recurrent spillover events of novel SARS-CoV-2 from mink to humans and other mam-

mals. For this reason, many countries have increased surveillance efforts and in some cases implemented large-scale culls (ie, selective slaughter) of mink on farms.

Lineage B.1.1.7 and N501Y

Lineage B.1.1.7 (also called 501Y.V1) is a phylogenetic cluster that is rapidly spreading in southeastern England⁸ (Figure). It had accumulated 17 lineage-defining mutations prior to its detection in early September, which suggests a significant amount of prior evolution, possibly in a chronically infected host. As of December 28, 2020, this variant accounted for approximately 28% of cases of

SARS-CoV-2 infection in England, and population genetic models suggest that it is spreading 56% more quickly than other lineages.⁹ Unlike D614G, which could plausibly have benefited from early chance events, lineage B.1.1.7 expanded when SARS-CoV-2 cases were widespread and has seemingly achieved dominance by out-competing an existing population of circulating variants. This is strongly suggestive of natural selection of a virus that is more transmissible at a population level. While public health interventions like masks, physical distancing, and limitations on large gatherings should remain effective, control of a more transmissible variant would likely require more stringent application and widespread adoption of these measures.

Eight of the lineage B.1.1.7 mutations are in the spike glycoprotein, including N501Y in the receptor binding domain, deletion 69_70, and P681H in the furin cleavage site. All of these mutations could plausibly influence ACE2 binding and viral replication. The 501Y spike variants are predicted to have a higher affinity for human ACE2, and a different variant, also with an N501Y mutation, is rapidly spreading in South Africa. The effects of these mutations on antigenicity are currently unclear.

Antigenicity and Vaccine Effectiveness

Genomic surveillance of SARS-CoV-2 variants has largely focused on mutations in the spike glycoprotein, which mediates attachment to cells and is a major target of neutralizing antibodies. There is intense interest in whether mutations in the spike glycoprotein mediate escape from host antibodies and could potentially

compromise vaccine effectiveness, since spike is the major viral antigen in the current vaccines. At this point, strong selection of a variant at the population level is probably not driven by host antibody because there are not sufficient numbers of immune individuals to systematically push the virus in a given direction. In contrast, if a variant has one or more mutations in spike that increase transmissibility, it could quickly outcompete and replace other circulating variants. Because current vaccines provoke an immune response to the entire spike protein, it is hoped that effective protection may still occur despite a few changes at antigenic sites in SARS-CoV-2 variants.

Separating cause from consequence is important in evaluating data on antibody neutralization of spike variants. Regardless of why the mutations were selected, it is reasonable to expect that many mutations in spike might affect neutralization by convalescent sera. It is therefore important to consider both the magnitude of the change in neutralization and the number of serum samples evaluated. Another issue is that viral glycoproteins are subject to evolutionary trade-offs. Sometimes a mutation that enhances one viral property, such as binding to a receptor, can reduce another property, such as escaping host antibody. Indeed, recent evidence suggests this could be the case for D614G.¹⁰ It is possible that mutations in spike that are “good” for the virus right now could also make it less fit in the context of population-level immunity in the future. Defining these dynamics, and their potential influence on vaccine effectiveness, will require large-scale monitoring of SARS-CoV-2 evolution and host immunity for a long time to come.

ARTICLE INFORMATION

Published Online: January 6, 2021.
doi:10.1001/jama.2020.27124

Correction: This article was corrected on February 15, 2021, to fix the heading “Spike N453Y and Mink” to the correct substitution of Y453F.

Conflict of Interest Disclosures: Dr Lauring reported receiving personal fees from Sanofi as a consultant on oseltamivir and influenza and personal fees from Roche as a member of a steering committee for a clinical trial of baloxavir and influenza, outside the submitted work. No other disclosures were reported.

Abstract

Background: Concern about the health impact of novel coronavirus SARS-CoV-2 has resulted in widespread enforced reductions in people's movement ("lockdowns"). However, there are increasing concerns about the severe economic and wider societal consequences of these measures. Some countries have begun to lift some of the rules on physical distancing in a stepwise manner, with differences in what these "exit strategies" entail and their timeframes. The aim of this work was to inform such exit strategies by exploring the types of indoor and outdoor settings where transmission of SARS-CoV-2 has been reported to occur and result in clusters of cases. Identifying potential settings that result in transmission clusters allows these to be kept under close surveillance and/or to remain closed as part of strategies that aim to avoid a resurgence in transmission following the lifting of lockdown measures.

Methods: We performed a systematic review of available literature and media reports to find settings reported in peer reviewed articles and media with these characteristics. These sources are curated and made available in an editable online database.

Results: We found many examples of SARS-CoV-2 clusters linked to a wide range of mostly indoor settings. Few reports came from schools, many from households, and an increasing number were reported in hospitals and elderly care settings across Europe.

Conclusions: We identified possible places that are linked to clusters of COVID-19 cases and could be closely monitored and/or remain closed in the first instance following the progressive removal of lockdown restrictions. However, in part due to the limits in surveillance capacities in many settings, the gathering of information such as cluster sizes and attack rates is limited in several ways: inherent recall bias, biased media reporting and missing data.

REVISED Amendments from Version 1

This article has been updated in response to reviewer comments, and to include 49 new transmission events which have been added to our online database. We now discuss a total of 201 transmission events (previously 152), classified into 22 setting types (previously 18).

Any further responses from the reviewers can be found at the end of the article

Introduction

The novel coronavirus SARS-CoV-2, responsible for coronavirus disease 2019 (COVID-19), was first identified in Wuhan, China at the end of 2019, and has since spread around the world (European Centre for Disease Prevention and Control, 2020). The capacity of the virus for human-to-human transmission, coupled with the lack of immunity in the population due to the novelty of SARS-CoV-2, has led to the implementation of severe reductions in people's movements in an effort to reduce disease impact. These strong measures are broadly described as "lockdowns". Due to the highly restrictive nature of lockdowns, and their impact on people's health, wellbeing and finances, it is likely that such interventions cannot be sustained for prolonged periods of time, and will have to be lifted, at least to some extent, before an effective vaccine becomes available.

To successfully remove these lockdown restrictions while avoiding a resurgence in SARS-CoV-2 transmission, we must better understand in which types of settings the virus is most likely to be transmitted. Determining particular places that are linked to clusters of cases could reveal settings that are responsible for amplifying the heterogeneity in transmission that has been reported: potentially 80% of transmission is being caused by only 10% of infected individuals (Endo *et al.*, 2020). Notably, the difference in transmission risk between households and larger communal settings is unclear, as is the difference between indoor and outdoor transmission.

Quantifying these differences in transmission can be further facilitated by the fact that, in many countries now under lockdown, intensive contact tracing of imported cases was performed in the early stages of the epidemic, resulting in the detection of clusters of cases. This data, on the first detected clusters in a country, can give knowledge of the types of settings facilitating transmission before intensive social and physical distancing took place.

The aim of our work is therefore to gather information on reported clusters of COVID-19 cases to determine types of settings in which SARS-CoV-2 transmission occurred. This could inform post-lockdown strategies by identifying places which should be kept under close surveillance and/or should still remain closed to avoid a resurgence in transmission.

Methods

Outline

We searched for scientific literature and media articles detailing clusters of SARS-CoV-2 transmission (details below) and extracted

data into a Google Sheets file (accessible at <https://bit.ly/3ar39ky>; archived as *Underlying data* (Leclerc *et al.*, 2020)). We defined "settings" as sites where transmission was recorded resulting in a cluster of cases. We restricted our definition of "cluster" to the first-generation cases that acquired the infection due to transmission in a single specific setting at a specific time. For example, if a person was infected on a cruise ship, and later infected additional people after disembarking, we would not consider that the latter were part of that "cruise ship cluster", since they were not infected on the ship. We recorded the country and further details about the type of setting, the numbers of primary and secondary cases in the cluster, cluster sizes, and attack rates. We defined a case as a person reported to be infected with the SARS-CoV-2 virus, regardless of symptoms.

Search strategy

References were found in four ways. Firstly, we performed a systematic literature review for COVID-19 clusters in PubMed on the 30th March 2020 (search term below). A total of 67 papers were found. Two reviewers (GMK and QJL) performed data extraction into the online database. We chose to only search this database and use peer reviewed articles as a quality threshold. We included data from English abstracts (where possible), but otherwise excluded non-English publications.

PubMed search: ("COVID-19"[All Fields] OR "COVID-2019"[All Fields] OR "severe acute respiratory syndrome coronavirus 2"[Supplementary Concept] OR "severe acute respiratory syndrome coronavirus 2"[All Fields] OR "2019-nCoV"[All Fields] OR "SARS-CoV-2"[All Fields] OR "2019nCoV"[All Fields] OR ("Wuhan"[All Fields] AND ("coronavirus"[MeSH Terms] OR "coronavirus"[All Fields])) AND (2019/12[PDAT] OR 2020[PDAT])) AND cluster [All Fields]

Secondly, we used the online Google search engine to find media articles detailing settings of SARS-CoV-2 transmission in general. We searched for combinations of either "COVID", "COVID-19", "COVID-2019", "severe acute respiratory syndrome coronavirus 2", "2019-nCoV", "SARS-CoV-2", "2019nCoV" or "coronavirus", and the words "transmission cluster" (e.g. "COVID transmission cluster" or "SARS-CoV-2 transmission cluster"). We only included online articles in English. From the collated list of settings, we then performed a further search for transmission in each of these settings (week beginning 6th April 2020).

Thirdly, we investigated whether information on the settings in which the first 100 "transmission events" in countries with current COVID-19 outbreaks existed by searching for publicly available data sources. As substantial investigation of cases often occurs early in an outbreak, any clusters linked to the first ~100 cases in countries outside China could give information on the transmission of SARS-CoV-2 in the absence of any social distancing measures.

Finally, following the original publication of this article on 01/05/2020, we included a "Suggested updates" tab in our publicly available database (<https://bit.ly/3ar39ky>). This allows other individuals to suggest new clusters we should include in our analysis. We review these suggestions regularly, and add

those with sufficient detail to our “Latest updated results” tab. In this revised version, we have updated our analysis to include suggestions we reviewed up to 26/05/2020.

Cluster characteristics and setting definition

With the above data, we then aimed to estimate both the final (proportion of people in that setting who became infected) and secondary (proportion of contacts of one case who became infected) attack rates in each setting. These were previously identified as key metrics, particularly within households, to estimate whether transmission is driven by a relatively small number of high-risk contacts (Liu *et al.*, 2020).

We defined a setting when several reports mentioned clusters linked to spaces with certain characteristics. For example, “Religious” includes churches and mosques, while “Public” here means public communal shared spaces such as markets or welfare centres. Where settings were a mixture of indoor and outdoor spaces, we used a mixed indoor/outdoor classification.

Results

We found evidence of SARS-CoV-2 transmission clusters for 201 events, which we classified into 22 types of settings (Table 1 and Table 2). All the studies with relevant data are compiled in an online database (accessible at <https://bit.ly/3ar39ky>; see also *Underlying data* (Leclerc *et al.*, 2020)). Many of the published reports with setting specific data came from China (47/201) and Singapore (51/201).

The vast majority of these clusters were associated with indoor or indoor/outdoor settings (21/22). Large clusters, such as those linked to churches and ships, were infrequently reported. Almost all clusters involved fewer than 100 cases (181/201), with the outliers being transmission in hospitals, elderly care, worker dormitories, food processing plants, prisons, schools, shopping and ship settings. Religious venues provided a further setting with large cluster sizes: there were separate clusters in South Korea, France, India and Malaysia (Ananthalakshmi & Sipalan, 2020; BBC, 2020; Salaün, 2020; Shin *et al.*, 2020). In addition to these settings with maximum cluster sizes of more than 100 cases per cluster, we identified five further settings with maximum cluster sizes between 50 and 100: sport (65 cases) (Korean Centre for Disease Control & Prevention, 2020), bar (80 cases) (Sim, 2020), wedding (98 cases) (Ministry of Health – New Zealand, 2020), work (97 cases) (Park *et al.*, 2020) and conference (89 cases) (Marcelo & O’Brien, 2020).

We found a notably high number of transmission events reported in worker dormitories (21/201), although all of these were from Singapore. This type of setting had the second highest total cluster size out of all the recorded events we found, with 797 cases reported in the S11 dormitory cluster in Singapore (Data Against COVID19 SG, 2020).

We found only a small number of clusters linked to schools (8/201), and there the SARS-CoV-2 cases reported were most often in teachers or other staff. For example, for two school clusters in Singapore (Ministry of Health - Singapore, 2020),

16/26 and 7/8 cases were staff. Some children were also found to be infected in these clusters, as was the case in the Salanter Akiba Riverdale school in New York, USA (Ailworth & Berzon (2020)), although testing for infection was not always universal. In a retrospective close cohort study in a French high school however, 133 children and staff were seropositive for anti-SARS-CoV-2 antibodies, 92 of whom were pupils (Fontanet *et al.*, 2020).

We identified 9 clusters linked to food processing plants in 4 different countries (USA, Germany, Canada, Netherlands). These transmission events have led to large clusters, such as in a meat processing plant in South Dakota where a total of 518 employees were infected by SARS-CoV-2 (Cannon, 2020).

The setting with the greatest number of reported clusters of SARS-CoV-2 transmission was households (36/201). Again, most were from China (25/36) with all cluster sizes being less than 10. However, for 27 out of 36 studies, we were unable to calculate either the secondary or final attack rates due to a lack of information on total household size.

We aimed to estimate secondary and final attack rates in other settings but, as for households, we found that there was substantial missing data. In particular, the number of individuals in a setting was missing, and so we were unable to perform this analysis. Where attack rates could be estimated for individual clusters, these are reported in the online database.

Although information on the index and early cases in a setting was often reported, further information on the subsequently reported 10–100 cases in a country was difficult to extract. Moreover, the index cases were often quarantined and hence not linked to further transmission in most settings.

Discussion

In this review of SARS-CoV-2 transmission events, we found that clusters of cases were reported in many, predominantly indoor, settings. Note that we restrict cluster size to only include individuals infected within a specific setting, and exclude secondary infections which occurred outside the settings. Most clusters involved fewer than 100 cases, with the exceptions being in healthcare (hospitals and elderly care), large religious gatherings, food processing plants, schools, shopping, and large co-habiting settings (worker dormitories, prisons and ships). Other settings with examples of clusters between 50–100 cases in size were weddings, sport, bar, shopping and work. The majority of our reports are from China and Singapore.

Limitations

The settings collated here are biased due to the nature of our general search for SARS-CoV-2 transmission described above. Although based on a systematic review of published peer-reviewed literature, many of the reports included came from media articles where relevant epidemiological quantities were not always reported, resulting in many missing data. Many of the more detailed studies originated from the early outbreak in China, especially those providing household information. The settings

Table 1. Summary of gathered reported events as of 20th April 2020. Where only one study for this setting is reported, the minimum, maximum and median number of secondary cases in the cluster and/or total cluster size correspond to this single reported number (if given). Total cluster size accounts for all primary and secondary cases in the cluster. For references see the online database, accessible at <https://bit.ly/3ar39ky>.

Setting type	Number of reported events	Secondary cases			Total cluster size			Total number of cases across all clusters	Countries	Indoor / outdoor
Bar	12	2	9	16	3	13	80	319	Germany, Austria, Italy, Singapore, Japan, USA, Australia, New Zealand, Brazil	Indoor / outdoor

Table 2. Definition used for each of our transmission setting types. The definitions describe in what environment transmission was deemed to occur.

Transmission setting	Definitio
Bar	Indoor space such as a bar, club, pub, small live music venues etc.
Building site	Outdoor space where construction work takes place.
Conference	Indoor professional event with many people interacting and meeting, shaking hands, eating together, team activities, etc.
Elderly Care	Care homes for the elderly; includes staff and residents. Transmission can occur between staff and residents but also from visitors.
Food processing plant	Any establishment that processes food for human consumption, such as a meat or vegetable packing plant.
Funeral	Indoor or outdoor burial ceremony; includes close contact with others such as hugging, shaking hands, eating together, singing, praying, etc.
Hospital	Any transmission that occurs within a hospital between patients and/or staff, in a COVID19 ward or not.
Hotel	Any transmission that occurs within the hotel e.g. hotel rooms, shared spaces, reception desk, etc.
Household	Transmission between individuals in a shared living space
Meal	When people eat together. Meals included took place in restaurants, hotels, cafes, home, etc. Transmission occurs over a meal by speaking, sharing foods, touching the same surfaces, etc.
Prison	Any transmission that occurs within a prison between prisoners and/or staff.
Public	Where transmission occurs on public property and does not fall into any of the other settings e.g. park, welfare centre, foodbank, etc.
Religious	Transmission occurs at a religious event such as at mass, services, prayer time, choir practice, etc.
School	Childcare or learning environments (schools, nurseries, kindergartens etc). Includes staff and children.
Ship	Any ship at sea. Includes crew and/or passengers onboard.
Shipyards	Large indoor or outdoor space where ships are made or repaired. Includes those working on the ship as well as customers
Shopping	A shop or shopping centre. Includes customers and those working in the shop.
Sport	Participation in a sporting activity indoor or outdoor e.g. gym or running.
Transport	Any means of public transportation, such as bus, plane, metro etc.
Wedding	Indoor or outdoor wedding celebration.
Work	In the workplace, typically an office.
Worker dormitories	A shared living space for workers.

we identified here therefore might not be representative of settings from a global perspective. Bias is present when relying on media coverage - a cluster is more likely to be reported if controversial or if there is an interesting social narrative. This is then compounded by the method search engines use to provide results where priority is given to high traffic stories. Overall, this can lead to some settings being overly represented in our database, which is why the numbers of clusters per settings should be compared cautiously.

Similarly, there is a bias in our reports which means that attendance in settings with many individuals is more likely to be linked to a cluster: recall bias (Spencer *et al.*, 2017). The accuracy of memories is influenced by subsequent events and experiences such that special, one-off events may be more likely to be

remembered and potentially reported. If multiple single transmission events had occurred whilst walking in a park, for example, these would be less likely to be remembered, and more difficult to detect and hence record. Networks of close contacts also tend to be small, resulting in multiple opportunities for transmission, and hence potentially increase the importance of households or workplace for transmission instead of single outstanding settings of potential transmission. Hence, we cannot determine with any reliability the relative importance of the reported different types of settings beyond the record that clusters have been linked to such places.

Other events, such as large music concert (Dalling, 2020), political (Jones, 2020) and sporting (Hope, 2020; Roan, 2020; Wood & Carroll, 2020) gatherings, could potentially have been

linked to clusters of COVID-19. But, in the absence of rigorous surveillance systems and widespread testing that would allow countries to link and report the transmissions of such events, such connections remain speculation. An example of this lack of surveillance would be the UK, where only 4/201 clusters have been recorded. The outlier for this is Singapore which appears to investigate clusters systematically and provides a well-designed online dashboard with details of all clusters detected ([Data Against COVID19 SG, 2020](#)).

In many settings, only symptomatic cases of disease severe enough to require hospitalization are tested and ultimately reported. This misses those infections that result in mildly symptomatic or asymptomatic symptoms, although there is mounting evidence for a significant proportion of infections to remain asymptomatic ([Gudbjartsson *et al.*, 2020](#); [He *et al.*, 2020](#); [Lavezzo *et al.*, 2020](#)). For some of the clusters, primarily households, all contacts were tested for infection; but for most of the data collated here, the number of COVID-19 symptomatic cases was the only information provided. These reported cases are a subset of all infections and in the absence of more comprehensive data, such as could be collated through widespread cluster investigation and community testing, we cannot conclude anything about clusters of infections, nor that we have included all relevant settings in which transmission can occur. We were also unable to estimate attack rates from the available data, meaning that comparison between rates of transmission in settings is impossible to achieve.

Settings associated with large cluster sizes

One type of setting that was associated with large numbers of eventual cases was religious venues. The common features of these meetings are the large number of attendees, confined spaces and physical contact. For example, there were eventually more than 5000 COVID-19 cases linked to transmission at the Shincheonji Church of Jesus in South Korea ([Shin *et al.*, 2020](#)). In this particular religious venue, no preventative action was taken despite knowing members were infected with SARS-CoV-2. In other venues, transmission events took place without prior knowledge of any infections and before the WHO declared pandemic status. Other large clusters in this setting type were associated with annual religious events that took place over a few days or weeks ([Ananthalakshmi & Sipalan, 2020](#); [BBC, 2020](#); [Salaün, 2020](#)). Attendees returned to their home countries where they continued to transmit. This generated many secondary cases internationally as well as locally. However, it is clear from smaller “first-generation” clusters, which our analysis focuses on, that these settings provide ideal conditions for transmission: we found 7/16 identified religious clusters had 10 cases or less, whilst 9/16 had 23 or more (see online database <https://bit.ly/3ar39ky> and *Underlying data* ([Leclerc *et al.*, 2020](#)) for more information). The number of cases in each cluster is an approximation, and little is known about the number of index cases in these religious meetings to begin with, with the exception of the South Korea cluster. Religious events are well known sources of heightened transmission; there is a focus on vaccination recommendations for attendees to the annual Hajj pilgrimage for example, which is currently being postponed for 2020 ([Aljazeera, 2020](#)).

Worker dormitories have been recognised as key places linked to transmission in Singapore, with 893 out of 942 new cases recorded on April 18th being residents in such dormitories ([Asia, 2020](#)). We found 21 reported clusters, one of which had the second largest cluster size of all the events we report here; 797 cases which from the data we believe is a first-generation cluster. Worker dormitories are similar to households ([Dalling, 2020](#)) in the sense that they are places where people live together and come in frequent close contact; however, the number of residents in dormitories is higher than in most other households. This probably contributes to the higher cluster sizes seen in this setting. Additionally, hygiene facilities can be limited in worker dormitories ([Paul *et al.*, 2020](#)), which could also explain the higher transmission. These points also apply to prisons, another type of large co-habiting setting for which we have identified 4 clusters with a maximum cluster size of 353 cases. It would be beneficial to compare attack rates across households, worker dormitories and prisons, to better understand which factors influence the risk of transmission between people who share a living space. Unfortunately, we were unable to identify the total number of residents in these dormitories and prisons, which prevented us from deriving attack rates and making this comparison.

In addition to religious events and worker homes, we also identified clusters of more than 100 cases in elderly care homes, hospitals and ships. These are all known to be at risk of clusters of infectious disease ([Blanco *et al.*, 2019](#); [Kak, 2015](#); [Lansbury *et al.*, 2017](#)). Moreover, people in these settings are often older than the general population and hence at greater risk of severe forms of COVID-19 disease ([U.S Centers for Disease Control and Prevention, 2020](#)). The increased mortality and likely dependence on availability of personal protective equipment (PPE) mean that healthcare clusters are more politically sensitive and hence more likely to be reported.

A more unexpected setting type is perhaps food processing plants, in which we identified clusters of up to 518 cases ([Cannon, 2020](#)). These plants have been the source of clusters in multiple countries. It is possible that the cold atmosphere in this setting has facilitated the spread of the virus ([Molteni, 2020](#)). Other possible explanations include the close proximity of workers for prolonged periods shared welfare spaces, as well as the need to speak loudly to communicate over the noise of the machines, which could lead to an increased projection of viral particles. Another explanation is that we may not be seeing clusters from other manufacturing settings with similar working environments, as fewer have been in operation due to lockdown guidelines during the pandemic, whereas food production has continued.

We identified seven additional setting types with cluster sizes above 50 or 100 cases (school, sport, bar, shopping, wedding, work and conference), which shared characteristics with the settings described above (see online database for more information <https://bit.ly/3ar39ky> and *Underlying data* ([Leclerc *et al.*, 2020](#))). Notably, sport, bars, shopping areas and conferences are predominantly indoor settings, where people are in close proximity. For conferences and work, like religious events, transmission within the cluster is facilitated by the duration

of the events over several days, as well as the combination of interactions there (workshops, dinners etc...). This can also apply to weddings, where transmission is further increased due to the close-proximity interactions between people (kissing, hugging, dancing etc...). As for bars and shopping areas, these are places with important fluxes of people, which increases the diversity of contacts. Finally, schools, like religious groups, can sometimes represent tightly knit communities which facilitates disease transmission amongst individuals, as was the case with the Salanter Akiba Riverdale school in New York, with a cluster size of at least 60 cases (Ailworth & Berzon (2020)).

The first 100 transmission events & under reporting

The pursuit of the first 100 transmission events revealed little on settings of transmission. This reflects the wider issue we found of under reporting and is likely to reflect the fact that many public health surveillance systems were quickly overwhelmed and could not continue outbreak investigations. An example of this is the UK where only limited information on case follow-up and cluster investigation appears to be available. The impact of such under reporting is that we cannot say with certainty what contribution each setting had to overall transmission – we do not have the denominator information on time and contact in all settings. Nor do we have universal screening for detection of all infections, many of which will be asymptomatic. The importance of such universal testing for infection in interpreting whether transmission has occurred in a setting is highlighted by the difference between the low number of clusters linked to schools and the high level of infection reported in one French high school study (Fontanet *et al.*, 2020).

Further work could pursue data from early investigation of cases where available, to explore the relative importance of different settings to transmission. Importantly, this may counter a bias towards small cluster sizes: with a lack of follow-up only some of the cases actually linked to a setting may be reported and linked. Detailed outbreak investigations should also be explored to get information on the places where transmission is unlikely to have occurred, e.g. if a COVID-19 patient reports 30 contacts at place “A”, “B” and “C”, but only contacts in “C” subsequently become infected this reflects reduced risk in settings “A” and “B”.

Implications for further work

We found that many clusters of cases were linked to indoor settings, but this may be because early spread in China was during their winter, with people naturally spending more time inside close spaces. Increasing evidence suggests that transmission of SARS-CoV-2 can occur via airborne droplets (Morawska & Cao, 2020); however, it is likely that outdoor transmission risk is lower (Nishiura *et al.*, 2020). Further work is needed to clarify this. We found only few clusters in school settings. However, there were many clusters associated with household transmission, and children could be the entry point for the virus into this setting. Although it should be noted in this context that the Report of the WHO-China Joint Mission on Coronavirus Disease 2019

(COVID-19) did not find a single instance where people recalled transmission from a child to an adult (WHO-China Joint Mission Members, 2020). More generally, the role of children in widespread transmission of the virus is unclear, and whether reopening schools could trigger increased introductions of the virus into households and further within-household spread will have to be carefully monitored.

Further investigation of settings that facilitate clusters of transmission could provide important information for containment strategies as countries lift some of the current restrictions. Previous work has suggested that there might be considerable heterogeneity in individual transmission, which would imply a disproportionate impact from preventing large transmission events from occurring (Endo *et al.*, 2020). Whilst widespread contact tracing is often considered part of future containment strategies, there is a need for this to be complemented with retrospective investigation of clusters in order to better understand the extent to which certain settings and behaviours are at particular risk of generating clusters of transmission. This could, in turn, inform contact tracing efforts and might be particularly relevant in the context of contact tracing using mobile phone apps, which has recently been suggested in support of more traditional contact tracing (Ferretti *et al.*, 2020). For example, past co-location in certain settings could be a trigger for notification of risk from an app instead of, or in addition to, individual contacts.

Online database of collected reports

The online database (accessible at <https://bit.ly/3ar39ky>) provides information on all collected reports, references and information on cluster sizes as well as notes about the study. This database will be kept as a static source linked to this report, but with an additional tab for newly reported settings. Readers can submit information in the “Suggested updates” tab and we will aim to update information if evidence for substantial new clusters are found linked to a setting that was not in this study.

Conclusions

In conclusion, we found evidence of SARS-CoV-2 transmission in many types of settings. Our results provide a basis to identify possible places that are linked to clusters of cases and could be closely monitored, for example by linking to app-based contact tracing, and/or remain closed in the first instance following the progressive removal of lockdown restrictions. However, reporting should be improved in the majority of settings, with implementation of systematic reporting on the number of potentially exposed individuals and the number of confirmed and suspected cases from these settings, to allow the estimation of attack rates.

Data availability

Underlying data

Figshare: COVID19 settings of transmission - collected reports database. <https://doi.org/10.6084/m9.figshare.12173343.v3> (Leclerc *et al.*, 2020).

This project contains 'COVID-19 settings of transmission - database.xlsx', which contains the data extracted from the initial search, as well as an updated version of the dataset from 26/05/2020.

Up to date information on all collected reports is provided in an open-access online database (accessible at <https://bit.ly/3ar39ky>).

This database provides references and information on cluster sizes as well as notes about the studies.

Data are available under the terms of the [Creative Commons Zero "No rights reserved" data waiver](#) (CC0 1.0 Public domain dedication).

Acknowledgments

We would like to thank Dr Joël Mossong for his review of our article. We would also like to thank all the anonymous individuals who suggested updates for transmission events in our online database.

Samuel V. Scarpino 

Network Science Institute, Northeastern University, Boston, MA, USA

In this manuscript, the authors conduct a thorough literature review and identified SARS-CoV-2 transmission clusters. After assembling their data set, the authors discuss the possible similarities in settings associated with transmission. As stated, understanding how transmission risk varies across settings is critical for the safe relaxation of measures implemented to control the spread of COVID-19.

This paper provides a valuable resource and synthesis of what is currently known. I should note that this article has already been evaluated and I believe the authors have adequately addressed the points raised by the previous reviewer. However, I do have a few additional comments/questions, which I hope the authors find constructive.

1. While Google Sheets is a convenient tool for entering and sharing small data sets, it is not "permanent" and also has the potential to be corrupted or heavily modified. There is also no easy way for authors to cite the "version" of the sheet used. The authors do provide a Figshare, but that appears to date back prior to the revised version. I would strongly suggest regularly archiving a version of the data set and assigning each update a version number. At a minimum, please provide a DOI for the revised data set.
2. I am concerned that one reason we don't see more evidence for transmission at schools is that schools were closed early in nearly all locations. To my knowledge, Sweden is not reporting data on whether there have been significant transmission in their schools (as the authors know not all of which are open). I believe the authors should provide a strong disclaimer, either in the abstract or early in the discussion that we really don't have much to go on w.r.t. schools. (Of course this is my opinion and likely subject to debate).
3. The authors state, "More generally, the role of children in widespread transmission of the virus is unclear, and whether reopening schools could trigger increased introductions of the virus into households and further within-household spread will have to be carefully monitored." But, I also feel that given the uncertainty in whether children are import for ongoing transmission, there are other settings we should caveat.

4. The authors note that they, "use peer reviewed articles as a quality threshold," and, while I strongly disagree with the exclusion of pre-prints, I think the authors should at least provide some information on how many studies or clusters were excluded. Given the long (and increasing lag) between pre-print and publication, is this study missing half of all clusters that are currently published or in-review? 10% 95%? Providing information around what's been excluded is standard practice for such reviews and feels critical in this case.

Is the work clearly and accurately presented and does it cite the current literature?

Yes

Is the study design appropriate and is the work technically sound?

Partly

Are sufficient details of methods and analysis provided to allow replication by others?

Partly

If applicable, is the statistical analysis and its interpretation appropriate?

Not applicable

Are all the source data underlying the results available to ensure full reproducibility?

Partly

Are the conclusions drawn adequately supported by the results?

Yes

Competing Interests: No competing interests were disclosed.

Reviewer Expertise: Epidemiology

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.

Joël Mossong

Epidemiology and Microbial Genomics, Laboratoire National de Santé, Dudelange, Luxembourg

This manuscript aims to provide a descriptive analysis of transmission settings of Covid19 based on published articles or media reports, which is of major interest for controlling the epidemic.

I have several major concerns:

1. Most settings reported herein are not representative of settings from a global perspective, most are from the initial epidemic in Asia (mainly from the Singapore dashboard and <20% of settings in the manuscript are outside of Asia). This needs to be added to the discussion as a major limitation.
2. Some important and widely reported outbreaks in particular settings are missing. e.g. the outbreak of the megachurch in Mulhouse France (<https://www.dailymail.co.uk/news/article-8168819/French-megachurch-meeting-blamed-sparking->) and the Ruby Princess outbreak (reported in

<https://www1.health.gov.au/internet/main/publishing.nsf/Content/1D03BCB527F40C8BCA258503C1>) or the cluster in the french ski resort (<https://www.bbc.com/news/uk-51425702>). This somehow questions the completeness of the systematic review. The authors could have widened their search terms to include the settings (church, ship, etc.) and outbreak when searching media reports.

3. Given that this manuscript from a team in the UK, it is surprising that only 4 outbreak settings were reported for the UK. The authors need to discuss why they were not able to find more reports from the local and national media outlets in English speaking countries like UK, Ireland, and possibly also Australia, Canada and the US.
4. The authors should discuss reasons for under reporting: public health surveillance systems in many countries were quickly overwhelmed to investigate transmission settings and chains of transmissions. Transmission clusters in elderly care and hospitals homes due to political sensitivity, linked to increased mortality, lack of adequate PPE equipment
5. Meat factories and slaughter houses have recently emerged as high risk setting in the US (<https://edition.cnn.com/2020/04/08/business/meat-plant-closures-coronavirus/index.html>) and Germany (<https://www.dw.com/en/coronavirus-breaks-out-in-third-german-slaughterhouse/a-53389860>). This setting should be included separately in Table 1.

Minor comments:

1. Add the sum of cases for all clusters per setting in table 1.
2. p.3.& p. 7 "the first 100 transmission events". While this is an interesting concept, it isn't really being addressed in this article. No country presented herein has collected more than 100 events. The paragraph in the discussion on this seems therefore irrelevant and could be deleted.
3. p. 7. The authors mention that there is increasing evidence for airborne transmission. The current consensus is that most transmission occurs via airborne droplets, which is different to aerosol transmission. I suggest to replace "be airborne" by "occur via airborne droplets".

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

Author Response 01 Jun 2020

Quentin Leclerc, London School of Hygiene & Tropical Medicine, London, UK

This manuscript aims to provide a descriptive analysis of transmission settings of Covid19 based on published articles or media reports, which is of major interest for controlling the epidemic.

Thank you for taking the time to review our article. Please note that we have now updated our analysis to include an additional 49 transmission events (201 events total) and 4 new settings type ("Food processing plant", "Prison", "Transport" and "Wedding"; 22 setting types total). Some of these new elements overlap with your suggestions. Our Discussion section has also been updated to reflect these new results.

I have several major concerns:

- 1. Most settings reported herein are not representative of settings from a global perspective, most are from the initial epidemic in Asia (mainly from the Singapore dashboard and <20% of settings in the manuscript are outside of Asia). This needs to be added to the discussion as a major limitation.**

Thank you for raising this point. We already mentioned in the Discussion - Limitations section that many studies originated from the early outbreak in China, but have included an additional sentence there to clarify that this could prevent our results from being directly applicable to other countries. That said, please note that in our updated analysis, 98/201 (50%) events are from China and Singapore, compared to 92/152 (60%) in our original analysis, which improves the coverage of our results.

The added sentence is "The settings we identified here therefore might not be representative of settings from a global perspective."

- 1. Some important and widely reported outbreaks in particular settings are missing. e.g. the outbreak of the megachurch in Mulhouse France (<https://www.dailymail.co.uk/news/article-8168819/French-megachurch-meeting-blamed>) and the Ruby Princess outbreak (reported in <https://www1.health.gov.au/internet/main/publishing.nsf/Content/1D03BCB527F40C8BC> or the cluster in the french ski resort (<https://www.bbc.com/news/uk-51425702>). This somehow questions the completeness of the systematic review. The authors could have widened their search terms to include the settings (church, ship, etc.) and outbreak when searching media reports.**

Thank you for suggesting these additional clusters; we have now added the Ruby Princess and the French ski resort events.

Our initial analysis was focused on trying to find distinct *settings* in which transmission had occurred. Hence we were initially trying to prioritise examples of new *settings* linked to clusters rather than gathering all data on all outbreaks linked to all settings. This has changed somewhat with the open source database and we are happy to act as a gathering point for cluster data. For the outbreak in Mulhouse, this falls into the category of events that we do not include in our analysis. This because we are interested in understanding transmission only within specific settings; for example, for a cruise ship, the cluster size we report corresponds to the number of people infected on that ship only, not the people that these might have infected after disembarking. If we included people infected by passengers after disembarking, this would not reflect the “cruise ship” setting, as this additional transmission could occur in a variety of other settings (household, meal etc...).

We had already highlighted this in the Methods – Outline section, but have now repeated that point at the beginning of the Discussion to hopefully make this distinction clearer (“Note that we restrict cluster size to only include individuals infected within a specific setting, and exclude secondary infections which occurred outside the settings.”)

1. **Given that this manuscript from a team in the UK, it is surprising that only 4 outbreak settings were reported for the UK. The authors need to discuss why they were not able to find more reports from the local and national media outlets in English speaking countries like UK, Ireland, and possibly also Australia, Canada and the US.**

Our initial search was at the end of March. At that time, the number of confirmed cases in the UK was around 20,000, compared to more than 200,000 now. Therefore, there was little information at the time on clusters in these countries compared with Asia, which is why we were less likely to find media reports on that topic for the UK. For similar reasons, we had little information for English-speaking countries. In addition, because of the lack of widespread testing in the UK and/or follow-up of cases, information on clusters does not appear to be widely available in the UK. As of 26/05/2020, we have now identified 39 transmission events in English-speaking countries (19% of all the transmission events we have identified so far). Therefore, our updated analysis is more geographically balanced.

1. **The authors should discuss reasons for under reporting: public health surveillance systems in many countries were quickly overwhelmed to investigate transmission settings and chains of transmissions. Transmission clusters in elderly care and hospitals homes due to political sensitivity, linked to increased mortality, lack of adequate PPE equipment**

Thank you for this suggestion. In line with your comments on the “first 100 transmission events” we have adapted the paragraph in the discussion to discuss reasons for under reporting.

We have also added a sentence to the paragraph on healthcare clusters in the discussion to reflect the likely increased reporting of clusters linked to these settings due to political sensitivity.

1. **Meat factories and slaughter houses have recently emerged as high risk setting in the US**
<https://edition.cnn.com/2020/04/08/business/meat-plant-closures-coronavirus/index.html>
and Germany
<https://www.dw.com/en/coronavirus-breaks-out-in-third-german-slaughterhouse/a-5336161>
This setting should be included separately in Table 1.

Thank you for raising this point. Our online database had been updated to reflect this, and we have now added the “Food processing plant” setting type in our analysis, and comment on this in the Results and Discussion sections of our article.

This also applies to our new “Prison”, “Transport” and “Wedding” setting types.

Minor comments:

1. **Add the sum of cases for all clusters per setting in table 1.**

We have now implemented this suggestion in the revised article.

1. **p.3.& p. 7 "the first 100 transmission events". While this is an interesting concept, it isn't really being addressed in this article. No country presented herein has collected more than 100 events. The paragraph in the discussion on this seems therefore irrelevant and could be deleted.**

We agree it was frustrating not to find this data, which would have been an interesting angle, giving us “denominator” information. In line with the comments above we have adapted this paragraph to link to under reporting.

1. **p. 7. The authors mention that there is increasing evidence for airborne transmission. The current consensus is that most transmission occurs via airborne droplets, which is different to aerosol transmission. I suggest to replace "be airborne" by "occur via airborne droplets".**

Thank you for this suggestion, we have now rephrased this accordingly.

Barney Duncan, Ex-Wellcome Biotechnology Ltd, Abermaw, Gwynedd, UK

Back in the 1980's Wellcome Biotechnology Ltd (owned & operated by the Wellcome Trust) expended much effort in trying to eliminate the use of blood fractions from nutrient media used for growing and maintenance of animal & human cell lines prior to inoculation with virus in the making of rabies and foot & mouth disease vaccines as well as interferon. At the time, it was found that without blood, cell growth and virus titres were poorer.

I have recently observed locally in North Wales 2 major clusters from the 2 Sisters Poultry processing plant on Anglesey and a meat processing plant in Wrexham. This caused me to look further into commonality of Covid outbreaks in other meat processing plants. It resulted in me coming across your paper.

I am mindful of the fact that the first outbreak was traced back to a food market in Wuhan China. The *coronavirus* likely jumped to people in a wet *market* there where meat, seafood, and live animals were handled.

I believe there may be real significance in the quantities of blood on workers overalls and working surfaces in slaughterhouses & meat processing factories. Blood deposits would surely provide a site where virus impregnated droplets from an infected worker could act as inoculum and allow virus to replicate rapidly

In consequence of these facts I would suggest the following recommendations for the next update

- 1 Add wet/cattle markets to the transmission settings list
- 2 Split food processing plant into two fractions meat and non-meat

Thank you to all participants/contributors to your paper. It is most creditable & worthwhile and I believe will prove most valuable line of research.

Barney Duncan
Chemical Engineer (ret'd)

Competing Interests: None unless you consider being a Wellcome pensioner influences my judgement but I'm sure Bill Castell (former CEO of Wellcome Biotechnology and Chairman of Wellcome Trust) could & would readily dispel any such notions !

David Henry, Bond University, Gold Coast, Queensland, Australia

This is an important topic. I am concerned about your search. I may have missed it, but I think having done this scoping exercise that you should rerun your searches with specific terms (and synonyms) for the settings of interests: schools churches, weddings, meatworks (lots of synonyms) etc. I am guessing that you will get a lot more hits. I don't think that 'transmission cluster' is a sufficiently sensitive term. I'd also like to see a PRISMA flow diagram.

María Margarita Ronderos Torres, Independent Consultant in Epidemiology, Colombia

I would like to draw to your attention the football match between Atalanta from Bergamo and Valencia from Spain on the 19th Feb at the San Siro Stadium in Milan. Aprox 40,000 fans from the Region attended the match. 35% of the Valencia team delegation when returning to Spain tested positive for COVID19. The region only went into lockdown on the 4th of March. This gave ample time (1.5 t 2 incubation periods) for household transmission with high intergeneration mix and known high elderly population. Further study is needed but this could be very well explain the explosion of cases that followed and is in line with your proposed explanation for super spread of the virus.

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Household transmission of SARS-CoV-2 and risk factors for susceptibility and infectivity in Wuhan: a retrospective observational study

Fang Li*, Yuan-Yuan Li*, Ming-Jin Liu*, Li-Qun Fang, Natalie E Dean, Gary W K Wong, Xiao-Bing Yang, Ira Longini, M Elizabeth Halloran, Huai-Ji Wang, Pu-Lin Liu, Yan-Hui Pang, Ya-Qiong Yan, Su Liu, Wei Xia, Xiao-Xia Lu, Qi Liu, Yang Yang, Shun-Qing Xu

Summary

Background Wuhan was the first epicentre of COVID-19 in the world, accounting for 80% of cases in China during the first wave. We aimed to assess household transmissibility of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and risk factors associated with infectivity and susceptibility to infection in Wuhan.

Methods This retrospective cohort study included the households of all laboratory-confirmed or clinically confirmed COVID-19 cases and laboratory-confirmed asymptomatic SARS-CoV-2 infections identified by the Wuhan Center for Disease Control and Prevention between Dec 2, 2019, and April 18, 2020. We defined households as groups of family members and close relatives who did not necessarily live at the same address and considered households that shared common contacts as epidemiologically linked. We used a statistical transmission model to estimate household secondary attack rates and to quantify risk factors associated with infectivity and susceptibility to infection, accounting for individual-level exposure history. We assessed how intervention policies affected the household reproductive number, defined as the mean number of household contacts a case can infect.

Findings 27 101 households with 29 578 primary cases and 57 581 household contacts were identified. The secondary attack rate estimated with the transmission model was 15.6% (95% CI 15.2–16.0), assuming a mean incubation period of 5 days and a maximum infectious period of 22 days. Individuals aged 60 years or older were at a higher risk of infection with SARS-CoV-2 than all other age groups. Infants aged 0–1 years were significantly more likely to be infected than children aged 2–5 years (odds ratio [OR] 2.20, 95% CI 1.40–3.44) and children aged 6–12 years (1.53, 1.01–2.34). Given the same exposure time, children and adolescents younger than 20 years of age were more likely to infect others than were adults aged 60 years or older (1.58, 1.28–1.95). Asymptomatic individuals were much less likely to infect others than were symptomatic cases (0.21, 0.14–0.31). Symptomatic cases were more likely to infect others before symptom onset than after (1.42, 1.30–1.55). After mass isolation of cases, quarantine of household contacts, and restriction of movement policies were implemented, household reproductive numbers declined by 52% among primary cases (from 0.25 [95% CI 0.24–0.26] to 0.12 [0.10–0.13]) and by 63% among secondary cases (from 0.17 [0.16–0.18] to 0.063 [0.057–0.070]).

Interpretation Within households, children and adolescents were less susceptible to SARS-CoV-2 infection but were more infectious than older individuals. Presymptomatic cases were more infectious and individuals with asymptomatic infection less infectious than symptomatic cases. These findings have implications for devising interventions for blocking household transmission of SARS-CoV-2, such as timely vaccination of eligible children once resources become available.

Introduction

About a year into the COVID-19 pandemic, the global cumulative incidence of cases is still climbing, reaching more than 83.6 million as of Jan 1, 2021.¹ The resumption of economic activities depends on our understanding of important transmission venues such as households, workplaces, and schools for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), drivers of transmission, and availability of effective control measures. Households are major transmission

venues for many respiratory pathogens. The WHO-China Joint Mission on Coronavirus Disease 2019 (COVID-19) suggested that most epidemiologically linked clusters in China were households and urged prioritisation of studies on risk factors for household transmission.² In resource-limited areas, including Wuhan in China early on in the epidemic, isolation of cases and quarantine of close contacts often occurred at home, enabling onwards transmission within households. Although children are less likely to develop

Research in context

Evidence before this study

Households offer an ideal setting for assessing person-to-person transmissibility of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and risk factors for infectivity and susceptibility to infection. We searched PubMed and medRxiv for articles published between Dec 1, 2019, and Aug 20, 2020, using the search terms ("COVID-19" OR "SARS-CoV-2" OR "2019-nCoV") AND ("household" OR "family") AND ("transmissibility" OR "risk factors"). We identified 22 relevant articles. Secondary attack rate estimates varied across countries from 4.6% in Taiwan to 31.6% in Zhejiang Province, China, and were mostly based on studies with fewer than 300 households. Some studies found that older age groups were associated with increased susceptibility to infection or disease, and a study in Israel identified infants as a highly susceptible group. A study in Guangzhou found no effect of age on infectivity, probably due to a small sample size. A study in South Korea reported a high infection rate among household contacts of index cases aged 10–19 years old, but not in household contacts of younger index cases. A few studies confirmed efficient presymptomatic transmission of the virus. Two studies reported much lower infectivity of asymptomatic infections than symptomatic cases, with odds ratios of 0.028 and 0.25.

Added value of this study

Based on contact-tracing records from more than 27 000 households in Wuhan up to April 18, we found that

SARS-CoV-2 was transmitted with moderate efficiency within households at the very beginning of the pandemic, with an overall secondary attack rate of 15.6% (95% CI 15.2–16.0). Children and adolescents were less susceptible to infection, but more infectious once infected, than individuals aged 20 years or older. Children's higher infectivity was affected by household size. Our study confirmed higher susceptibility of infants (aged 0–1 years) to infection than older children (≥ 2 years of age). Although children and adolescents were much less likely to have severe disease, they were as likely as adults to develop symptoms. We confirmed the high infectiousness of cases during the incubation period and found asymptomatically infected individuals were about 80% less infectious than symptomatic cases. Finally, we found isolation of cases and quarantining of household contacts away from home effectively reduced household transmission.

Implications of all the available evidence

The high infectivity of children with SARS-CoV-2 infection highlights the need for careful planning of school reopening. Additionally, the susceptibility of infants supports caregivers of infants being prioritised for vaccination. When feasible, cases could be isolated and household contacts quarantined away from their homes to prevent household transmission, particularly when presymptomatic.

severe disease than adults,² their ability to transmit to household contacts is not well characterised, yet it is highly relevant for preventing transmission in schools and households.

Households are ideal settings for assessing transmissibility of a pathogen and associated determinants of susceptibility and infectivity. The household secondary attack rate is defined as the probability that an infected person will transmit the pathogen to a susceptible household member during their infectious period. A meta-analysis estimated the household secondary attack rate for SARS-CoV-2 as approximately 15–22%,³ higher than the estimated rates of 5–10% for SARS-CoV and 1–5% for Middle East respiratory syndrome coronavirus.⁴ Most studies neither distinguished between secondary and tertiary transmissions nor controlled for exposure history. Some household studies revealed that children were less susceptible to the virus than older adults, and that the transmissibility of SARS-CoV-2 was inversely related to household size.^{4–6} Whether infectivity differs by age is less clear,³ in part because when there are coprimary cases within a household, it is not possible to resolve which resulted in secondary infections. The relative importance of the presymptomatic (incubation) period versus the symptomatic period has been noted or quantified in some studies.^{4,7} However, few studies

have assessed the relative infectivity of asymptomatic infections, although some modelling studies have used values extrapolated from viral load data of mild and severe cases.^{3,8,9}

Here, we present an analysis of a large number of households extracted from contact tracing records in Wuhan, the first epicentre of the COVID-19 pandemic, where 80% of confirmed cases in China were reported. We estimated the transmission probability of SARS-CoV-2 within households and evaluated drivers for infectivity of cases and susceptibility of their household contacts, while adjusting for measured confounders and individual-level exposure history. We assessed the infectivity levels of both presymptomatic cases and asymptomatic infections. Finally, we estimated the effectiveness of case isolation and quarantine of household contacts away from home in reducing household transmission in Wuhan.

Methods

Study population

In response to the COVID-19 outbreak, the Wuhan Center for Disease Control and Prevention (CDC) conducted epidemiological investigations to trace the close contacts of ascertained cases, following the Prevention and Control Plan for COVID-19 issued

by the National Health Commission of China.¹⁰ The retrospective cohort analysed here includes all laboratory-confirmed or clinically confirmed cases and laboratory-confirmed asymptomatic infections identified between Dec 2, 2019, and April 18, 2020, in Wuhan, China, together with their household contacts. Data on demographics, clinical symptoms, laboratory test results, and time and location of quarantine or isolation were recorded for all investigated individuals.

Written informed consent was waived by the National Health Commission of China for outbreak investigations of notifiable infectious diseases. All identifiable personal information was removed from the data by Wuhan CDC before any analysis. The study was approved by the ethics committee of Wuhan CDC (WHCDCIRB-K-2020012).

Definitions

COVID-19 cases were defined according to the National Health Commission of China's Guidelines for Diagnosis and Management of COVID-19, with seven editions released over the study period (appendix 2 pp 3–4). Clinically confirmed cases were defined as suspected cases of COVID-19 with typical pneumonia manifestations who were negative for SARS-CoV-2 nucleic acid by real-time RT-PCR. Laboratory-confirmed cases were individuals with positive detection of SARS-CoV-2 nucleic acid by real-time RT-PCR using respiratory specimens, and included asymptomatic infection (appendix 2 p 3). For this study, a household contact of an identified case was broadly defined as a family member or close relative who had unprotected contact with the case within 2 days before the symptom onset or test-positive specimen collection of the case but did not necessarily live at the same address. For each household, the date with the earliest symptom onset (symptomatic infection) or the first test-positive specimen (asymptomatic infection) was designated as day 1. Primary cases were defined as cases (including asymptomatic infections) who had symptom onset or the first test-positive specimens collected on day 1 or day 2, enabling households to have coprimary cases. Later cases were classified as secondary cases.

Statistical analysis

Households that shared common contacts were considered epidemiologically linked and were merged into a single household for all analyses, although we retained the original household size for analyses of household size as a risk factor (appendix 2 pp 7–8). We evaluated the overall household secondary attack rate in the primary analysis but also distinguished individuals who lived at the same address from those who did not in a sensitivity analysis.

Characteristics of primary cases, secondary cases, and uninfected or untested household contacts were compared using the χ^2 test for discrete variables and

Wilcoxon rank sum test for continuous variables. The observed secondary attack rate was calculated as the proportion of secondary infections among all household contacts, assuming untested contacts were uninfected. Total numbers of confirmed COVID-19 cases, proportions of confirmed cases among the population (ie, community-level attack rates), total numbers of contact-traced households, and average observed household secondary attack rates were mapped at the community level in Wuhan using ArcGIS (version 10.2; Esri, Redlands, CA, USA). Population data were obtained from the Hubei Health Statistics and Information Platform. A generalised estimating equation (GEE) regression model with a logistic link function and an exchangeable correlation structure for each household was used to assess individual-level and household-level risk factors for infection of household contacts. Both the observed secondary attack rate and GEE model were restricted to households with a single primary case. Both assumed that all secondary cases were infected by the primary case, and that all household contacts were equally exposed to the primary case. All descriptive analyses and the GEE modelling were done using R (version 3.6.1).

To account for individual-level exposure history and potential tertiary transmission, we also used a chain-binomial transmission model to estimate the secondary attack rate. This model was also used to evaluate determinants of infectivity and susceptibility to infection (appendix 2 pp 11–17). Here, both infectivity and susceptibility refer to a combination of biological effects (eg, immune response or viral shedding) and physical exposure, and our analysis cannot distinguish one mechanism from another. We assumed that each susceptible individual was exposed to any infected household members as well as a non-specific external force of infection, and that two household members had contact with each other when neither was isolated or quarantined at centralised facilities. Households with only primary cases but no exposed household contacts were excluded from the transmission analyses. A Monte Carlo expectation maximisation algorithm was used to account for uncertainties in the infection date of asymptomatic infections (appendix 2 pp 13–14).¹¹ We performed analyses under several plausible assumptions about the distributions of the incubation and infectious periods based on the literature (appendix 2 pp 9–11, 23).^{12,13} We report results assuming a mean incubation period of 5 days and a maximum infectious period of 22 days for the primary analysis. We compared household reproductive numbers, defined as the mean number of household contacts an infectious person can infect, across three time windows—before Jan 24, 2020 (before lockdown), Jan 24–Feb 10 (moderate control), and after Feb 10 (strong control)—to assess the effectiveness of general interventions such as case isolation, quarantine of close

See Online for appendix 2

Panel: Timeline of key control events during the outbreak of COVID-19 in Wuhan, China

Dec 2, 2019

Symptom onset of the earliest case recorded in surveillance.

Dec 30, 2019–Jan 1, 2020

Active case finding began, the National Health Commission and WHO were notified, and Huanan Seafood Market was closed.

Jan 23, 2020

Lockdown of Wuhan was declared. All public transportation within the city and inbound and outbound transportation were suspended.

Jan 24, 2020

Patients with fever were required to self-report to community health-care centres. Individuals with mild symptoms but not identified as suspected cases were told to isolate either at home or in designated facilities. Severe or suspected COVID-19 cases were admitted to hospital.

Feb 2, 2020

The government required district-level centralised isolation and treatment of all confirmed cases, suspected cases, and feverish patients with pneumonia symptoms; quarantine of close contacts of cases at designated facilities; and reporting of asymptomatic infections.

Feb 11–13, 2020

Tightened management of all residential communities and restricted within-community movement were initiated. Communities initiated door-to-door symptom screening.

Feb 20–22, 2020

Body temperature of each resident was monitored twice a day. Discharged patients who had been admitted with COVID-19 were told to isolate for an additional 14 days at home. A 3-day campaign was initiated on Feb 20 to test (real-time PCR) all confirmed cases, suspected cases, feverish individuals, and close contacts of cases.

April 22, 2020

Public ground transportation fully returned to normal.

April 26, 2020

National Health Commission declared no hospitalised cases in Wuhan.

contacts, and restriction of human movement in communities (panel).

From Feb 23, 2020, all household contacts were tested for SARS-CoV-2 regardless of symptom status. Before then, a substantial number of household contacts without symptoms were not tested, creating uncertainty in their infection status. We used a two-step imputation approach with the first step imputing infection status and the second step imputing a time interval that is

informative about the potential infection time of each imputed asymptomatic infection (appendix 2 pp 17–18). The imputation involves regression models based on characteristics of the household contacts, the primary cases, and the household itself that are related to whether asymptomatic household contacts were tested or not and were potentially related to the infection outcome (appendix 2 pp 24–25). For both the GEE analysis and the chain-binomial transmission analysis, the results were averaged over 300 sets of imputed data. Households with members with missing ages were excluded from all age-related analyses.

Role of the funding source

The funder of the study had no role in study design, data collection, data analysis, data interpretation, or writing of the report. All authors had full access to all the data in the study and had final responsibility for the decision to submit for publication.

Results

From Dec 2, 2019, to April 18, 2020, 29 405 households with at least one clinically confirmed or laboratory-confirmed COVID-19 case were identified. After merging epidemiologically linked households, we obtained 27 101 households with 29 578 primary cases, including coprimary cases. These primary cases had 57 581 household contacts, consisting of 10 367 secondary cases, 29 658 test-negative contacts, and 17 556 untested contacts (table 1). The median household size (before merging) was three people (IQR 2–4), and 72.7% (21 385/29 405) of the households had two or three household members. Large households tended to be younger and were more often detected later in the epidemic (appendix 2 p 26). The median age among all cases was 56 years (43–66), and 20 760 (52.0%) cases were female. Age data were missing for 1112 test-negative or untested contacts in 806 households. Primary cases and secondary cases shared similar age and sex profiles (table 1). Compared with uninfected or untested contacts, secondary cases were older, more likely to be female, and more likely to live in smaller households (table 1). Secondary cases were more likely to be laboratory confirmed than primary cases (table 1).

The cases included in this study accounted for 76.7% (39 945/52 070) of all reported cases in Wuhan as of April 18 (appendix 2 p 20). The majority of reported cases had symptom onset between Jan 24 and Feb 10 (table 1). More cases were reported and more infected households were contact traced in densely populated districts in central Wuhan such as Wu-Chang, Jiang-Han, Jiang-An, Qiao-Kou, Han-Yang, and Hong-Shan (figure). The community-level attack rates showed a similar distribution, with higher rates in central Wuhan, but average observed household secondary attack rates were spatially more evenly distributed (figure).

NA=not applicable. SARS-CoV-2=severe acute respiratory syndrome coronavirus 2. *Including 8619 asymptomatic contacts who might have been tested but whose laboratory test records were missing; these individuals were treated as untested in all analyses. Age data were missing for 1112 test-negative or untested household contacts. † χ^2 test comparing secondary cases to uninfected contacts. ‡Severity categories were measured at the time of clinical assessment or laboratory testing. Mild cases include 280 cases for whom severity was missing. A total of 2060 cases died. § χ^2 test comparing proportion of asymptomatic infections between secondary and primary cases. ¶ χ^2 test comparing secondary with primary cases.

Table 1: Demographic and clinical characteristics of cases and test-negative or untested contacts of SARS-CoV-2-infected households in Wuhan, China, from Dec 2, 2019, to April 18, 2020

Secondary cases were less severe clinically than primary cases, with more asymptomatic cases (4.2% vs 1.9%) and fewer severe or critical cases (13.9% vs 19.2%; table 1). Clinical severity was missing for 280 cases and was assumed to be mild for these cases in all subsequent analyses. Among the 4903 primary and secondary cases with symptoms recorded, the most common systemic symptoms were fever (in 2970 [60.6%]), fatigue (in 1325 [27.0%]), and myalgia (in 626 [12.8%]), and the most common respiratory symptoms were dry cough (in 1776 [36.2%]), shortness of breath (in 846 [17.3%]), productive cough (in 661 [13.5%]), and chest tightness or pain (in 633 [12.9%]; appendix 2 p 27). Radiological evidence of pulmonary abnormality was confirmed in 3247 (66.2%) of 4903 cases. Secondary cases had lower rates of systemic or respiratory symptoms but a higher rate of radiological evidence than primary cases (appendix 2 p 27). Using data after Feb 22, 2020, when most household contacts

were laboratory tested, we estimated the proportion of secondary cases who developed symptoms after infection (pathogenicity) to be 84.0% (95% CI 81.7–86.1; 913/1087; appendix 2 p 28). Young adults aged 20–39 years were less likely to develop symptoms upon infection than those aged 60 years or older (78.8%, 95% CI 73.0–83.8 [186/236] vs 87.5%, 83.9–90.6 [351/401]). The pathogenicity of infection in children and adolescents (84.7%, 76.0–91.2 [83/98]) resembled that of adults aged 40 years or older, although symptomatic cases among children and adolescents were much less likely to be severe or critical than for those aged 60 years or older (2.4%, 95% CI 0.3–8.4 [two of 83] vs 18.8%, 14.9–23.3 [66/351]). Neither pathogenicity nor disease severity differed between the two sexes (appendix 2 p 28).

For the 24 985 households that had only a single primary case, the overall observed secondary attack rate was 16.0% (95% CI 15.7–16.3; table 2). The secondary

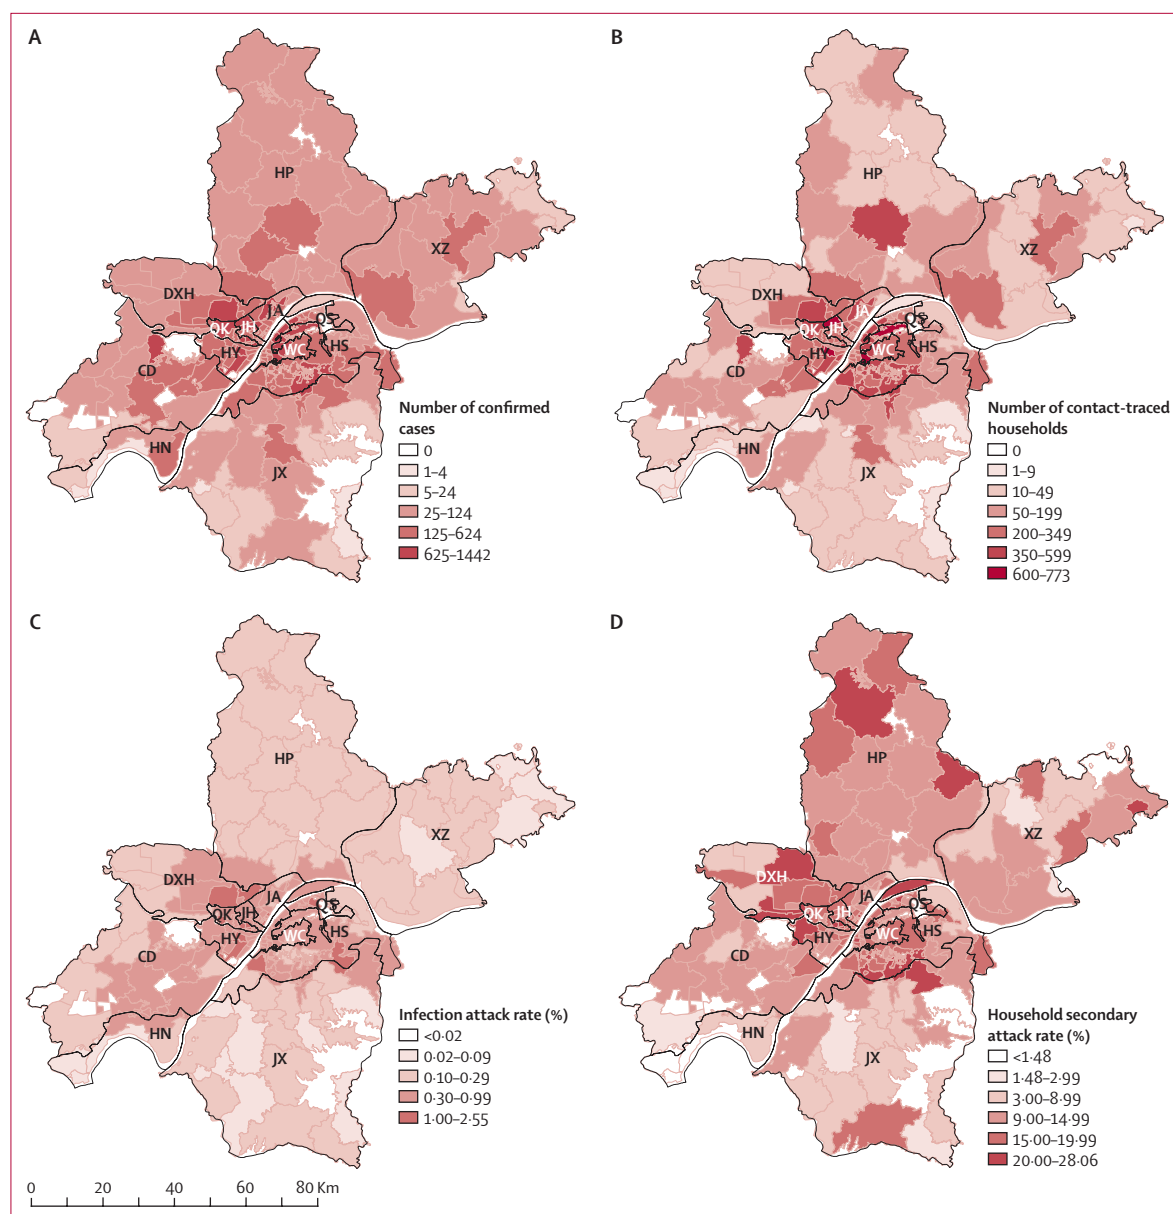

Figure: Spatial distribution of all confirmed COVID-19 cases and the retrospective cohort of contact-traced households reported during Dec 2, 2019–April 18, 2020, at the community level in Wuhan, China

(A) Distribution of all clinically or laboratory confirmed COVID-19 cases in Wuhan. (B) Distribution of all contact-traced households included in this study. (C) The community-level infection attack rate (ie, the cumulative number of confirmed cases as a percentage of the total population) in each district in Wuhan. (D) The observed household secondary attack rate (ie, the proportion of secondary infections among household contacts) among households with a single primary case included in this study. In B and D, the community of each household was determined by the community of the primary case, or the case with the earliest symptom onset if there were coprimary cases. CD=Cai-Dian. DXH=Dong-Xi-Hu. HN=Han-Nan. HP=Huang-Pi. HS=Hong-Shan. HY=Han-Yang. JA=Jiang-An. JH=Jiang-Han. JX=Jiang-Xia. QK=Qiao-Kou. QS=Qing-Shan. WC=Wu-Chang. XZ=Xin-Zhou.

attack rate estimated by the chain-binomial transmission model was similar, 15.6% (15.2–16.0), under the assumption of a mean incubation period of 5 days and a maximum infectious period of 22 days (table 3; appendix 2 p 30). The model-estimated secondary attack rate for contacts living at the same residential address was 16.1% (15.6–16.5), higher than the 12.6%

(11.4–13.9) rate estimated for contacts from the same household but living in different residences—eg, grandparents and grandchildren (appendix 2 p 31).

Based on the chain-binomial model adjusted for all covariates, household transmissibility of SARS-CoV-2 was inversely associated with household size (table 3; appendix 2 p 32). The GEE model showed a

similar household size effect (table 2). Compared with Jan 24–Feb 10, 2020, odds of daily household transmission between an infectious individual and a susceptible individual was lower after Feb 10 (table 3). A greater reduction was seen in the observed household secondary attack rate, from near 20% in the periods before Feb 10 to 4.1% after (table 2).

In general, both the observed secondary attack rate and model-estimated odds of infection (with regard to susceptibility) increased with age of the household contacts (tables 2, 3). Individuals aged 60 years or older were the most susceptible age group to SARS-CoV-2 infection. The least susceptible age group was children aged 2–5 years. The transmission model estimated that individuals younger than 20 years were about 66–84% (ORs ranging from 0.16 to 0.34) less susceptible than adults aged 60 years or older, and adults aged 20–59 years were 31–49% (ORs ranging from 0.51 to 0.69) less susceptible (table 3). Infants (aged 0–1 years) were more susceptible to infection than toddlers (2–5 years; OR 2.20, 95% CI 1.40–3.44) and elementary-school-aged children (6–12 years; 1.53, 1.01–2.34). Female contacts were slightly more susceptible than male contacts (table 3). The GEE model yielded similar ORs, although it estimated slightly larger differences in susceptibility between older contacts (≥ 60 years) and younger ones (table 2).

According to the transmission model, cases younger than 20 years were more likely to infect others than cases older than 60 years (table 3). Sex and disease severity did not seem to have an appreciable impact on infectivity, although disease severity was statistically associated with onwards transmission in the transmission model (table 3). Clinically diagnosed cases were less infectious than laboratory-confirmed cases (table 3). The GEE and transmission models produced largely concordant results regarding infectivity across age groups, except that the GEE model identified primary cases younger than 20 years old as being less infectious than older ones, whereas the transmission model suggested the opposite (tables 2, 3). The GEE model also found individuals older than 80 years to be similar to those aged 60–79 years in terms of both infectivity and susceptibility to infection (table 2), and these two age groups were thus combined for transmission modelling.

Both models found infected individuals who remained asymptomatic during the whole infection course to be much less infectious than symptomatic cases. The GEE model estimated an OR of 0.34 (95% CI 0.21–0.54) for asymptomatic individuals versus patients with mild and moderate disease (table 2). The transmission model estimated an OR of 0.42 (0.17–1.04) for asymptomatic versus symptomatic individuals up to Feb 1, which decreased to 0.21 (0.14–0.31) afterwards (table 3). Asymptomatic

Untested contacts were treated as uninfected in the calculations. Secondary attack rates are not based on the transmission model. Odds ratios are calculated from a multivariable generalised estimating equation model. NA=not applicable. *Age was missing for 1027 contacts in 744 single-primary-case households; these households were excluded from the estimation of observed secondary attack rates by age group and from the multivariate generalised estimating equation model.

Table 2: Estimates of observed secondary attack rates among households with a single primary case

infections were formally required to be reported in Wuhan from Feb 1, which suggests greater ascertainment bias before Feb 1. For this reason, the estimated relative infectivity after Feb 1 is probably more accurate, implying that an asymptotically infected individual was associated with about 80% lower

Data are secondary attack rate (95% CI) or odds ratio (95% CI). Overall secondary attack rates, regardless of characteristics of the infector, infectee, or household, were estimated with a separate model with fewer covariates than the model used to estimate odds ratios (appendix p 30), as some covariates will change the interpretation of the secondary attack rate. Estimates of baseline daily transmission probabilities within households and from an external source, as well as estimates of daily transmission probabilities between different age groups within households, are shown in the appendix (pp 32–33). *Primary analysis.

Table 3: Model-based estimates of secondary attack rates and odds ratios reflecting covariate effects on susceptibility and infectivity

infectivity than a symptomatic case after symptom onset. When allowing infectivity to differ before and after symptom onset among symptomatic cases, the transmission model estimated the presymptomatic (incubation) period was more infectious than the symptomatic period (table 3).

When exploring how the effective household reproductive numbers changed over the pandemic periods, we found a decrease from 0.25 (95% CI 0.24–0.26) up to Feb 10 to 0.12 (0.10–0.13) after among primary cases, marking a 52% reduction (table 4). The reduction was more substantial for secondary cases, from around 0.17 (0.16–0.18) to 0.063 (0.057–0.070), a 63% reduction.

The model-estimated secondary attack rate was moderately sensitive to assumptions around incubation and infectious periods, varying from 10.4% (95% CI 10.1–10.7) to 17.1% (16.7–17.5), with larger estimates associated with a longer incubation period or a longer infectious period (table 3). An extension of the infectious period to 27 days (21 days after symptom onset) led to a further increase in the secondary attack rate estimate to 17.8% (17.4–18.2; appendix 2 p 34). This sensitivity results from the fact that how the transmission model allocates secondary infections between the external force of infection and infectious household members depends on the durations of the incubation and infectious periods. Data in parentheses are 95% CIs. Epidemic phases are defined by intervention policy (lockdown from Jan 23 to April 7, 2020, and tightened community management since Feb 11; panel). *Primary analysis.

Table 4: Estimates of effective household reproductive numbers for primary cases and secondary cases in different epidemic stages in 2020

risk factors are robust to varying assumptions about the natural history of disease (table 3). The estimated infectivity of asymptomatic infections versus symptomatic infections varied moderately (ORs 0.16–0.53) on or after Feb 2, whereas that of presymptomatic infections versus symptomatic infections varied more notably (ORs 0.76–2.92), between the extreme values for the incubation and infectious periods (table 3). When primary cases were defined as those with the earliest symptom onset or test-positive specimen collection date in their households (excluding the following day), the estimate of secondary attack rate increased slightly to 17.0% (16.6–17.4; appendix 2 p 35). Limiting analysis to the 15922 households with all contacts tested, which accounted for about 60% of all households, the estimates of risk factors' effects were qualitatively similar, but the estimated secondary attack rates increased—eg, to 20.6% (95% CI 20.0–21.2) under the assumption of a mean incubation period of 5 days and a maximum infectious period of 22 days—suggesting households with more secondary cases were more likely to have complete testing (appendix 2 p 36). When the effect of age on infectivity was stratified by household size, the higher infectivity of children than adults was mainly limited to households with more than three members (appendix 2 p 37). The transmission model provided satisfactory goodness-of-fit to the data, especially under the longer infectious period (appendix 2 p 22).

Discussion

We characterised the transmissibility of SARS-CoV-2 within households and associated risk factors in Wuhan, China, based on a large amount of household contact-tracing data available from early in the COVID-19 pandemic. Using a statistical transmission model, we found individuals older than 60 years were more likely to be infected than the younger population, especially those younger than 20 years. Additionally,

infants were more likely to be infected than older children. Once infected, children and adolescents were as likely as adults to develop symptoms, although much less likely to have severe disease. In addition, children and adolescents were more likely to infect others than were older age groups. Individuals with asymptomatic infection were less likely to infect others than were symptomatic cases. Symptomatic cases were more infectious during the incubation period than during the symptomatic period.

The estimated household secondary attack rate of SARS-CoV-2 in Wuhan is similar to that in Guangzhou (15.6% vs 15.5%) found by a previous study using comparable methods.⁴ Moreover, our observed household secondary attack rate in Wuhan (16.0%) was similar to that in Guangzhou (13.2%) and Shenzhen (14.9%), but lower than that in Beijing (23%) and Zhejiang province (31.6%).^{5,6,14,15} Secondary attack rate estimates in mainland China have tended to be higher than those for other locations—eg, 10.5% in the USA and 4.6% in Taiwan.^{16,17} The heterogeneity in household secondary attack rates across different regions is probably due to differences in control measures, surveillance practices, and crowdedness in households.

It has been reported that children are less, and elderly adults are more, prone to severe clinical outcomes from COVID-19,^{18,19} and several studies have found that older age groups are more likely to get infected.^{4,20,21} Similar to this study, a study in Bnei Brak, Israel, observed a higher risk of infection among infants aged 0–1 years than in older children.²⁰ A possible explanation for this finding is that infants have weaker innate immune systems and closer contact with parents than older children. We also found that SARS-CoV-2 was less likely to cause symptoms upon infection among young adults in their 20s and 30s, but its pathogenicity in children and adolescents was similar to that in adults aged 40 years or older. Similar levels of pathogenicity in children were noticed before in China and South Korea

based on a much smaller number of observations, but no comparison was made with other age groups in those studies.^{22,23}

Using the transmission model, we found that cases younger than 20 years were nearly 60% more likely to infect others than cases aged 60 years or older. This finding seems to contradict the observed secondary attack rates of the two groups and the GEE-based odds ratio estimates (table 2). The observed secondary attack rate and the GEE model did not account for individual-level exposure history and should be interpreted as unconditional results—ie, not adjusted for the amount of exposure. By contrast, the chain-binomial model evaluated how risk factors change transmission probability per daily exposure. In addition, GEE-based estimates did not consider tertiary transmissions from secondary cases to household contacts. We found children with SARS-CoV-2 infection, particularly those who were secondary cases, were more likely than adults to infect household members who were actually exposed to them during their infectious periods (appendix 2 pp 18–19, 29). This fact, together with the much faster isolation of child cases (appendix 2 p 38), which implied a short duration of exposure of contacts to infected children, supports the higher infectivity of children than adults suggested by the chain-binomial model. A survey during the early epidemic phase in Wuhan found higher contact frequency between the age groups 0–20 years and 30–50 years than between any other age groups, which could explain in part the higher infectivity of children.²⁴ The infectivity of children could be modified by other factors, which merits further investigation. For example, the higher infectivity of children than of adults was mainly limited to households with more than three members in our study. Moreover, a recent study in South Korea reported a high infection rate among household contacts of index cases aged 10–19 years but not among household contacts of younger index cases.²⁵

Using the transmission model on data available after Feb 1, we estimated that individuals with asymptomatic infections were about 80% less likely to infect others than symptomatic cases. While it has long been speculated that individuals with asymptomatic infection can transmit the disease, strong epidemiological evidence has been scarce, and a reliable assessment of the relative infectivity of asymptomatic infections versus symptomatic infections was lacking before this study.^{3,26,27} A study in Anhui province of China compared secondary attack rates among general contacts between 131 individuals with asymptomatic infections and 16 symptomatic cases, with an OR of 0.25.²⁸ All 16 symptomatic cases tested positive before symptom onset, implying the possibility of selection bias. A recent meta-analysis estimated household secondary attack rates to be 19.9% for

symptomatic index cases and 0.7% for asymptomatic ones, suggesting an OR of 0.028, which is much lower than our estimate of 0.21.³ Some modelling studies extrapolated the relative infectivity of asymptomatic or subclinical infections from viral load dynamics of mild and severe cases, and their results tended to be lower than our estimates.^{8,9}

Our results show the importance of isolating cases and quarantining household contacts outside of the home to prevent onwards transmission within households. During the period Jan 24–Feb 10, when many people with mild COVID-19 were isolated at home, the observed secondary attack rate and the model-estimated effective reproductive number within households remained essentially unchanged compared with before Jan 24 (tables 2, 4). When massive case isolation and quarantine of household contacts at designated places reached full coverage near mid-February, both the observed household secondary attack rate and household effective reproductive numbers were substantially reduced, consistent with a previous modelling study.²⁹ Such dramatic reduction in household transmissibility of the virus was mainly driven by the reduced number of days of exposure of household contacts to the cases due to the interventions (appendix 2 pp 21, 29). The daily transmission probability between an infectious case and an exposed household contact was, however, less affected by the interventions (table 3). More dramatic reduction in transmissibility for secondary cases than for primary cases was expected, as the household contacts were still exposed to primary cases during their incubation period before isolation or quarantine occurred (appendix 2 pp 21, 29).

Our study has several limitations. Although we have imputed asymptomatic infections among untested contacts in the early stage, bias cannot be ruled out as there was no protocol for laboratory testing and there could be unmeasured confounders not adjusted for in the imputation. Asymptomatic infections might still have been under-detected even after household contacts were universally tested. The overall proportion of asymptomatic infections after Feb 22 was 16%, somewhat lower than the 18% or 32% observed (depending on whether abnormal lung CT is counted as a clinical sign) in the outbreak on the *Diamond Princess* cruise.^{30,31} The GEE analysis was applied only to households with a single primary case, but these households tended to have more secondary cases aged 60 years or older (appendix 2 p 39), which might affect the generalisability of the GEE results. In addition, our data do not offer strong evidence in favour of any particular scenario of the incubation and infectious periods, and the variation in results across the different assumptions should be considered as part of the uncertainty in these estimates. Finally, we merged epidemiologically linked households, but the mixing

pattern between these households could be more complex than what was assumed.

Our study has implications for forecasting and control of the global pandemic of SARS-CoV-2. Differential susceptibility and infectivity between age groups, as well as other epidemiological parameters estimated in this study, are key inputs for modelling studies projecting the future trajectory of the pandemic. The relatively high infectivity of children in households should be considered carefully when making decisions around school reopenings, as infected children can pass the virus to their family members. Finally, given the vulnerability of infants to infection, their caregivers should be prioritised for vaccination.

Contributors

FL, X-BY, H-JW, P-LL, Y-HP, Y-QY, SL, and GL contributed to the epidemiological investigation and collected the data. YY, S-QX, and Y-YL conceived the statistical analysis plan. M-JL, Y-YL, FL, L-QF, and QL accessed, verified, and analysed data under the supervision of YY and S-QX. Y-YL and YY drafted the manuscript. All authors contributed to interpretation of results and critical revision.

Accepted 25 February 2016.

Background To prepare for a possible influenza pandemic, a better understanding of the potential for the airborne transmission of influenza from person to person is needed.

Objectives The objective of this study was to directly compare the generation of aerosol particles containing viable influenza virus during coughs and exhalations.

Methods Sixty-one adult volunteer outpatients with influenza-like symptoms were asked to cough and exhale three times into a spirometer. Aerosol particles produced during coughing and exhalation were collected into liquid media using aerosol samplers. The samples were tested for the presence of viable influenza virus using a viral replication assay (VRA).

Results Fifty-three test subjects tested positive for influenza A virus. Of these, 28 (53%) produced aerosol particles containing viable influenza A virus during coughing, and 22 (42%) produced aerosols with viable virus during exhalation. Thirteen subjects had

both cough aerosol and exhalation aerosol samples that contained viable virus, 15 had positive cough aerosol samples but negative exhalation samples, and 9 had positive exhalation samples but negative cough samples.

Conclusions Viable influenza A virus was detected more often in cough aerosol particles than in exhalation aerosol particles, but the difference was not large. Because individuals breathe much more often than they cough, these results suggest that breathing may generate more airborne infectious material than coughing over time. However, both respiratory activities could be important in airborne influenza transmission. Our results are also consistent with the theory that much of the aerosol containing viable influenza originates deep in the lungs.

Keywords Aerosols, air microbiology, airborne transmission, cough, infectious disease transmission, influenza.

Introduction

During an influenza pandemic, measures to stop the transmission of influenza virus will be a critical part of the public health response. Although influenza is known to be transmitted through respiratory secretions containing the virus, infectious material can be passed from person to person in many different ways. The relative importance of the different pathways is uncertain and probably varies depending upon the setting, the severity of the illness, the characteristics of the viral strain, environmental conditions, and other factors.⁽¹⁾ In order to choose the appropriate interventions to block the spread of the virus, it is necessary

to understand which routes of transmission occur and when they are likely to be important.

The role of airborne transmission in the spread of influenza has been a question of particular concern to the public health community while planning for a possible pandemic.^(2,3) If patients can readily infect others via aerosols (small airborne particles) produced during coughing, speaking, sneezing, and breathing, then interventions such as patient isolation and cohorting, increased air ventilation and filtration, air disinfection, and the use of respirators or other personal protective equipment may help to protect health-care workers and other patients from the illness. On the other hand, such interventions can be costly and time-consuming

and would place additional burdens on healthcare systems when they are already under considerable strain during a pandemic. Because of these issues, organizations such as the Institute of Medicine and the World Health Organization have called for more research to provide a better understanding of influenza transmission, especially airborne transmission.^(3,4)

Several reports have provided support for the idea that airborne influenza transmission can occur.^(5–8) Influenza virus RNA has been detected in respirable airborne particles collected in healthcare facilities and other locations.^(9–16) Influenza virus RNA also has been found in aerosol particles collected directly from infected patients while they were coughing and breathing.^(17–23) Six studies have demonstrated that influenza patients expel airborne particles containing viable virus.^(13,18,19,21,24,25) Pantelic *et al.* found that subjects with influenza emitted up to 1000 viable influenza virions over 30 minutes during normal tidal breathing.⁽²⁵⁾ Lindsley *et al.* detected viable influenza A virus in airborne particles produced during coughing by 7 of 17 influenza patients (41%).⁽²⁴⁾ However, even with these reports, the likelihood of airborne transmission is still unclear, in part because many questions remain about the production of aerosols carrying infectious influenza during respiratory activities. For example, no studies have compared the production of virus-laden airborne particles between different types of respiratory activities, such as coughing and exhalation. This is an important question, because the airflow dynamics of coughs and exhalations are very different. Coughing produces a high-velocity jet that can propel a plume of aerosol particles long distances, which disperses the airborne particles widely.⁽²⁶⁾ Exhalations have much lower velocities and are likely to produce higher particle concentrations in the immediate vicinity of a patient and lower concentrations further away. Exhalations are also more common than coughs, which could affect the amount of infectious aerosol that is generated. These differences could have a significant impact on disease transmission and on the choice of interventions.

A comparison of infectious particle production during coughing and exhaling also would provide clues as to the sites of origin of influenza-laden particles from within the respiratory tract. Humans produce more aerosol particles when they cough vs. when they exhale.^(27,28) Most of the aerosol particles produced during normal breathing are thought to originate deep in the respiratory tract, while coughing may produce aerosol both from the lower airways and also from the upper airways.^(29–31) Thus, if coughing produces much more infectious aerosol than exhaling, this would suggest that much of the virus in cough-generated particles may be coming from the upper airways. Conversely, if the production of infectious aerosol particles during coughing and exhaling is similar, then that would suggest

that much of the virus-laden aerosol is originating in the bronchioles and alveoli.

The purpose of this study was to directly compare the production of aerosol particles containing viable influenza virus by infected people during coughs and exhalations. Greater knowledge about the generation of infectious aerosol particles during different respiratory maneuvers will help to better understand the likelihood and dynamics of the possible modes of influenza transmission in different scenarios and will assist in the selection and evaluation of interventions to prevent the spread of disease.

Methods

All procedures involving human subjects were reviewed and approved by the National Institute for Occupational Safety and Health (NIOSH) and West Virginia University (WVU) Institutional Review Boards. Written informed consent was obtained from all study participants.

Aerosol particle collection system

Cough- and exhalation-generated aerosols were collected using an aerosol particle collection system (Figure 1) similar to that described previously.⁽²⁴⁾ An ultrasonic spirometer (Easy One, NDD Medical Technologies) measured the volume and flow rate of each cough, and a modified 10-liter piston-style mechanical spirometer (SensorMedics model 762609) served as an accumulation chamber for the cough and exhalation aerosols. Aerosol particles were collected using an SKC BioSampler with a 5-ml vessel (#225-9593, SKC) containing 5 ml of viral transport media (VTM) consisting of Hank's balanced salt solution (HBSS;

Figure 1. Collection system for airborne particles produced by subjects during coughing and exhalation. Before each respiratory activity, the piston spirometer was purged and partially filled with 4 liters of dry filtered air. The subject then sealed their mouth around the mouthpiece and coughed or exhaled as instructed. The cough or exhalation traveled through the ultrasonic spirometer, which measured the volume and flow rate, and then into the piston spirometer. When the subject was finished, the valve was closed and the SKC BioSampler was used to collect the aerosol particles produced by the subject.

Invitrogen) supplemented with 0.1% bovine serum albumin (BSA; Sigma-Aldrich), 100 units/ml penicillin G, and 100 units/ml streptomycin (Invitrogen). The particle collection efficiency for the SKC BioSampler (i.e., the percentage of particles of a given size that are collected by the sampler) is approximately 10% for particles with aerodynamic diameters of 0.1 μm ; 50% for 0.3 μm particles; 96% for 1 μm particles; 100% for 2 μm particles; and 50% for 8 μm particles.^(32–34) Particles larger than 10–15 μm are expected to be removed by the sampler elbow and not collected.

Sample collection procedure

Potential test subjects presenting with influenza-like symptoms at an outpatient clinic were recruited after they had been seen by their healthcare provider. Potential participants were excluded from the study if they reported respiratory illnesses such as severe asthma, chronic obstructive pulmonary disease, or tuberculosis; serious illnesses such as diabetes or heart disease; pregnancy; or any condition that would make it difficult or uncomfortable to inhale deeply and cough and exhale forcefully. After the study was explained to the test subject and informed consent was obtained, two nasopharyngeal swabs and an oropharyngeal swab were taken from the subject and placed in 3 ml of VTM (these will be referred to as NOP swabs). The subject's oral temperature was measured and a brief health questionnaire was administered. The subject was then asked to sit in front of the aerosol collection system. The subject was instructed to inhale as deeply as possible, seal their mouth around the mouthpiece, and cough into the machine using as much of the air in their lungs as possible. After each cough, the cough-generated aerosol was collected using the aerosol sampler. This procedure was repeated for a total of three coughs from each subject. Next, the subject was asked to repeat the procedure but to exhale as much and as rapidly as possible rather than coughing. This was also repeated three times, and the exhalation-generated aerosol was collected after each exhalation using the aerosol sampler. The order of the coughing and exhalation was alternated so that odd-numbered subjects were asked to cough three times followed by three exhalations, while even-numbered subjects were asked to exhale three times followed by three coughs. To prevent cross-contamination, the collection system was purged three times with clean dry air after each cough or exhalation, and a new mouthpiece was used for each subject. After the coughs or exhalations were completed, the VTM were removed from the SKC BioSampler and placed in a storage tube. All samples in VTM were kept on ice until the end of the day and then transported to the laboratory and stored at -80°C until analysis. Each subject was only asked to perform one test session.

Viral replication assay (VRA)

In previous studies of cough and exhalation aerosols by our group and others, the largest problem has been detecting the small amounts of viable virus present in these aerosol samples.^(13,18,19,21,24) In this study, a viral replication assay (VRA) was used to determine whether viable influenza virus was present in the samples that were collected.⁽³⁵⁾ The VRA is more sensitive and easier to use with small sample quantities than a traditional viral plaque assay or tissue culture infectious dose assay.⁽³⁵⁾ In experiments with aerosols containing viable influenza virus, the VRA amplified the amount of infectious virus in the samples by a factor of 4.6×10^5 .⁽³⁵⁾

Detection of viable influenza virus in NOP swab samples

For the NOP swab samples, Madin Darby canine kidney (MDCK) cells (CCL-34) were plated at a density of 5.0×10^4 per well in a 96-well plate (CoStar 96-well tissue culture plate, Corning). Triplicate wells were treated with 100 μl of each sample for 45 minutes. The wells were washed by adding 100 μl of phosphate-buffered saline (PBS) ml to the inoculum and removing the resulting supernatant. The cells were overlaid with 100 μl supplemented Dulbecco's modified Eagle's medium (DMEM)/F12 and incubated for 20 hours at 35°C in a humidified 5% CO_2 incubator to allow for viral replication. Total RNA was isolated from the cells and supernatant with the MagMaxTM-96 Total RNA Isolation Kit (Ambion) and transcribed into cDNA using the High Capacity cDNA Reverse Transcription Kit (Life Technologies). A 5 μl cDNA volume was analyzed using quantitative PCR (qPCR) with a custom primer/probe set specific for the matrix (M1) gene or the H3 hemagglutinin gene of influenza A virus. Details about the primers and probes are provided in the online supporting information.

Detection of viable influenza virus in cough and exhalation aerosol samples

For the cough and exhalation aerosol samples, a 6-well formatted VRA assay was used to increase the sensitivity for detecting influenza virus in the aerosol samples. MDCK cells plated at a density of 1.5×10^6 per well (CoStar 6-well tissue culture plate, Corning) were incubated at 35°C in a humidified 5% CO_2 incubator overnight. For each sample, duplicate wells with confluent cellular monolayers were next washed two times with 2 ml PBS (Invitrogen) and treated with a 1.2 ml sample volume for 45 minutes. The wells were washed by adding 1.2 ml of PBS to the inoculum and removing the resulting supernatant. One ml of supplemented Dulbecco's modified Eagle's medium (DMEM)/F12 containing 100 units/ml penicillin G/100 $\mu\text{g}/\text{ml}$ streptomycin (Invitrogen), 2 mM L-glutamine (Invitrogen), 0.2% BSA

(Sigma-Aldrich), 10 mM HEPES (Invitrogen), 0.22% sodium bicarbonate (Invitrogen), 0.01% DEAE-dextran (MP BioMedicals, LLC, Solon, OH), and 2 µg/ml N-p-tosyl-L-phenylalanine chloromethyl ketone (TPCK) (Sigma-Aldrich) was added to each well. Treated MDCK cells were subsequently incubated for 20 hours at 35°C in a humidified 5% CO₂ incubator to allow for viral replication. The treated cellular monolayer was lysed with 1 ml of MagMax™ Lysis/Binding Solution Concentrate (Ambion) and the lysate was pooled with the reserved culture supernatant (final volume of ~2 ml) and stored at -80°C until total RNA was isolated.

To account for the larger sample volume in the 6-well formatted VRA, total RNA was isolated using a modified MagMax™-96 Total RNA Isolation Kit (Ambion) protocol. A 1 ml volume of molecular-grade 2-propanol (Sigma) was mixed by inversion into each thawed, pooled sample followed by the addition of 20 µl prepared Bead Mix (Thermo Scientific). Samples were then gently shaken for 5 minutes and magnetically captured. The supernatant was discarded and the resulting RNA-bound bead pellet was resuspended in 150 µl Wash Solution 1 and transferred to a 96-well processing plate. The manufacturer's instructions were followed for the remainder of the total RNA isolation procedure. Total RNA was eluted with 30 µl of elution buffer and transcribed into cDNA using the High Capacity cDNA Reverse Transcription Kit (Life Technologies). A 5 µl cDNA volume was analyzed for the M1 gene using qPCR.

Data analysis

During the qPCR assay portion of the VRA, the samples were subjected to 45 PCR amplification cycles. The limit of quantitation (LOQ) of the qPCR assay was 15 viral copies per PCR tube, which corresponded to a threshold cycle (C_t) value of 34.1. The limit of detection (LOD) based on qPCR only was 10 viral copies per tube, which corresponded to a threshold cycle (C_t) value of 35.8. In cases where a PCR product was detected but the C_t value was higher than the C_t value for the LOQ, then the PCR product was evaluated by agarose gel electrophoresis to verify that the PCR product was the correct size (101 base pairs for the M1 matrix gene). Sample volumes of 10 µl were loaded into a 4.5% agarose gel (Nusieve GTG Agarose, Lonza) along with 10 µl of a 100-bp DNA ladder (N3231L, New England Biolabs). Electrophoresis was carried out in 1X TAE at 90 volts for approximately 90 minutes. DNA was visualized by ethidium bromide staining. The LOD with this additional step was as little as 1 viral copy per reaction tube. For additional verification, DNA sequence analysis was performed on randomly chosen cough and exhale samples by a commercial laboratory (Genewiz, Inc.) using pre-defined Sanger DNA sequencing.

Because of the low concentration of influenza virus in the cough and exhalation aerosol samples, in many cases the amount of virus detected using the qPCR assay was below the

limit of quantitation for the assay. For this reason, the results are reported here only as positive or negative for influenza A. To reduce the possibility of false-positive results, only test subjects who had NOP swabs that were positive for influenza by the M1 and H3 gene assays were considered to be confirmed to have an influenza infection and were used in the data analysis.

When analyzing the experimental data, a sample was considered to be positive for influenza if a PCR product was detected in one or more of the qPCRs and the product was confirmed to be the correct size by gel electrophoresis. For example, each cough or exhalation aerosol sample was tested by inoculating and incubating two culture wells of MDCK cells, isolating and reverse transcribing the RNA produced by the cells in each well, and conducting duplicate qPCR assays for each well. Because of the low amounts of viable influenza found in the cough and exhalation aerosols, many of the qPCRs had C_t values that were close to the maximum limit of 45 cycles for the qPCR assay. For this reason, if any one of the four qPCRs yielded a PCR product of the correct size, then that sample was considered influenza positive even if no PCR product was detected in the other three reactions. The full results from the qPCR assays are presented in the supporting information with the online version of this article.

Statistical analyses included comparison of proportion of positive coughs and exhalations using McNemar's test for paired dichotomous data.⁽³⁶⁾ The chi-square test was performed to test for differences in positive cough and exhalation proportions between the two orders of testing (cough then exhalation vs. exhalation then cough). All tests were two-tailed and performed using a 0.05 significance level.

Results

For this study, 61 adult volunteer subjects were recruited from college students presenting with influenza-like symptoms at WVU Medicine Student Health Services in Morgantown, West Virginia, USA, during January and February in 2015. A summary of the demographic information, oral temperatures, cough volume, cough peak flow rate, and symptoms reported by the test subjects in which viable influenza A virus was detected is shown in Table 1.

Nasopharyngeal and oropharyngeal (NOP) swabs were tested for viable influenza A virus using the viral replication assay (VRA) with qPCR assays for the M1 matrix gene. Fifty-three NOP swab samples (87%) were positive for viable influenza A. The H3-type hemagglutinin gene was detected in all 53 samples, consistent with the prevalence of H3N2 influenza A in the United States during the 2014-2015 influenza season. Only test subjects with influenza-positive NOP swabs were considered to be confirmed to be infected with influenza and were used in the data analysis.

Table 1. Demographic and medical information for study participants confirmed to be infected with influenza. Information for all of the patients is included in the online supporting information

# Of subjects	53	
Gender	30 Male, 23 Female	
	Mean	SD
Age (years)	21.0	3.4
Height (cm)	172	10
Weight (kg)	76.6	20.0
Temperature (°C)	37.4	0.7
# of days of symptoms	2.2	2.1
Cough volume (liters)	2.7	1.1
Peak flow rate during coughs (liters/second)	7.5	2.2
Exhalation volume (liters)	3.5	1.0
Peak flow rate during exhalation (liters/second)	4.8	2.1
Number of subjects reporting		
Fever/chills	43	
Headache	40	
Fatigue	43	
Cough	44	
Sore throat	41	
Sinus congestion	32	
Runny nose	37	
Sneezing	28	
Muscle aches	43	
Took medication for symptoms	27 yes, 26 no	
Received influenza vaccine within last 6 months	6 yes, 43 no, 4 unsure	

Viable influenza A virus was found in cough aerosol samples from 28 of 53 subjects and in exhalation aerosol samples from 22 of 52 subjects confirmed to have influenza (one exhalation aerosol sample was lost before analysis). The difference in the number of influenza-positive coughs vs. influenza-positive exhalations was not statistically significant ($P = 0.2207$). 37 subjects had influenza-positive NOP swabs and influenza-positive cough or exhalation aerosols, while for 15 subjects, influenza was detected in the NOP swabs but not in the cough or exhalation aerosols. Thirteen subjects had both cough aerosol and exhalation aerosol samples that contained viable influenza A virus, 15 had positive cough aerosol samples but negative exhalation samples, 9 had positive exhalation samples but negative cough samples, and 15 had negative cough and exhalation samples. The order in which the experiment was performed (coughs followed by exhalations, or exhalations followed by coughs) did not have a significant effect on the results ($P = 0.2499$). The influenza results for all test subjects are shown in Table 2.

To confirm that the qPCRs in the VRA were amplifying influenza virus, the size of the PCR products were verified by agarose gel electrophoresis. An example electrophoretic gel is

shown in Figure 2. A total of 484 qPCRs were performed to analyze the cough and exhalation aerosol samples from the 61 subjects. Of these, a matrix gene PCR product was detected in 89 reactions. In 79 reactions (89%), gel electrophoresis of the PCR product produced a 101-base pair band, indicating the presence of influenza A. In the remaining 192 PCRs, a PCR product was not detected and no

Figure 2. Electrophoretic gel used to determine the presence or absence of a 101-base pair PCR product corresponding to the influenza A M1 matrix gene. The PCR products for the NOP swabs, cough aerosols, and exhalation aerosols for three test subjects are shown. (+) indicates the sample is positive for influenza A. (—) indicates the sample is negative. The PCR products for the cough and exhalation samples for subject FC178 were confirmed to be from the influenza A M1 matrix gene by DNA sequence analysis. The negative control contained all PCR reagents, primers, and probe but no template. The positive control contained 10^4 M1 copies and was run in parallel with the experimental samples.

101-base pair bands were observed. The PCR products from 12 H3 gene analyses of the NOP swabs also were tested and found to be of the correct size (150 base pairs). As additional verification, the VRA M1 gene PCR products from 7 cough aerosol samples and 9 exhalation aerosol samples were sent to a commercial laboratory for sequence analysis. All 7 of the cough aerosol PCR products and 7 of the 9 exhalation aerosol PCR products were confirmed to match the matrix gene segment M1 from influenza A. Two of the exhalation aerosol PCR products could not be sequenced.

Discussion

Humans infected with influenza virus have been shown to expel small airborne particles containing viable virus into the environment when they cough or exhale, which suggests that the potential exists for the airborne transmission of influenza.^(13,18,19,21,24) However, it is not clear how often airborne transmission actually occurs or what factors affect the likelihood of transmission by the airborne route, in part because many questions remain about the processes involved in infectious aerosol production and the dynamics of these aerosols in the environment. Consistent with previous studies, our results show that aerosol particles containing viable influenza virus are produced by infected individuals both during coughing and during exhalation. Viable virus was detected more often in cough aerosol samples (53% of influenza-positive subjects) compared to exhalation aerosols (42% of influenza-positive subjects). However, this difference is not substantial and was not statistically significant. As people breathe constantly but cough sporadically, this suggests that patients infected with influenza may release more virus into the air over time in small airborne particles by breathing compared to coughing. On the other hand, as coughing involves much higher air velocities than breathing, coughing may spread the virus further in a given location. Thus, both mechanisms for producing infectious aerosols may be important depending upon such factors as the distance from a patient, the timescale, the infectious dose, and the air flow within a room.

Viable influenza virus was detected in the cough aerosol, exhalation aerosol, or both from 37 of 53 influenza-positive test subjects (70%), which suggests that this is a common phenomenon. It should be noted that the aerosol collection system used in these experiments does not capture particles larger than 10–15 μm in the collection media, and thus collects only small particles capable of airborne transmission and not the “large droplets” often referenced in droplet disease transmission. Viable influenza was detected in both the cough and exhalation aerosols for 35% of these subjects (13/37), while it was only detected in the cough aerosol for 41% (15/37) and only in the exhalation aerosol for 24% (9/37). These results are consistent with somewhat more

infectious aerosol being released during coughing than breathing, although they probably also reflect the fact that the airborne viable virus concentrations are quite low and are difficult to detect.

Two patients had influenza-positive cough aerosols but negative NOP swabs, while one had a positive exhalation aerosol but a negative NOP swab. One possible explanation is that, because some patients did not tolerate the nasopharyngeal swabs well, the sample obtained may not have been sufficient for detection of influenza. Alternatively, Milton *et al.*⁽¹⁹⁾ reported that the amount of influenza RNA detected in NOP swabs was only weakly correlated with the amount detected in exhaled breath; thus, it may be that these three patients had sufficient influenza virus in their lower respiratory tract to produce infectious aerosol particles but insufficient virus in their nasopharyngeal region to be detected. Finally, the possibility of a false-positive cough or breath sample or a false-negative NOP swab result cannot be excluded. For consistency and to reduce the possibility of false-positive results, only patients with positive NOP swabs were considered to be confirmed to be infected with influenza and included in our analysis.

Because of the low concentrations of airborne viable influenza virus in the cough and exhalation aerosol samples, we were not able to quantify the amount of airborne viable virus present in the original samples in our experiments. However, this should not be interpreted to mean that the risk of infection is low. Our samples were collected from only three coughs and three exhalations, while a person infected with influenza would be expected to cough dozens of times and breathe hundreds of times per hour and thus could still release a considerable amount of airborne infectious material over the course of a day. In addition, the infectious dose for airborne influenza is very low; one study found that inhalation of small aerosol particles containing only 0.7 to 3.5 plaque-forming units (PFU) of influenza was sufficient to cause seroconversion in 50% of the human subjects tested.⁽³⁷⁾

The fact that the number of aerosol samples with viable influenza was not significantly greater for coughing than for exhalation is consistent with the theory that a substantial portion of the influenza-laden aerosol produced by infected people originates in the deepest parts of the lungs rather than in the upper airways and oropharyngeal region. Smaller aerosol particles have been proposed to be produced in the alveolar and bronchial regions during both breathing and coughing by the formation and rupture of menisci as airways contract and expand. Larger particles are thought to be created by shear forces acting on fluid-covered upper airways, where air velocities are much higher than in the deeper regions. This phenomenon is thought to occur primarily during coughing because the air flow rates are much higher than during breathing.^(29–31) Since, in this

theory, deep lung particle generation occurs during both breathing and coughing while upper airway particle generation occurs only during coughing, then the modest increase in the number of positive samples seen during coughing compared to exhalation in our experiments supports the idea that much of the infectious aerosol is originating in the deep lung regions.

The ability of our system to collect cough and exhalation aerosols separately was useful for the present study, but it also significantly limited the study because of the small amount of aerosol that was collected. By comparison, the system used by Milton *et al.* collects aerosols produced by natural coughs and exhalations over a 30-minute period, and that group has reported greater success in detecting and quantifying airborne influenza virus.^(19,25,38) Thus, our results suggest that future work studying infectious aerosol production and the presence of infectious aerosols in the environment should collect sample volumes that are as large as practically possible, which would likely entail using high sample flow rates and long sample times. Unfortunately, however, maintaining high flow rates and long sample times while attempting to collect airborne viruses and maintain their viability is very challenging, especially when the viruses are contained in submicrometer aerosol particles.

Finally, it is important to acknowledge the limitations of our experiments. First, the single most difficult aspect of studying the production of aerosols containing viable influenza virus during respiratory activities is the low concentration of such viruses in the air and the difficulty in collecting enough material and maintaining viability to detect the viable virus. To maximize the sensitivity of our assays and reduce the possibility of false-negative results as much as possible, the evaluation criteria for our results were designed to provide the greatest likelihood of detecting small amounts of viable influenza virus, with steps then taken to minimize the possibility of false-positive results. However, we recognize that the possibility of some false-positive outcomes cannot be ruled out in our analysis.

Second, our test subjects were asked to inhale as deeply as possible and then cough or exhale using as much of the air in their lungs as possible. Most natural coughs and normal tidal breathing use smaller fractions of the total lung capacity, which may reduce aerosol generation. On the other hand, natural coughs are stimulated by a need to clear secretions from the airways, and thus, natural coughs may produce more aerosol particles than forced coughs. It is also possible that the ratio of the amount influenza-laden aerosol particles produced during natural coughing to that produced during natural breathing may be different than the ratio we found when comparing forced coughs to forced exhalations.

Third, the particle collection efficiency of the SKC BioSampler decreases from about 96% for 1 μm aerosol particles to about 50% for 0.3 μm particles and 10% for

0.1 μm particles.^(32–34) Thus, many of the smallest particles carrying influenza virus may not have been collected in our experiments. As noted earlier, particles larger than 10–15 μm were not collected and thus their potential contribution to disease transmission is not known. In addition, some cough aerosol particles may have deposited inside the system before they could be collected. In our previous study using the cough aerosol collection system,⁽²⁴⁾ swab samples from the face of the spirometer piston and the BioSampler elbow found little influenza, suggesting that particle losses in these locations were minimal. However, other parts of the system, such as the mouthpiece, were not tested.

Last, influenza viral shedding peaks around the first day of acute respiratory illness and then declines rapidly.^(19,21,39–41) In our study, patients presented at the clinic an average of two days after their symptoms developed (Table 1), well after the expected maximum in viral shedding. In addition, our test subjects were college-aged ambulatory outpatients with no other reported respiratory illnesses or significant health conditions. Patients who are more severely ill would generally be expected to have higher viral loads and may be more likely to produce cough and exhalation aerosols containing infectious influenza virus, especially in the early stages of illness.^(40,42) Patients who are younger or older, immunocompromised, or have underlying pulmonary illness such as asthma or chronic obstructive pulmonary disease also may have very different infectious aerosol generation patterns. This could be an important factor during an influenza pandemic, when healthcare facilities would be expected to receive large numbers of severely ill patients.

Conclusions

The purpose of this study was to directly compare the expulsion of aerosol particles containing potentially infectious influenza virus during coughing and exhalation. Our results confirm that the production of aerosols containing viable influenza virus is common among infected people. Viable virus was detected more often in cough aerosols than in exhalation aerosols, but the difference was not large. As individuals breathe more often than they cough, these results suggest that breathing may generate more airborne infectious material than coughing over time. However, both respiratory activities could be important in airborne influenza transmission. Our results are also consistent with the theory that much of the aerosol containing viable influenza originates deep in the lungs, although more direct investigation would be needed to verify this.

ABSTRACT

Few studies have focused on the transmission efficiency of asymptomatic carriers of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection. Our follow-up study was performed on 147 asymptomatic carriers in Anhui Province. Of these, 50.0% were male, 50.3% were older than 40 years, 43.8% were farmers, and 68.7% were from the north of Anhui Province. 16 of the 147 asymptomatic carriers developed symptoms in the following 14 days of isolated observation, and were subsequently diagnosed as confirmed cases. The possible latent infection period was found to range from 1–5 days before onset, with a median time of 2 days. The second attack rate for the 16 confirmed cases who had transferred from being asymptomatic carriers was 9.7% (23/236 close contacts), while for the 131 asymptomatic carriers the rate was 2.6% (24/914 close contacts), showing a significant difference in second attack rate between the two groups ($p < 0.001$). Our study indicated that COVID-19 cases are contagious during the incubation period, and that close contact screening should be extended to include the incubation period. Our results also showed that the transmission efficiency for asymptomatic carriers was lower than that for confirmed case.

Introduction

COVID-19 is a novel infectious disease caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). This disease mainly affects the lung, but can also cause damage to the intestinal tract, liver, and nervous system, with corresponding symptoms (Lu et al., 2020). The outbreak originated in Wuhan city, Hubei Province in December 2019, and quickly spread to provinces and cities across the country and aboard (Li et al., 2020; WHO, 2020; Zhu et al., 2019). As of 28 August, 2020, there were 85 022 confirmed cases in China, including 4634 deaths and 80 126 recovered cases (China NHCotPsRo, 2020a). Human-to-human transmission of SARS-CoV-2 had been demonstrated mainly through respiratory droplets and contact (Chan et al., 2020). The continuing challenges of the epidemic and research progress in China have led to emergency responses from the Chinese government, including the issuance of regulatory documents (China NHCotPsRo, 2020b; China NHCotPsRo, 2020c).

Clinical symptoms of SARS-CoV-2 infection include fever, cough, and fatigue, and in a few cases stuffy nose, runny nose, and diarrhea (China NHCotPsRo, 2020b). Severe cases result in acute respiratory distress syndrome, septic shock, and coagulopathy caused death (Huang et al., 2020). As a highly contagious infectious disease, its sources of infection include not only confirmed cases, but also asymptomatic carriers (Huang et al., 2020; Cohen, 2020). Asymptomatic carriers of SARS-CoV-2 infection are always without clinical symptoms, but positive for the viral nucleic acid test. Most are found during the screening of close contacts, and because the laboratory tests are performed at an early stage, some asymptomatic cases go on to develop illness after screening.

For this study, we conducted a follow-up study on asymptomatic carriers in Anhui Province, and analyzed the features of these infections. Our findings provide evidence for the need to modify the preventive measures.

Materials and methods

Study design

This was a follow-up study, conducted in Anhui Province, China.

Study cases

147 asymptomatic carriers of SARS-CoV-2 infection were recruited for this study from Anhui Province. All asymptomatic carriers fulfilled the following criteria: (1) without symptoms of fever, cough, and fatigue; (2) no radiographic evidence of pneumonia; (3) with normal white cell count and normal lymphocyte count; and (4) positive nucleic acid test for SARS-CoV-2.

Data collection

A questionnaire was formulated to gather data on: (1) demographic information, such as name, age, gender, and occupation; (2) clinical symptoms, including fever, chill, cough, and fatigue if these developed during the 14-day observation period; (3) laboratory testing related to SARS-CoV-2 infection, including nucleic test result and timing of test; (4) close contact information, such as numbers, confirmed cases, and asymptomatic carriers.

Laboratory testing

Respiratory samples, including sputum and throat swab samples, were collected from all asymptomatic carriers by trained inspection personnel. Viral RNA was extracted using a TANBead nucleic acid kit (Taiwan Advanced Nanotech Inc, Taiwan, China) in a biosafety level-2 laboratory. Tests for the *ORF1ab* and *N* genes in respiratory samples were carried out using a 2019-nCoV dual fluorescent PCR kit (Shanghai BioGerm Medical Biotechnology Co., Ltd, Shanghai, China and DAAN Gene Co., Ltd, Sun Yat-sen University, Guangdong, China).

Statistical analysis

Microsoft Office software (version 2019) was employed to input and check the data, and SPSS software (version 11.0) was used to analyze the data. Categorical variables were summarized as frequencies and percentages, and continuous variables were described using medians. The frequencies of categorical variables were compared using the chi-square test, as appropriate. Tests with a *p*-value less than 0.05 were considered statistically significant.

Ethical statement

Collection of data and samples from patients was part of a routine surveillance and outbreak investigation, and was therefore

exempt from assessment by the institutional review board (IRB). The IRB of Anhui Provincial Center for Disease Control and Prevention reviewed the study.

Results

Demographic features

Table 1 shows the demographic features of the 147 asymptomatic carriers. Of these, 15.6% (23/147) were under 20 years old, and 64.6% (95/147) were aged 20–59 years. 51.7% (76/147) of the carriers were male, and 94.6% (139/147) were found by close contact screening. A total of 16 asymptomatic carriers developed symptoms during the following 14-day observation period.

Latent infectivity assessment

The results of our latent infectivity assessment are shown in Figure 1. The latent infectivity period was evaluated using the 16 confirmed cases who had transferred from being asymptomatic carriers. Two cases had tested positive 5 days before developing symptoms, one case 4 days before, three cases 3 days before, seven cases 2 days before, and three cases just 1 day prior to becoming ill. The median period was calculated as 2 days (range 1–5).

Transmission efficiency assessment

A comparison of second attack rates for asymptomatic carriers and confirmed cases is shown in Table 1. A total of 1150 close contacts was determined in relation to the 147 asymptomatic carriers. 47 close contacts tested positive for SARS-CoV-2 infection during the 14-day observation period. The 16 confirmed cases who had previously been asymptomatic accounted for 236 close contacts, with a second attack rate of 9.7%, while the remaining 131 asymptomatic carriers accounted for 914 close contacts, with a second attack rate of 2.6%. There was a significant difference between two groups (χ^2 (Li et al., 2020) = 24.257; $p < 0.001$).

Discussion

Asymptomatic infection, as part of the SARS-CoV-2 infection spectrum, has been reported in a previous study (Chan et al., 2020). An asymptomatic carrier is defined as someone with a positive SARS-CoV-2 test from respiratory samples, including sputum and throat swab, but who displays no symptoms. Some

Table 1
Demographic features and transmission efficiency assessment for asymptomatic carriers of SARS-CoV-2 infection.

Variables	n (%)			p-value
	All carriers (n = 147)	Asymptomatic carriers (n = 131)	Confirmed cases transferred from asymptomatic carriers (n = 16)	
Age				0.195
< 20 years old	23 (15.6)	23 (17.6)	0 (0.0)	
20–39 years old	50 (34.0)	43 (32.8)	7 (43.8)	
40–59 years old	45 (30.6)	41 (31.3)	4 (25.0)	
≥ 60 years old	29 (19.7)	24 (18.3)	5 (31.2)	
Gender				0.500
Male	76 (51.7)	69 (52.7)	7 (43.8)	
Female	71 (48.3)	62 (47.3)	9 (56.2)

Figure 1. Assessment of latent infectivity, based on 16 confirmed cases who had transferred from being asymptomatic carriers.

studies have examined asymptomatic carriers and analyzed the incubation period (Pan et al., 2020; Wang et al., 2020). However, none has been conducted on the assessment of transmission efficiency and latent infection period with regards to asymptomatic infection. We performed this follow-up study in Anhui Province to examine these topics. Our findings could provide evidence to support the revision of control measures for SARS-CoV-2 infection.

Asymptomatic carriers can be identified in four ways. First, and most important, is active detection among close contacts. The second is based on epidemiological investigations surrounding suspected or confirmed cases. The third involves looking at the exposed population identified by tracking the SARS-CoV-2 infection source. Finally, asymptomatic carriers can be found through active surveillance in the epidemic areas. Our study confirmed that close contact screening was the main way to locate asymptomatic carriers, with the same result also being reported in a previous study (Pan et al., 2020). This revealed that close contacts identified by screening should be isolated because they are at risk of infection.

According to guidelines aimed at preventing SARS-CoV-2 infection, as potential infectious sources, asymptomatic carriers should be quarantined for 14 days from the first positive laboratory test (China NHCotPsRo, 2020d). 10.9% of the asymptomatic carriers in our study subsequently developed symptoms during the observation period to become confirmed cases. Those cases occurred during the incubation period, a median of 2 days after testing positive (range 1–5 days). Thus, close contact screening should not only focus on patients who have developed illness, but should also be extended to include asymptomatic cases during the incubation period, in order to reduce the infection risk of SARS-CoV-2 (Hu et al., 2020). Our study also assessed the transmission efficiency of asymptomatic carriers. Although the attack rate was lower than that for confirmed cases, it was shown to cause infection in 2.6% of close contacts.

In conclusion, although the transmission efficiency of asymptomatic carriers is lower than that for confirmed cases, the transmission risk from carriers should not be ignored. Second, close contacts of those infected with SARS-CoV-2 should undergo detailed observation and active laboratory screening, with these measures being included in the formulating of guidelines relating to SARS-CoV-2. Finally, close contact screening should be extended to include those present up to 5 days before the onset of illness in confirmed cases.

Funding

This study was supported by grants from Anhui Provincial Department of Science and Technology, Anhui Provincial Health Commission Emergency Research Project of Novel Coronavirus Infection (grant numbers 202004a07020002; 202004a07020004).

Conflicts of interest

The authors declare that they have no conflicts of interest.

Acknowledgements

We would like to thank the physicians and staff at the 16 municipal centers for Disease Control and prevention in Anhui Province for collecting the information of asymptomatic carriers of SARS-CoV-2 infection.

Transmission Dynamics of COVID-19 Outbreaks Associated with Child Care Facilities — Salt Lake City, Utah, April–July 2020

Adriana S. Lopez, MHS¹; Mary Hill, MPH²; Jessica Antezano, MPA²; Dede Vilven, MPH²; Tyler Rutner²; Linda Bogdanow²; Carlene Claflin²; Ian T. Kracalik, PhD¹; Victoria L. Fields, DVM¹; Angela Dunn, MD³; Jacqueline E. Tate, PhD¹; Hannah L. Kirking, MD¹; Tair Kiphibane²; Ilene Risk, MPA²; Cuc H. Tran, PhD¹

On September 11, 2020, this report was posted as an MMWR Early Release on the MMWR website (<https://www.cdc.gov/mmwr>).

Reports suggest that children aged ≥ 10 years can efficiently transmit SARS-CoV-2, the virus that causes coronavirus disease 2019 (COVID-19) (1,2). However, limited data are available on SARS-CoV-2 transmission from young children, particularly in child care settings (3). To better understand transmission from young children, contact tracing data collected from three COVID-19 outbreaks in child care facilities in Salt Lake County, Utah, during April 1–July 10, 2020, were retrospectively reviewed to explore attack rates and transmission patterns. A total of 184 persons, including 110 (60%) children had a known epidemiologic link to one of these three facilities. Among these persons, 31 confirmed COVID-19 cases occurred; 13 (42%) in children. Among pediatric patients with facility-associated confirmed COVID-19, all had mild or no symptoms. Twelve children acquired COVID-19 in child care facilities. Transmission was documented from these children to at least 12 (26%) of 46 nonfacility contacts (confirmed or probable cases). One parent was hospitalized. Transmission was observed from two of three children with confirmed, asymptomatic COVID-19. Detailed contact tracing data show that children can play a role in transmission from child care settings to household contacts. Having SARS-CoV-2 testing available, timely results, and testing of contacts of persons with COVID-19 in child care settings regardless of symptoms can help prevent transmission. CDC guidance for child care programs recommends the use of face masks, particularly among staff members, especially when children are too young to wear masks, along with hand hygiene, frequent cleaning and disinfecting of high-touch surfaces, and staying home when ill to reduce SARS-CoV-2 transmission (4).

Contact tracing* data collected during April 1–July 10, 2020 through Utah's National Electronic Disease Surveillance System (EpiTrax) were used to retrospectively construct transmission chains from reported COVID-19 child care facility outbreaks, defined as two or more laboratory-confirmed COVID-19 cases within 14 days among staff members or attendees at the same

facility. EpiTrax maintains records of epidemiologic linkage between index patients and contacts (defined as anyone who was within 6 feet of a person with COVID-19 for at least 15 minutes ≤ 2 days before the patient's symptom onset) and captures data on demographic characteristics, symptoms, exposures, testing, and the monitoring/isolation period. A confirmed case was defined as receipt of a positive SARS-CoV-2 real-time reverse transcription–polymerase chain reaction (RT-PCR) test result. A probable case was an illness with COVID-19–compatible symptoms,[†] epidemiologically linked to the outbreak, but with no laboratory testing. For this report, the index case was defined as the first confirmed case identified in a person at the child care facility, and the primary case was defined as the earliest confirmed case linked to the outbreak. Pediatric patients were aged < 18 years; adults were aged ≥ 18 years.

Persons with confirmed or probable child care facility–associated COVID-19 were required to isolate upon experiencing symptoms or receiving a positive SARS-CoV-2 test result. Contacts were required to quarantine for 14 days after contact with a person with a confirmed case. Facility attack rates were calculated by including patients with confirmed and probable facility-associated cases (including the index patient) in the numerator and all facility staff members and attendees in the denominator. Overall attack rates include facility-associated cases (including the index case) and non-facility contact (household and nonhousehold) cases in the numerator and all facility staff members and attendees and nonfacility contacts in the denominator; the primary case and cases linked to the primary case are excluded.

During April 1–July 10, Salt Lake County identified 17 child care facilities (day care facilities and day camps for school-aged children; henceforth, facilities) with at least two confirmed COVID-19 cases within a 14-day period. This report describes outbreaks in three facilities that experienced possible transmission within the facility and had complete contact investigation information. A total of 184 persons, including 74 (40%) adults (median age = 30 years; range = 19–78 years) and 110 (60%)

* <https://www.cdc.gov/coronavirus/2019-ncov/php/contact-tracing/contact-tracing-plan/contact-tracing.html>.

[†] <https://www.cdc.gov/coronavirus/2019-ncov/symptoms-testing/symptoms.html>.

children (median age = 7 years; range = 0.2–16 years), had a known epidemiologic link to one of these three facilities with an outbreak; 54% were female and 40% were male. Among these persons, 31 confirmed COVID-19 cases occurred (Table 1); 18 (58%) cases occurred in adults and 13 (42%) in children. Among all contacts, nine confirmed and seven probable cases occurred; the remaining 146 contacts had either negative test results (50; 27%), were asymptomatic and were not tested (94; 51%) or had unknown symptoms and testing information (2; 1%).

Among the 101 facility staff members and attendees, 22 (22%) confirmed COVID-19 cases (10 adult and 12 pediatric) were identified (Table 2), accounting for 71% of the 31 confirmed cases; the remaining nine (29%) cases occurred in contacts of staff members or attendees. Among the 12 facility-associated pediatric patients with confirmed COVID-19, nine had mild symptoms, and three were asymptomatic. Among 83 contacts of these 12 pediatric patients, 46 (55%) were nonfacility contacts, including 12 (26%) who had confirmed (seven) and probable (five) COVID-19. Six of these cases occurred in mothers and three in siblings of the pediatric patients. Overall, 94 (58%) of 162 contacts of persons with facility-associated cases had no symptoms of COVID-19 and were not tested. Staff members at two of the facilities had a household contact with confirmed or probable COVID-19 and went to work while their household contact was symptomatic. These household contacts represented the primary cases in their respective outbreaks.

Facility A Outbreak

Facility A, which had been deemed an essential business and had not closed before the outbreak occurred, required daily temperature and symptom screening for the 12 staff members and children and more frequent cleaning and disinfection; staff members were required to wear masks. Two COVID-19 cases in staff members were associated with facility A (Figure). The index case at facility A (patient A1) occurred in a staff member who reported symptom onset on April 2, self-isolated on April 3, and had a positive SARS-CoV-2 RT-PCR test result from a nasopharyngeal (NP) swab specimen obtained on April 6. Three days after patient A1's symptom onset, a second staff member (patient A2) experienced symptoms and had a positive SARS-CoV-2 test result 1 day later. Ten facility contacts (nine children aged 1–5 years and one staff member) remained asymptomatic during the monitoring period and were not tested. The last reported exposure at facility A was on April 3, when the facility closed. Among the 15 nonfacility contacts of patients A1 and A2 (including four children aged 1–13 years), 10 remained asymptomatic throughout their monitoring period and were not tested, and three received negative test results; the symptom and testing information for two nonfacility contacts was unknown. The primary patient, a household contact of the index patient, reported symptom onset 9 days before

TABLE 1. Characteristics of all staff members, attendees, and their contacts associated with COVID-19 outbreaks at three child care facilities — Salt Lake County, Utah, April 1–July 10, 2020

Characteristic	No. (% with available information)		
	Total*	Adult*	Pediatric*
Facility staff members, attendees, and contacts	184 (100)	74 (100)	110 (100)
Age, yrs, median (range) [†]	9 (0.2–78)	30 (19–78)	7 (0.2–16)
Sex			
Female	100 (54)	42 (57)	58 (53)
Male	74 (40)	31 (42)	43 (39)
Unavailable	10 (5)	1 (1)	9 (8)
Linkage to facility			
Facility staff member or attendee	101 (55)	18 (24)	83 (75)
Nonfacility contact [§]	83 (45)	56 (76)	27 (25)
Confirmed[¶] COVID-19 cases			
Total	31 (17)	18 (24)	13 (12)
Symptomatic	24 (13)	15 (24)	9 (8)
Index case at facility	3 (2)	3 (4)	0 (—)
Asymptomatic	4 (2)	0 (—)	4 (4)
Probable[¶] COVID-19 cases	7 (4)	5 (7)	2 (2)
Contacts[§]			
Total	146 (79)	51 (60)	95 (86)
Contacts with a negative test result	50 (27)	27 (36)	23 (21)
Asymptomatic contacts, not tested	94 (51)	22 (30)	72 (65)
Contacts with unknown symptoms and testing	2 (1)	2 (3)	0 (—)

Abbreviation: COVID-19 = coronavirus disease 2019.

* Does not include two persons with primary cases or their six contacts; two adult contacts had unknown symptom and testing information. Percent is calculated as a percentage of the total.

[†] Age data were missing for 11 contacts.

[§] Includes pediatric and adult household and nonhousehold contacts.

[¶] A confirmed case was defined as a positive SARS-CoV-2 reverse transcription–polymerase chain reaction test result. A probable case was an illness with symptoms consistent with COVID-19 and linked to the outbreak but without laboratory testing.

symptom onset in patient A1 and received a positive SARS-CoV-2 test result from an NP specimen collected on April 6. The facility attack rate (excluding the primary case) for facility A was 17% (two of 12) and was 7% overall (including contacts) (two of 27).

Facility B Outbreak

Facility B was closed during March 13–May 4. Upon reopening, temperatures of the five staff members and children were checked daily, and more frequent cleaning was conducted; only staff members were required to wear masks. Five COVID-19 cases in three staff members and two children were associated with facility B (Figure). The index case (B1) occurred in a staff member who was tested on May 31 while presymptomatic (because of a household contact with COVID-19) and received a SARS-CoV-2-positive test result; patient B1 experienced mild COVID-19 symptoms on June 3 and last worked on May 29. A second staff member (patient B2), experienced symptoms on June 8, was tested, and received a positive test result 2 days later. Patients B3 and B4, children aged 8 months

TABLE 2. Classification of contacts with known linkage to facility-associated confirmed adult and pediatric cases* at three child care facilities — Salt Lake County, Utah, April 1–July 10, 2020

Classification	No. (%)					
	Total [†]	Adult [†]	Pediatric	Facility		
				A	B	C
COVID-19 cases at facilities [§]	22	10	12	2	5	15
Contacts [¶] linked to cases at facilities	162	79	83	25	28	109
Contacts [¶] with confirmed COVID-19	9 (6)	2 (3)	7 (8)	0 (—)	4 (14)	5 (5)
Contacts [¶] with probable COVID-19	7 (4)	2 (3)	5 (6)	0 (—)	3 (11)	4 (4)
Contacts [¶] with negative test results	50 (31)	25 (32)	25 (30)	3 (12)	13 (46)	34 (31)
Asymptomatic contacts, not tested	94 (58)	48 (61)	46 (55)	20 (80)	8 (29)	66 (61)
Contacts with unknown symptoms and testing	2 (1)	2 (3)	0 (—)	2 (1)	0 (—)	0 (—)
Interval (days)						
Facility case onset to contact onset, median (range)**	4 (1–8)	6 (4–6)	3 (1–8)	1 (1–1)	4.5 (1–6)	4 (3–8)
Facility case onset to testing, median (range) ^{††}	2.5 (0–6)	1 (0–4)	4 (1–6)	2.5 (1–4)	1 (0–3)	2 (0–10)

Abbreviation: COVID-19 = coronavirus disease 2019.

* A confirmed case was defined as a positive SARS-CoV-2 reverse transcription–polymerase chain reaction test result. A probable case was an illness with symptoms consistent with COVID-19 and linked to the outbreak but without laboratory testing.

[†] A positive adult case linked to facility attendee from Facility B is included because they were a staff member.

[§] Includes index cases.

[¶] Includes pediatric and adult household and nonhousehold contacts.

** For cases in persons who were asymptomatic, onset for contact is date of receipt of positive test result.

^{††} Does not include three pediatric facility cases in persons who were asymptomatic who did not have symptom onset dates.

and 8 years, respectively, experienced mild signs and symptoms (fever, fatigue, runny nose) 7 and 8 days, respectively, after symptom onset in patient B2; both children were tested and received positive test results the day after their symptoms commenced. A third staff member, patient B5, experienced symptoms 9 days after symptoms occurred in patient B4, was tested, and received a positive test result 1 day later. The two children likely transmitted SARS-CoV-2 to their contacts including two confirmed cases (in one child's mother and father, both symptomatic 2 and 3 days, respectively, following the child's illness onset) and three probable cases (in two adults, including one mother and a child). The index patient (B1) was a household contact of the primary patient who had symptom onset May 26, was tested on May 29, and received a positive SARS-CoV-2 test result. The facility attack rate for facility B was 100% (five of five) and the overall attack rate was 36% (12 of 33).

Facility C Outbreak

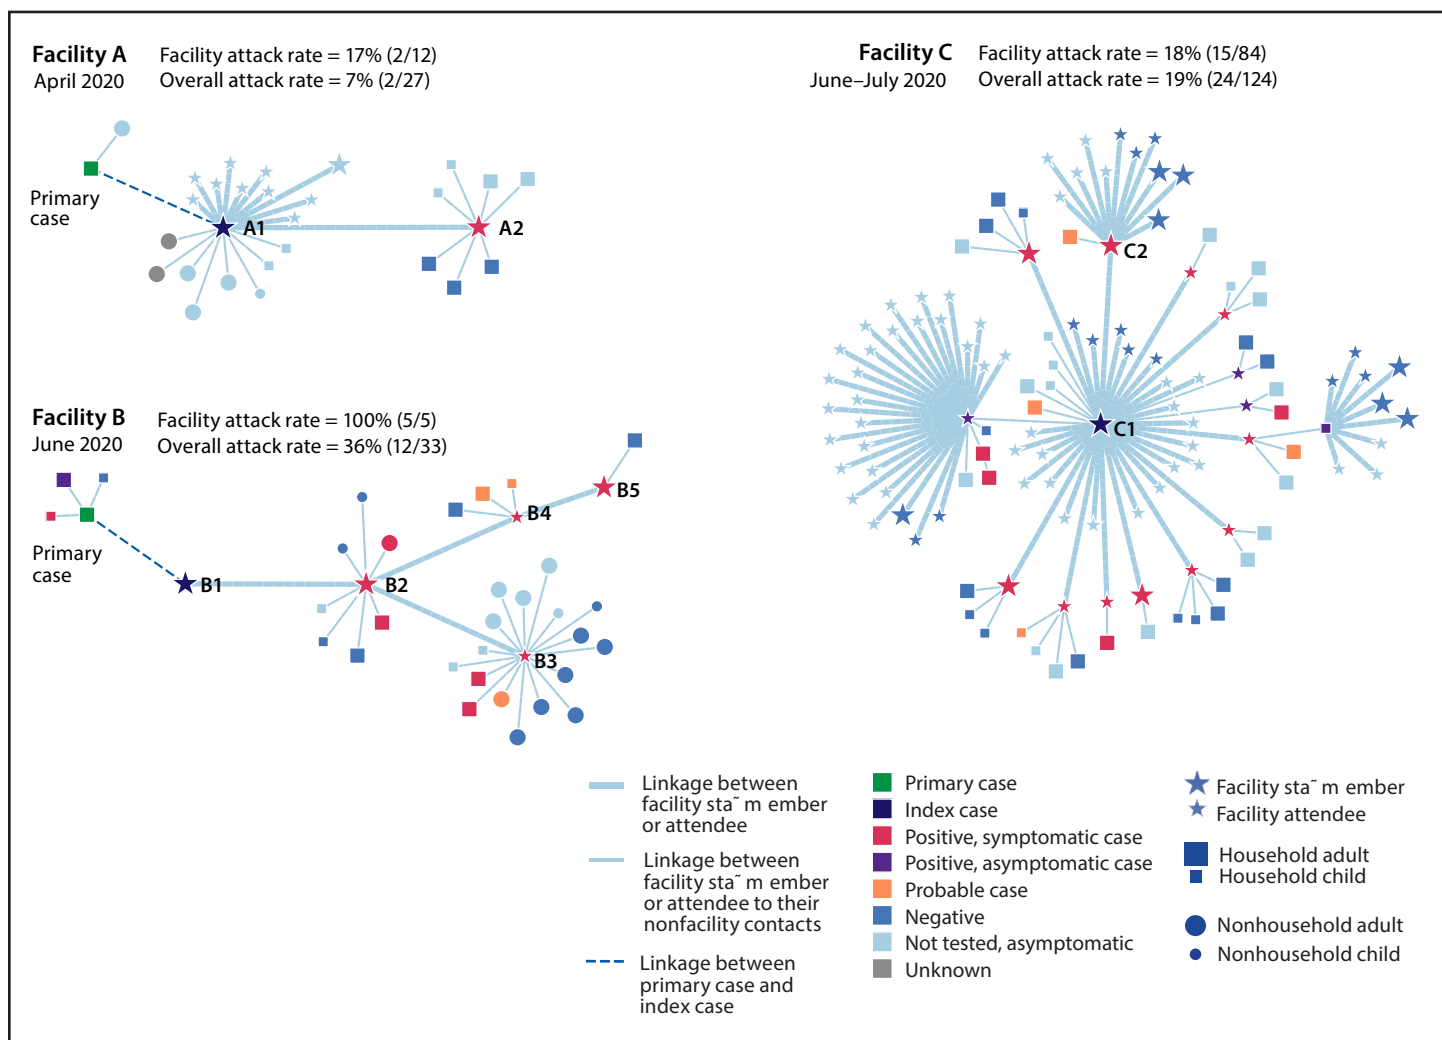

Facility C was closed during March 13–June 17. Upon reopening, the facility requested that 84 staff members and children check their temperature and monitor their symptoms daily; masks were not required for staff members or children. Fifteen COVID-19 cases (in five staff members and 10 children) were associated with facility C (Figure). Two staff members and two students reported symptoms on June 24 and self-isolated. The index case occurred in a staff member (patient C1), who had a positive test result from an NP specimen obtained on June 25.

The second staff member, patient C2, was tested 2 days later and received a positive SARS-CoV-2 test result, and the two students (aged 7 and 8 years) were tested on June 28 and 29, respectively and received positive test results. Over the subsequent 8 days, an additional eight students (aged 6–10 years), three of whom were asymptomatic, and three staff members (all symptomatic) received positive SARS-CoV-2 test results. Pediatric patients at the facility likely transmitted SARS-CoV-2 to their contacts, including five confirmed cases in household contacts (three mothers, one aunt, and one child) and two probable household cases (one mother and one child). Symptoms developed 3 and 5 days following the child's illness onset when onset date was known. One mother who was presumably infected by her asymptomatic child was subsequently hospitalized. Among the seven cases in symptomatic children, fever was the most common sign, followed by symptoms of headache and sore throat. The source for this cluster was not identified. The facility attack rate for facility C was 18% (15 of 84) and the overall attack rate was 19% (24 of 124).

Discussion

Analysis of contact tracing data in Salt Lake County, Utah, identified outbreaks of COVID-19 in three small to large child care facilities linked to index cases in adults and associated with transmission from children to household and nonhousehold contacts. In these three outbreaks, 54% of the cases linked to the facilities occurred in children. Transmission likely occurred from children with confirmed COVID-19 in a child care facility to 25% of their nonfacility contacts.

FIGURE. Transmission chains* and attack rates^{†,§} in three COVID-19 child care center outbreaks^{¶,,††} — Salt Lake County, Utah, April 1–July 10, 2020**

Abbreviation: COVID-19 = coronavirus disease 2019.

* Transmission chains developed using Microbe Trace software. <https://www.biorxiv.org/content/10.1101/2020.07.22.216275v1>.

† Facility attack rates include index cases and all facility staff members and attendees.

§ Overall attack rates include all facility staff members and attendees (including the index case) and nonfacility contacts (household and nonhousehold). It does not include the primary case or the cases linked to the primary case.

¶ A confirmed case was defined as a positive SARS-CoV-2 reverse transcription–polymerase chain reaction test result. A probable case was an illness with symptoms consistent with COVID-19 and linked to the outbreak but without laboratory testing.

** The index case was defined as the earliest confirmed case in a person at the child care facility.

†† A primary case was defined as the earliest confirmed case linked to the outbreak.

Mitigation strategies[§] could have helped limit SARS-CoV-2 transmission in these facilities. To help control the spread of COVID-19, the use of masks is recommended for persons aged ≥ 2 years.[¶] Although masks likely reduce the transmission risk (5), some children are too young to wear masks but can

transmit SARS-CoV-2, as was seen in facility B when a child aged 8 months transmitted SARS-CoV-2 to both parents.

The findings in the report are subject to at least three limitations. First, guidance for contact tracing methodology changed during the pandemic and could have resulted in differences in data collected over time. Second, testing criteria initially included only persons with typical COVID-19 signs and symptoms of fever, cough, and shortness of breath, which

<https://www.cdc.gov/coronavirus/2019-ncov/if-you-are-sick/quarantine.html>.

[¶] <https://www.cdc.gov/coronavirus/2019-ncov/prevent-getting-sick/cloth-face-cover-guidance.html>.

Summary

What is already known about this topic?

Children aged ≥ 10 years have been shown to transmit SARS-CoV-2 in school settings.

What is added by this report?

Twelve children acquired COVID-19 in child care facilities. Transmission was documented from these children to at least 12 (26%) of 46 nonfacility contacts (confirmed or probable cases). One parent was hospitalized. Transmission was observed from two of three children with confirmed, asymptomatic COVID-19.

What are the implications for public health practice?

SARS-CoV-2 Infections among young children acquired in child care settings were transmitted to their household members. Testing of contacts of laboratory-confirmed COVID-19 cases in child care settings, including children who might not have symptoms, could improve control of transmission from child care attendees to family members.

could have led to an underestimate of cases and transmission. Finally, because the source for the outbreak at facility C was unknown, it is possible that cases associated with facility C resulted from transmission outside the facility.

COVID-19 is less severe in children than it is in adults (6,7), but children can still play a role in transmission (8–9). The infected children exposed at these three facilities had mild to no symptoms. Two of three asymptomatic children likely transmitted SARS-CoV-2 to their parents and possibly to their teachers. Having SARS-CoV-2 testing available, timely results, and testing of contacts of patients in child care settings regardless of symptoms can help prevent transmission and provide a better understanding of the role played by children in transmission. Findings that staff members worked while their household contacts were ill with COVID-19—compatible symptoms support CDC guidance for child care programs recommendations that staff members and attendees quarantine and seek testing if household members are symptomatic (4). This guidance also recommends the use of face masks, particularly among staff members, especially when children are too young to wear masks, along with hand hygiene, frequent cleaning and disinfecting of high-touch surfaces, and staying home when ill to reduce SARS-CoV-2 transmission.

COVID-19 Outbreak Associated with Air Conditioning in Restaurant, Guangzhou, China, 2020

Ana M. Rule

Author affiliation: Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland, USA

DOI: <https://doi.org/10.3201/eid2611.202948>

To the Editor: In the research letter by J. Lu et al. (1), the authors claim that “The air outlet and the return air inlet for the central air conditioner were located above table C (Figure, panel B).” This sentence does not describe the actual layout depicted in the Figure, in which the air conditioner is located by table C and the exhaust fan is between tables B and D.

Furthermore, the authors do not provide evidence of why “Virus transmission in this outbreak cannot be explained by droplet transmission alone.” Their discussion does not mention the possibility that persons move around and may have been infected by touching surfaces, going to the restroom at the same time, or engaging in other close contact.

It is hard to understand how the authors conclude that “... strong airflow from the air conditioner could have propagated droplets from table C to table A, then to table B, and then back to table C.” According to the figure, air flows from table C to the exhaust fan (tables B–D). The authors do not provide evidence that the exhaust fan was not working; they ignored its presence. A simple measurement of air flow would answer this question.

The fact that “... none of the staff or other diners in restaurant X were infected” is another indication that the air conditioner was probably working. Also puzzling is the authors’ conclusion that “... the smear samples from the air conditioner were all nucleotide negative.” This finding is less consistent with aerosol transmission.”

The authors’ conclusion that “... in this outbreak, droplet transmission was prompted by air-conditioned ventilation” is not supported by the data provided. They further conclude that “The key factor for infection was the direction of the airflow” but do not follow the airflow to the exhaust fan.

In Response: We thank Prof. Rule (1) for her comments on our letter (2). We welcome the opportunity to offer additional information on several of the points made.

We wish to explain that although she stated that, “The air outlet and the return air inlet for the central air conditioner were located above table C (Figure, panel B)” does not describe the actual layout depicted in the Figure, in which the air conditioner is located by table C and the exhaust fan is between tables B and D” (1). In fact, the air outlet and the return air inlet for the central air conditioner were located above table C (Figure 1). The central air conditioner is constructed in 2 parts: air outlet and air inlet, indicating no discrepancy between the text and the figure.

We agree that virus transmission in this outbreak could be explained by droplet transmission and the possibility that persons move around, touch surfaces, go to the restroom, or engage in other close contact. We con-

Figure 1. Inlet and outlet of air conditioner described in study of COVID-19 outbreak associated with air conditioning in restaurant, Guangzhou, China, 2020 (2).

Figure 2. Air flow (A) and seating diagram (B) for restaurant described in study of COVID-19 outbreak associated with air conditioning in restaurant, Guangzhou, China, 2020 (2).

sidered these scenarios but omitted their mention in the research letter. Instead, we reported what we considered to be the most likely scenario, which is that the droplet transmission was prompted by the air blown from right to left and then across tables C, A, and B successively. The air movement facilitated dispersion of droplets containing severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) from patient A1 to the 3 patients at table B. After the air had passed over tables C, A, and B, patients C1 and C2 acquired the infection from droplets mixed with SARS-CoV-2 as they returned to the air

inlet over table C. None of the 62 persons at the other 12 tables were infected, which suggests that the alternate scenarios (touching surfaces or going to the restroom at the same time) were less likely. Furthermore, some diners and waitresses also went to the restroom and were not infected. In addition, closed-circuit television tapes did not show that the patients in our study had gone to the restroom at the same time. The tapes showed that patient C1 walked in and out several times and passed table A on the way, which might be one of the reasons for the infection of patient C1.

We did not describe the exhaust fan in the text, but we drew an exhaust fan between tables B and D in the figure. To point out the exhaust fan, we drew it bigger than actual measurements, which were only 12 × 12 inches (305 mm × 305 mm); the fan was not strong enough to remove all air produced by the central air conditioner. After the initial publication, we revised the figure to show the appropriate size of the exhaust fan and added details about its size, emphasizing that the ventilation system was not well designed (Figure 2). The main air flow is discharged from the central air conditioning outlet and then returned to the air inlet. Because of the weak exhaust system, the ventilation in the restaurant was not good. We did not ignore the presence of the exhaust fan.

We conclude that the air conditioner prompted transmission of SARS-CoV-2; the customers in the airflow were at high risk for infection with SARS-CoV-2 in the poorly ventilated environment. Because the staff and other diners were not exposed to the airflow mixed with SARS-CoV-2 transmitted by patient A1, their risk for infection was lower.

We excluded the possibility of aerosol transmission (2). It has been reported that aerosols (<5 mm) can remain in the air and disperse long distances (>1 m) (3). The potential for aerosol transmission has been reported for severe acute respiratory syndrome coronavirus (4) and Middle East respiratory syndrome coronavirus (5,6). However, in our study, none of the 62 persons at the other 12 tables were infected. Moreover, the smear samples from the air conditioner were all negative by reverse transcription PCR.

We believe that the most likely scenario for SARS-CoV-2 transmission in the restaurant was

droplet transmission prompted by the air conditioning, although other scenarios are possible. The exhaust fan was not strong enough to modify the ventilation; the main mode of air circulation was the central air conditioning outlet with air returned to the air conditioning inlet. Because of the weak exhaust system, ventilation in the restaurant was poor. We recommend that air handling systems be sufficiently powered and maintained.

Pathological and molecular examinations of postmortem testis biopsies reveal SARS-CoV-2 infection in the testis and spermatogenesis damage in COVID-19 patients

Xixiang Ma¹, Chuhuai Guan², Rong Chen³, Yunyun Wang², Shenglei Feng¹, Rongshuai Wang⁴, Guoqiang Qu⁴, Sijia Zhao¹, Fengli Wang¹, Xiaoli Wang¹, Dingyu Zhang^{5,6}, Liang Liu², Aihua Liao¹ and Shuiqiao Yuan¹

Cellular & Molecular Immunology _#####_; <https://doi.org/10.1038/s41423-020-00604-5>

In late December 2019, the novel severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which causes coronavirus disease 2019 (COVID-19), was identified in Wuhan, China, and the ensuing pandemic has led to more than 50 million infected individuals and more than one million deaths by November 10, 2020 (<https://covid19.who.int/>). Pathologic investigations of autopsy tissue have focused primarily on the lung, heart, and kidney, whereas morphologic data on testis injury and the effects of SARS-CoV-2 infection on spermatogenesis are limited. Although two groups did not detect SARS-CoV-2 in the semen or testes of recovered COVID-19 patients,^{1,2} another group confirmed SARS-CoV-2 in the semen of patients.³ Therefore, it is currently unknown whether SARS-CoV-2 infection impacts spermatogenesis and male fertility. In the present study, we evaluated the effects of SARS-CoV-2 infection on spermatogenesis by examining the pathophysiology and molecular features of testes obtained from five male COVID-19 patients at autopsy.

First, the histological morphology of the testes from five COVID-19 patients and three uninfected controls was examined by periodic acid-Schiff (PAS) staining. The COVID-19 patients were aged 51, 62, 70, 78, and 83 years, and the control patients were aged 71, 78, and 80 years (Supplementary Table S1). In all five COVID-19 patients, numerous degenerated germ cells (GCs) had sloughed into the lumen of seminiferous tubules (Fig. 1a). In contrast, in the age-matched control tissues, GCs at various stages were well aligned around the whole seminiferous tubules (Fig. 1a). Strikingly, in four of the five cases, GC loss was massive, with only a few GCs left attached to the seminiferous tubules. In particular, many seminiferous tubules in the testes of patients 4 and 5 showed almost no intact GCs, similar to Sertoli cell-only syndrome. Consistent with this morphological observation, the number of DDX4 (a germ cell marker)-positive cells was dramatically reduced in all testicular specimens from the COVID-19 group (Supplementary Fig. S1a, b). Interestingly, the number of Sertoli cells in the testes of SARS-CoV-2-infected patients and uninfected controls was comparable (Supplementary Fig. S1c, d), suggesting that SARS-CoV-2 infection may not impair Sertoli cells. These morphological changes in the testes of COVID-19 patients

indicate that SARS-CoV-2 infection may impair male GC development and eventually lead to GC loss.

SARS-CoV-2 can induce cellular and humoral immune changes and destroy antiviral immunity at an early stage in COVID-19 patients.^{4,5} To ascertain how male GC loss occurs in patients with COVID-19, we investigated the presence of apoptosis and inflammatory reactions in the testicular cells. TUNEL assays revealed that the number of apoptotic cells in COVID-19 testes was significantly higher than that in control testes (Supplementary Fig. S1e, f), raising the possibility that SARS-CoV-2 damages the immune privilege and innate immune homeostasis of the testis. Indeed, immunohistochemical (IHC) staining for various immune cells revealed scattered infiltration of CD3⁺ T lymphocytes, CD20⁺ B lymphocytes, and CD68⁺ macrophages in the interstitial compartments of patients with COVID-19, whereas such infiltration was rarely detected in controls (Fig. 1b–d). In addition, we found CD38⁺ (activated B cells) and CD138⁺ (plasma cells) cells in the interstitial compartments of COVID-19 patient testes (Supplementary Fig. S2a, b). Correspondingly, extensive IgG precipitation was observed mainly in the seminiferous epithelium, interstitium, and some degenerated GCs, similar to the findings in SARS-infected testes (Fig. 1e).⁶ These data suggest that SARS-CoV-2 might trigger a secondary autoimmune response and contribute to the primary pathogenesis of viral orchitis and consequent testicular damage.

To further determine whether SARS-CoV-2 can directly attack testicular cells, we first detected the nucleic acid sequence of SARS-CoV-2 in the testes of COVID-19 patients. Through RT-qPCR-based virus nucleic acid detection, we found two testis samples (patients 1 and 3) to be positive for SARS-CoV-2 nucleic acid (Supplementary Table S2). To further confirm the presence of the virus, we examined the testes from COVID-19 patients by immunohistochemistry using an anti-SARS-CoV spike S1 antibody. As shown in Fig. 1f, the testicular sections from patients stained positively, indicating infection of testicular cells by SARS-CoV-2. (Fig. 1f) and suggesting that SARS-CoV-2 indeed infects testicular cells through the spike glycoprotein binding mechanism. Further transmission electron microscopy (TEM) analyses revealed coronavirus-like particles in the interstitial compartment of the

testes of COVID-19 patients (Fig. 1g and Supplementary Fig. S2c), providing direct evidence that SARS-CoV-2 enters and attacks human testicular tissues.

The SARS-CoV-2 spike protein binds to the angiotensin-converting enzyme 2 (ACE2) receptor through its receptor-binding domain. In turn, ACE2 employs the serine protease TMPRSS2 to activate the S protein, allowing its HR1 and HR2 domains to interact with each other and form a six-helical bundle (6-HB) to mediate membrane fusion between the virus and a target cell.^{7–9} Therefore, we next examined the protein and mRNA levels of ACE2 and TMPRSS2 in the testes. Although both ACE2 and TMPRSS2 proteins were predominantly expressed in the cytoplasm and membrane of spermatocytes, spermatids, and Sertoli cells in control testes, elevated ACE2 and TMPRSS2 levels were observed in the seminiferous tubules of all patients with COVID-19 (Fig. 1h and Supplementary Fig. S3a, b). Consistent with the immunohistochemistry results, RT-qPCR showed significantly increased mRNA levels of ACE2 and TMPRSS2 in the testes of all COVID-19 patient compared to control patient testes (Fig. 1i, j). Together, these results indicate that the signal intensity of ACE2- and TMPRSS2-positive cells in the testes of patients with COVID-19 is higher than that in the testes of uninfected controls, which further supports the hypothesis that SARS-CoV-2 is able to attack testicular cells. However, it is not clear how SARS-CoV-2 interferes with ACE2 and TMPRSS2 expression and/or their regulation. Some common diseases (COVID-19 comorbidities) are reported to be related to ACE2 expression,¹⁰ and it is possible that higher levels of ACE2 and TMPRSS2 are observed in COVID-19 patient testes because patients with severe COVID-19 are more susceptible to SARS-CoV-2 due to underlying disease or individual differences in ACE2 and TMPRSS2 expression.

To investigate the molecular changes associated with SARS-CoV-2 infection in testes, we extracted total RNA from control (controls 1, 2, and 3) and COVID-19 patient (patients 1, 2, and 3) testes and performed RNA-seq to analyze transcriptome changes. The analysis revealed 28,801 expressed coding RNAs and lncRNAs in control and COVID-19 patient testes (Supplementary Table S3), of which 2645 were upregulated and 2789 were downregulated in COVID-19 patients compared with controls (fold change > 2, FDR < 0.001) (Fig. 1k, Supplementary Fig. S4a and Table S4). These results suggest that SARS-CoV-2 infection triggers dynamic transcriptome alterations at the molecular level in testes during specific biological processes.

To further characterize changes in the transcriptome upon SARS-CoV-2 infection in the testes, we performed Gene Ontology term analysis of the differentially regulated genes. Consistent with our virus RNA detection and IHC results, the upregulated transcripts were significantly enriched in terms related to virus invasion, such as “viral gene expression” and “viral life cycle” (Supplementary Fig. S4b). Importantly, some inflammation-related processes were activated, including the “interleukin-6-mediated signaling pathway” and “regulation of B-cell proliferation”. Consistent with our histological results (Fig. 1a), the down-regulated genes were significantly enriched in “spermatogenesis” and “reproduction” (Supplementary Fig. S4c), further illustrating the impact of SARS-CoV-2 infection on male fertility. Moreover, we found 32 inflammatory cytokines to be considerably upregulated, with a *P* value < 0.05 and fold change > 2, in COVID-19 patient testes, and 10 of these cytokines (CMTM6, FAM3C, INHBA, IL33, TNFSF10, NAMPT, CMTM4, CCL28, IL2, and TIMP1) were significantly upregulated with an FDR < 0.001 (Supplementary Fig. S4d). These bioinformatics data suggest that SARS-CoV-2 infection may lead to dysfunction of the genes that regulate spermatogenesis and inflammation-related pathways, thereby causing inflammatory immune attack in the testes and defects in spermatogenesis.

Collectively, our findings provide direct evidence that SARS-CoV-2 can infect the testis and GCs, indicating the potential

impact of the COVID-19 pandemic on spermatogenesis and male fertility. Nevertheless, further study is essential to reveal the underlying mechanism of SARS-CoV-2 infection of testicular cells and the correlation of testis infection with the clinical course of COVID-19.

ACCESSION CODES

The RNA-seq data have been submitted to the NCBI GEO database (PRJNA661970).

ACKNOWLEDGEMENTS

We thank the patients and their families for their dedication to help others understand this disease. We are also grateful for the support of the clinical staff and technicians for performing the autopsy work. Frequency of coronavirus disease 2019 (COVID-19) symptoms in healthcare workers in a large health system

Jason H. Malenfant MD, MPH¹ , Caitlin N. Newhouse MD² and Alice A. Kuo MD, PhD, MBA³

¹Public Health & Preventive Medicine Program, David Geffen School of Medicine, University of California, Los Angeles (UCLA), Los Angeles, California,

²Division of Pediatric Infectious Diseases, David Geffen School of Medicine, University of California, Los Angeles (UCLA), Los Angeles, California and ³Division of Medicine-Pediatrics, David Geffen School of Medicine, University of California, Los Angeles (UCLA), Los Angeles, California

To the Editor—Since the early phases of the coronavirus disease 2019 (COVID-19) epidemic across the United States, identifying and tracking healthcare worker (HCW)-to-HCW transmission has been a major priority given the risk of exposing other colleagues, exposing vulnerable patients, and issues of limited staffing. Policy guidance regarding symptomatic screening for exclusion from work to mitigate transmission has not evolved much over the course of the pandemic to date.

From March 20 through April 10, 2020, a total of 2,193 severe acute respiratory coronavirus virus 2 (SARS-CoV-2) tests were ordered for HCWs in our institution, and 174 HCWs in our health system tested positive (8% positivity rate). Symptoms were not recorded for 3 individuals. Of the remaining 171 HCWs included in our symptom analysis, 69 (40%) were registered nurses, certified nursing assistants, or care partners; 31 (18%) were clinical administrative employees; 25 (15%) were physicians (of whom 11 were house staff); and 46 (27%) consisted of respiratory therapists, radiology technicians, custodial services, or other ancillary service delivery workers. In total, 119 HCWs (70%) worked in the inpatient setting, 41 (24%) worked in ambulatory clinics, and 11 (6%) had their primary workplace at an offsite office (eg, a telehealth call center).

The most common initial symptoms were cough (51%), fever (41%), and myalgia (38%). Additional common symptoms included headache (30%), nasal congestion and/or runny nose (28%), severe fatigue (26%), and sore or scratchy throat (25%). Loss of smell (16%) and loss of taste (15%) were also reported (Table 1). Variability was noted in the number of initial symptoms: 19% endorsed only 1 presenting symptom, 23% had 2 initial symptoms, 26% had 3 symptoms, and 33% had 4 symptoms or more.

Of those HCWs with only 1 initial symptom, the most common complaint was cough (47%), followed by a sore or scratchy throat (19%). Only 3 of the 32 HCWs with 1 initial symptom (9%) reported fever. Only 1 person (3%) reported loss of smell as their only initial symptom. Of those HCWs reporting 2 initial symptoms, the most common combination of initial symptoms was fever and cough (15%), followed by headache and myalgia

(10%). Approximately one-third of all HCWs did not report fever or cough as an initial presenting symptom.

Almost half (49%) of all HCWs surveyed reported working at least 1 day while symptomatic and before calling the HCW hotline to report symptoms. Of these, 57% worked for 1 day, 18% for 2 days, 10% for 3 days, and 15% for 4 or more days (maximum, 6 days).

Early reports from around the world described COVID-19 as an illness characterized primarily by fever and cough.^{1,2} Due to limited testing capacity, testing access was often initially limited to individuals who presented with these symptoms. Because of the potential for HCWs to spread SARS-CoV-2 to patients and coworkers, our health system opted for a low threshold for testing to better characterize the spectrum of disease and reduce inadvertent spread. Our data suggest that SARS-CoV-2 infection can present with a wider variety of mild symptoms than was suggested by early studies. In fact, one-third of HCWs in our study did not report fever or cough as one of their symptoms, and these individuals would have been missed by more restrictive testing guidelines. Additionally, almost half (49%) of the HCWs continued to work while experiencing symptoms, some for several days. There are several possible explanations for this. For example, it was early in the pandemic and the mild presentation of COVID-19 was not widely recognized.

Our findings have important implications for healthcare systems and other employers regarding when to test employees and when to implement mandatory stay-home-from-work policies. Employee health programs should message that early COVID-19 can present with subtle viral symptoms, including those mimicking mild upper-respiratory infections or allergies, and that individuals should have a low threshold to present for evaluation and testing.

Additionally, our data highlight the importance of universal symptom monitoring through either a daily survey or mandatory entry point at facility entrances. Screening HCWs solely for fever would have missed 60% of SARS-CoV-2-positive individuals in our sample. Health systems and other work places should consider strategies that screen for a variety of signs and symptoms of early COVID-19 infection. Universal symptom monitoring can help create a culture change in the work place, which includes being attuned to subtle changes in health and staying home from work for mild illness. This may be a difficult culture shift for various reasons including financial incentives to continue working, historical emphasis on presenteeism, and reluctance to miss work and call in a coworker for mild symptoms that may not impede one's ability to work. However, with the COVID-19 pandemic, this critical shift is

essential to stop potential transmission to vulnerable patients and other HCWs.

Health systems, school districts, and other work places can learn from this experience to develop pragmatic and effective infection control policies in the era of COVID-19. Often, areas for improvement in infection prevention can be identified to help mitigate the spread of SARS-CoV-2 within a critical work force. Especially with concern of a second and potentially multiple further waves of COVID-19, leaders can use these lessons to develop better strategies, further preparedness, and reduce burdens on our hospital systems and labor force.

Abstract

Since the outbreak of the COVID-19 pandemic, singing activities for children and young people have been strictly regulated with far-reaching consequences for music education in schools and ensemble and choir singing in some places. This is also due to the fact, that there has been no reliable data available on aerosol emissions from adolescents speaking, singing, and shouting. By utilizing a laser particle counter in cleanroom conditions we show, that adolescents emit fewer aerosol particles during singing than what has been known so far for adults. In our data, the emission rates ranged from 16 P/s to 267 P/s for speaking, 141 P/s to 1240 P/s for singing, and 683 P/s to 4332 P/s for shouting. The data advocate an adaptation of existing risk management strategies and rules of conduct for groups of singing adolescents, like gatherings in an educational context, e.g. singing lessons or choir rehearsals.

Introduction

Aerosols are liquid or solid particles, which are transported in the air and not influenced by gravitation usually determined by a size less than 5 µm, that escape from the respiratory system during breathing, speaking and singing. Besides droplets, they are widely accepted carriers for the transmission of SARS-CoV-2 viruses [1]. Due to the principles of voice production and the described accumulation of SARS-CoV-2-infections during choir rehearsals [2], it is assumed that singing is connected with increased aerosol emission rates. Recently, increased aerosol emissions during singing in comparison to speaking have been experimentally confirmed for adult singers [3, 4]. Further, an increased aerosol emission rate is found for raising vocal loudness [5]. This results in limitations and specific risk management strategies especially for choir singing during the COVID-19-pandemic. However, data about aerosol emission during singing for adolescents are still missing. But especially for children and young people the restrictions on ensemble and choir singing have far-reaching consequences in addition to severe cultural and financial losses. Singing together is an obligatory part of school education and an important factor for the socio-emotional development of children and young people. This applies not only to music lessons in school, but also to the extracurricular sector with music

schools and children and youth choirs. By now, the hygiene and performance concepts rely on aerosol emission rates during singing as collected from adults. For the first time, this pilot study presents data of aerosol formation when young people sing.

Materials and methods

Four girls and four boys, all 13 years old (except one girl aged 15 years), recruited in July 2020 by targeted call, participated in the study. They were members of a semiprofessional children's choir (Staats- und Domchor Berlin, Mädchenchor der Singakademie Berlin) and had perennial choir experience between five and nine years. All of them were before puberty voice changes, which was assessed by experienced choral directors. Apart from adolescent age, gender, perennial choir experience and pre-puberty voice status were no further inclusion criteria for this study.

The combination of adolescence and pre-puberty voice status allowed studying a representative group within boys' and girls' choir singers with advanced singing experience and cognitive development.

The study was conducted according to the ethical principles based on the WMA Declaration of Helsinki and was approved by the ethic committee of the Charité–Universitätsmedizin Berlin, Germany. Informed written consent was obtained from all subjects and their parents.

The investigations were carried out in a cleanroom (ISO-2-class) at the Hermann Rietschel Institute, Technische Universität Berlin, accessible through an airlock and equipped with terminal U15-filters.

To suppress the thermal plume at the subjects efficiently, the supply air in the whole cleanroom was introduced via a quasi-laminar vertical flow with a velocity of 0.3 m/s (Fig 1) [6]. Further, the room temperature was 295.15 ± 0.5 K, and the relative humidity was $46 \pm 2\%$. The static pressure in the cleanroom was about $20 \cdot (1 \pm 2\%)$ Pa greater than outside the room.

In this highly pure environment, the subjects wore cleanroom clothing and a headgear to further reduce the clothing's particle emission. To perform the experiments, subjects sat in front of the test equipment, consisting of a glass pipe with a diameter of 295 mm, through which a constant airflow of approximately $400 \text{ m}^3/\text{h}$ was generated by suction of a filter fan unit (FFU) (Ziehl-Abegg, Künzelsau, Deutschland) (Fig 1).

The vertical flow in the cleanroom and the glass-pipe construction ensured that emissions from other people (instructor, technical staff), who were necessarily in the cleanroom during measurements, were not directed to a laser particle counter (LPC) (Lighthouse Solair 3100 E, Lighthouse Worldwide Solutions, Fremont, CA).

The sampling probe (37 mm) of the LPC was placed centrally in the pipe. To reach a homogenous particle distribution at the measurement position, two baffles were inserted in the pipe to achieve a sufficient mixing of the particles at the sample point (Fig 1). The position of the LPC within the tube was based on the precedent setup of the measuring system utilizing visual (with stage fog) and quantitative (with an aerosol generator) assessments.

The particle counter was counting with a sampling flow rate of 28.3 l/min with a measuring time increment of 10 seconds. The detected particles were assigned to six size classes (>0.3 , >0.5 , >1.0 , >3.0 , >5.0 , $>10.0 \text{ }\mu\text{m}$) between $>0.3 \text{ }\mu\text{m}$ — $25.0 \text{ }\mu\text{m}$.

According to ISO 21501-4, the counting efficiency for particles of the size $0.3 \text{ }\mu\text{m}$ was $50 \pm 20\%$, and for particles of the size $0.5 \text{ }\mu\text{m}$ was $100 \pm 10\%$. An initial baseline measurement showed a count rate of <1 particles for 5 minutes. Between the trials and tasks, a time increment of 20–30 s and 60–90 s, respectively, was chosen to avoid remaining particles of the previous task. This was confirmed by the display of a zero count at the LPC.

Fig 1. Experimental setup. The subjects sat frontal with their head at the free end of a glass tube (inner diameter 295 mm, length of 1347 mm) during the phonatory tasks. The suction side of a FFU that produced a horizontal volume flow of 400 m³/h on average was placed at the opposite end. To achieve a fully developed turbulent flow at the position of the LPC at 810 mm, two baffle plates at distances of 340 mm and 420 mm from the entry were applied. All length units are in mm.

<https://doi.org/10.1371/journal.pone.0246819.g001>

The emission rate P_M was computed based on scaling of the particles measured at the LPC to the volume flow of the whole glass pipe. Apart from the particle measurement, the sound pressure level $L_{AF_{MAX}}$ was measured via a calibrated sound level meter (CENTER 322_ Datalogger Sound Level Meter, Center Technologies, Houston, TX).

In the first task, the emission rates for three different vocal test conditions were compared: (a) speaking, (b) singing, and (c) shouting. Condition (a) was reading a standardized text (“Der Nordwind und die Sonne” by Åsop), a reference text for voice assessments with balanced phoneme representation. Condition (b) was singing the Swedish folk song “Vem kan segla” in key G-Major, a piece very familiar to the choir singers which could be sung reliably. For condition (c), subjects were asked to cheer enthusiastically about a soccer game goal. The time window for a measured sequence was 30 seconds for test conditions (a) and (b) and 10 seconds for test condition (c). Each test condition was repeated five times.

In the second task, sustained phonation about 10 seconds was performed to investigate the impact of vocal loudness on the emission rate. Subjects were asked to sustain the syllable /la/, pitch G4 (392 Hz), at the two loudness conditions soft voice (piano) and loud voice (forte). To facilitate the 10 seconds measurement time, the young people were allowed to take a short breath within the recording and to repeat the syllable.

The emission rates were normalized to the respective time length of the tasks (10 or 30 seconds, respectively) and are time-averaged values.

Statistical analysis, individually handled for the two tasks, was carried out by using linear mixed-effects model (LMEM) analysis in the statistical software R (<https://www.r-project.org/>) including the package lmerTest [7]. This robust and flexible statistical framework was proven to have a high accuracy for multiple observations for numerous items [8]. For this study, log-valued P_M data were incorporated as the response variable and condition as fixed effect. Further, intercepts for subject and by-subject random slopes for the effect of condition were regarded as random effects. P-values were obtained using Satterthwaite's degree of freedom method. The raw data of this study and the R-script containing statistical analyses are deposited in S1 and S2 Files.

Results

Within the measuring range between 0.3 μm and 25 μm , about 99% of all measured particles for all test conditions were smaller than 5 μm and more than 70% smaller than 1 μm (Fig 2). With regard to the common understanding to denominate particles with a size smaller than 5 μm as aerosols, the following results are cumulatively given for particles of size 0.3 μm –5 μm .

The emission rates P_M for speaking were clearly lower than for singing (Fig 3). Whereas the median values for speaking were between 16 P/s (Particles/second) and 267 P/s, this measure was between 141 P/s and 1240 P/s for singing. For shouting, P_M was still higher with values from 683 P/s up to 4332 P/s. All subjects showed a clear individual increase in P_M for all three conditions.

Linear mixed modeling showed, that these increases in condition were significant (likelihood-ratio test; $p < .00001$). On average, the ratio of P_M between singing and speaking was 5.87 ± 1.28 (standard error). For shouting and speaking, this ratio was 36.22 ± 1.28 (standard error).

Fig 2. Size distributions. Distributions of emission rates P_M^D for different size classes and test conditions in%. These data were computed by summarizing all P_M -values for all subjects (separated by test condition) and were normalized to the sum for all size classes dependent on test condition (see S2 File for details).

<https://doi.org/10.1371/journal.pone.0246819.g002>

Fig 3. Emission rates. Boxplots of the emission rates (P_M in P/s, left y-axis) for the test conditions speaking, singing and shouting for subjects S1-S4 (girls) and S5-S8 (boys). The maximum sound pressure levels (L_{AF_MAX} in db SPL) are also shown (right y-axis) with different colored full circles for the test conditions.

<https://doi.org/10.1371/journal.pone.0246819.g003>

Both findings were significant ($p < .001$). Further, P_M was positively correlated with the maximum sound pressure level L_{AF_MAX} . An increase in one unit in L_{AF_MAX} resulted in an increase in 0.05 units of $\log_{10}(P_M)$. This finding was significant ($p < .001$).

For the sustained phonation task, the median values for soft phonation (piano) were between 58 P/s and 683 P/s, this measure was between 58 P/s and 1907 P/s for loud phonation (forte). In contrast to the first task, not all subjects showed a clear increase in P_M from piano to forte. This finding was mirrored by the results of the linear mixed modeling approach. The increase of P_M from piano to forte was 1.91 ± 1.47 , whereas the condition was not significant ($p = .133$). Nevertheless, a positive correlation to L_{AF_MAX} was found (Fig 4), which indicates that the emission rate increases with raising vocal loudness. Similar to the first task, an increase in one unit in L_{AF_MAX} results in an increase in 0.05 units of $\log_{10}(P_M)$, which was also significant ($p < .001$).

Fig 4. Emission rates vs. sound pressure level. Emission rate P_M plotted over maximum sound pressure level L_{AF_MAX} for sustained syllable /la/. All five repetitions for the two loudness conditions are represented by colored points as denoted in the legend. The black solid line represents the linear regression (see inset for details), the gray colored area represents the 95% confidence region, whereas the black dashed lines restrict the 95% prediction band.

Discussion

The present study confirms higher emission rates of aerosols for singing in comparison to speaking also for adolescents. As for measurements of adult professional singers, a strong intersubject variability of aerosol emission was found for singing adolescents, too. Finally, a positive correlation of particle emission with vocal loudness was confirmed, in particular reflected by the shouting condition. It should be noted that the results obtained must be viewed critically in terms of their transferability to a larger population. One limitation, for example, is that only a limited number of children and young people are active singers, who may differ in their singing techniques. In addition, the selection of the adolescents for this study is not representative of children and young singers in general in terms of the development of vocal skills and cognitive abilities during growing up.

Comparing these values with previously published data for adult professional singers [4] (<http://doi.org/10.5281/zenodo.4011701>) using the same experimental setup, similar values for speaking, but lower values for singing were observed (Fig 5). For singing, the ratio in medians between adults and adolescents was about 3.1. Shouting values for adolescents (not available for adults) were higher than singing values for adults. Regarding sustained phonation with loud voice, the ratio in medians between adults and adolescents for the forte condition was about 6.8. It must be noted that there were slight deviations between adults and adolescents in the execution of this task, such as adolescents were allowed to shortly breathe within the recording sequence. Except for shouting, determined values for adolescents are also lower than recently published data found in professional and non-professional adult singers [3]. In this study of 12 adult subjects, emission rates of 320–2870 P/s for singing at moderate to loud volumes are determined. On the other hand, Morawska et al. [9] reported values for 15 adults of 0.322 to 1.088 P/cm³ for voiced speech and normal speaking that can be approximately converted to emission rates by multiplying these values with a mean inhalation rate for males and females of about 9.5 l/min (see [10], p.18), to about 51 to 172 P/s. In a comprehensive study with 48 adult subjects, Asadi et al. [5] found loudness correlated emission rates of 1 to 50 P/s for normal speech. Further, Gregson et al. [11] estimated also loudness dependent particle concentrations in the order of 0.1 to 1.3 and 0.19 to 2.47 P/cm³ (corresponds to an emission rate of about 15.8 to 391.1 P/s) in a study with 25 adult subjects for speaking and singing tasks.

Fig 5. Comparison with data of adults singers. Boxplots of subject specific median emission rates (P_M in P/s) for the test conditions speaking, singing and shouting (adolescents only). Present data of young voices ($n = 8$) in comparison with previously measured corresponding data of professional adult singers ($n = 8$) (<http://doi.org/10.5281/zenodo.4011701>, see [4]).

<https://doi.org/10.1371/journal.pone.0246819.g005>

Quite lower values for adults in the order of 0.0049 to 0.0215 P/cm³ (corresponds to an emission rate of about 0.8 to 3.4 P/s) for talking tasks were also reported [12]. It can be summarized, that the adolescent's data for the speaking tasks presented here, are in the same order of magnitude than values reported earlier.

Regarding particle size distributions, it was found in several studies, that these distributions are mostly centered in a region of about 0.5 to 2 μm for singing [3, 11], and 0.8 to 1 μm for speaking [3, 5] and further skewed to smaller particle size. These observations were confirmed by our data for adolescents (see Fig 2).

There might be different reasons for the lower emission rates for child voices during singing. Before puberty voice changes, there are considerable differences in the vibration characteristics of the vocal folds in comparison to adults. Typical features of a child's vocal register in singing include differences in contact time and contact area of the vocal folds during each vibration cycle. There are also differences in the subglottic pressure between adults in general and young people [13, 14]. Further, there are smaller anatomical proportions of the child's airways and vocal folds are shorter before puberty voice changes. On the other hand, the fundamental frequency of the voice and accordingly the contact frequency of the vocal folds might be higher, especially in comparison with male adult voices.

Indeed, a major reason for the lower emission rates in comparison to professional singers might be the lower volume of the adolescent's voices during singing. This was especially evident in the task with intended loud singing, even if all subjects of this study had a longstanding choir experience. On the contrary, in the shouting condition, which is not related to limitations in the child's singing technique, some adolescents reached higher emission rates than adults during loud singing.

Our experimental setup uses a Laser Particle Counter (LPC) in cleanroom conditions (without a background concentration of particles) to assess the number and size of evaporated aerosols (or droplet nuclei) in their equilibrium state for different kinds of vocalisation. Estimating the precise number and size of these particles is of great interest to assess the concentration of those particles in closed rooms. Because of the great range of the exhaled air volume flow from zero (close mouth) up to at least 7.5–15 l/min for phonation [10, 15–17] and 24 l/min for blowing [18], the measurement setup must be both, highly sensitive to detect all particles and suitable to cover the whole volume flow range.

Thus, different considerations were included in designing the setup for this study. First of all, a filter fan unit with a high volume flow of 400 m³/h has been selected, whereas the flow of exhaled air is small and can be neglected. To further avoid any disturbances regarding stagnating flow at the measuring probe, this probe was positioned centrally in a glass pipe. Further, by placing a turbulence generating baffle between mouth opening and probe, there was a homogeneous particle density distribution in the cross sectional area of the glass pipe. This in turn required the choice of an adequate distance between mouth opening and LPC, which was chosen to about 0.81 m and resulted in a traveling time of the particles of about 0.14 s in maximum (see [4] for details). These experimental conditions, including a relative humidity of about 46%, result in approximately evaporated aerosols in their equilibrium state [19], which can be surveyed by the LPC with high accuracy and independently of the fluid flow at the mouth. Thus, the measured emission rates can serve as a realistic estimate for a possible carriage for viruses that propagate in the environment. Moreover, they allow a reliable comparison between the different vocalisation tasks. However, the emission rates reported in this study should not be interpreted as emitted droplets and aerosols directly at one's opened mouth [20]. Further issues with relevance for SARS-CoV-2-transmission during singing like the trajectory of larger droplets after emission from the mouth need to be studied with different methods like Particle Image Velocimetry or Phase Doppler Anemometry.

For the assessment of the risk of SARS-CoV-2-transmission during singing, both, droplets and aerosols are considered as virus carriers. While virus transmission via droplets can be mainly handled by distance and hygiene rules, the risk management of transmission through virus carrying aerosols has to be addressed with further strategies [21–23].

Activities to reduce the aerosol input in closed rooms during singing include limiting the number of singers and the rehearsal or performance time, which contributes to a lower cumulative aerosol concentration. Apart from these issues, the individual emission rates of the singers determine the aerosol input into closed rooms. For singing, an increased rate of aerosol emission compared to speaking has been found for adolescents, too. The lower aerosol emissions for adolescents' voices during singing in comparison to adult singers might contribute to develop more specific risk management strategies for different constellations of singing. Apart from singing, adolescents' aerosol emissions during shouting may be even higher than adult's emission rates during speaking. That should be considered for risk assessments in the corresponding areas, too.

Further, risk management strategies should incorporate other approaches like room size and air condition systems, which will affect the number and the concentration of potentially infectious aerosols in the room, too. Especially modern mechanical ventilation systems might significantly lower the risk of aerogenic virus transmission [24].

Based on the current prevalence of the disease, advanced risk management for singing together for instance in music lessons in school should combine the above-mentioned tools. The findings for aerosol emission for adolescent voices should be especially used to specify rehearsal and performance schedules for children's and adolescents' choirs because of the significance of education and socio-emotional development for children and young people.

Supporting information

S1 File. Raw data. R-readable data frame. In addition to data for ID, condition, cumulative PM, and SPL, the emission rates for the six size classes (C1–C6), corresponding to >0.3 – 0.5 , >0.5 – 1.0 , >1.0 – 3.0 , >3.0 – 5.0 , >5.0 – 10.0 , and >10.0 – $25\ \mu\text{m}$, are given. (CSV)

Seroprevalence

India

ABSTRACT

Background: Earlier serosurveys in India revealed seroprevalence of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) of 0.73% in May–June 2020 and 7.1% in August–September 2020. A third serosurvey was conducted between December 2020 and January 2021 to estimate the seroprevalence of SARS-CoV-2 infection among the general population and healthcare workers (HCWs) in India.

Methods: The third serosurvey was conducted in the same 70 districts as the first and second serosurveys. For each district, at least 400 individuals aged ≥ 10 years from the general population and 100 HCWs from subdistrict-level health facilities were enrolled. Serum samples from the general population were tested for the presence of immunoglobulin G (IgG) antibodies against the nucleocapsid (N) and spike (S1-RBD) proteins of SARS-CoV-2, whereas serum samples from HCWs were tested for anti-S1-RBD. Weighted seroprevalence adjusted for assay characteristics was estimated.

Results: Of the 28,598 serum samples from the general population, 4585 (16%) had IgG antibodies against the N protein, 6647 (23.2%) had IgG antibodies against the S1-RBD protein, and 7436 (26%) had IgG antibodies against either the N protein or the S1-RBD protein. Weighted and assay-characteristic-adjusted seroprevalence against either of the antibodies was 24.1% [95% confidence interval (CI) 23.0–25.3%]. Among 7385 HCWs, the seroprevalence of anti-S1-RBD IgG antibodies was 25.6% (95% CI 23.5–27.8%).

Conclusions: Nearly one in four individuals aged ≥ 10 years from the general population as well as HCWs in India had been exposed to SARS-CoV-2 by December 2020.

Introduction

Population-based serosurveys are recommended to estimate the proportion of a population already infected with severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2). Repeated cross-sectional serosurveys conducted in the same geographical location provide estimates to monitor trends over a period of time (World Health Organization, 2020a). Information from repeated cross-sectional surveys is valuable for public health decision makers to design and revise containment strategies. A meta-analysis undertaken by Chen et al. (2021) estimated that the overall global seroprevalence of SARS-CoV-2 was 8.0% in the general population and 17.1% among healthcare workers (HCWs).

With more than 10 million laboratory-confirmed cases and nearly 150,000 reported deaths as of 31 December 2020, India has the second highest reported number of cases of coronavirus disease 2019 (COVID-19) globally (World Health Organization, 2020b). The nationwide lockdown imposed between March and May 2020 in India was relaxed in a phased manner from June 2020, allowing interstate and interdistrict movement of people as well as restoration of economic activities (Ministry of Home Affairs, Government of India, 2020, 2021). Two population-based serial serosurveys conducted in 70 Indian districts indicated that the prevalence of SARS-CoV-2 infection among adults had increased

10-fold, from 0.73% [95% confidence interval (CI) 0.34–1.13%] in May–June 2020 to 7.1% (95% CI 6.2–8.2%) in August–September 2020 (Murhekar et al., 2020, 2021). The number of infections per reported COVID-19 case decreased from 81.6–130.1 in May–June 2020 to 26–32 in August–September 2020, mainly due to improvements in testing capacity and the number of tests performed in the country (Murhekar et al., 2020, 2021).

SARS-CoV-2 poses a high occupational risk to HCWs, who are at the forefront of management of COVID-19 cases in hospital settings. Knowledge of the burden of infection among HCWs is important to gauge the risk of within and outside hospital transmission of SARS-CoV-2, and evaluate in-hospital infection control practices and adherence to non-pharmaceutical interventions (Piccoli et al., 2021).

The number of cases of COVID-19 in India has shown a downward trend since mid-September 2020, with the reported number of cases declining from more than 90,000 per day in September 2020 to less than 20,000 cases per day in December 2020. This declining trend has been seen in all Indian states, except Kerala (FETP Network – Chennai, India, 2021). In this context, the authors conducted a third nationwide serosurvey between December 2020 and January 2021 to estimate the seroprevalence of SARS-CoV-2 antibodies in the general population, and determine the trends in infection since the previous serosurveys. In

addition, seroprevalence was estimated among HCWs working in subdistrict-level public health facilities.

Methods

Survey of general population

The third serosurvey followed the same methodology as the first and second nationwide serosurveys (Murhekar et al., 2020, 2021) (see online Supplementary material). Briefly, the third population-based serosurvey was conducted in the same 700 clusters (villages in rural areas and wards in urban areas) from 70 districts selected at random across India as in the first two serosurveys. The authors aimed to select a minimum of 400 individuals aged ≥ 10 years from each district, with a total sample size of 28,000 individuals (see online Supplementary material). The survey teams first selected four random locations from each cluster. Starting from a random household in each location, contiguous households were visited. All household members aged ≥ 10 years who were permanent residents in the area were enumerated, and consenting individuals present at the time of the visit of the survey team were included in the survey. No additional visits were made to include households which were locked or household members who were not present at the time of the first visit. In order to select at least 40 individuals from each cluster, the field teams visited a minimum of four households from each of the four random points, and enrolled at least 10 individuals per random starting location. If the teams did not identify 10 eligible individuals from the four households, more households were visited. The survey was conducted between 18 December 2020 and 6 January 2021.

Survey of HCWs

Two to three subdistrict-level public health facilities (e.g., 'taluk' or subdivisional hospital, community or primary health centre) closest to the selected cluster/s for the household survey were selected from each of the 70 districts identified for the general population survey. All consenting individuals working in these facilities were included to ensure participation of ≥ 100 HCWs from each district.

Data collection

Eligible individuals from the general population and HCWs who consented to participate were interviewed using the Open Data Kit mobile application (<https://opendatakit.org/>) to collect information on sociodemographic details, history of symptoms suggestive of COVID-19 since March 2020 (e.g., fever, cough, shortness of breath, sore throat, new loss of taste or smell, fatigue), contact with laboratory-confirmed COVID-19 cases, and history of COVID-19 illness. Venous blood (3–5 mL) was collected from each participant, and centrifuged serum samples were transported to ICMR National Institute of Epidemiology, Chennai under cold chain conditions.

Laboratory investigations

Serum samples collected from individuals from the general population were tested for the presence of immunoglobulin G (IgG) antibodies against SARS-CoV-2 on the Advia Centaur Immunoassay system using the Siemens SARS-CoV-2 IgG assay (Siemens Healthineers, India, Mumbai) and Abbott Architect i2000SR automated analyser using the Abbott SARS-CoV-2 IgG assay (Abbott Park, IL, USA). The Siemens assay detects IgG antibodies against the spike protein of the receptor binding

domain (S1-RBD), and the Abbott assay detects IgG antibodies against the nucleocapsid (N) protein of SARS-CoV-2. Serum samples from HCWs were tested only for IgG antibodies against the S1-RBD protein. Sensitivity and specificity of the Siemens IgG assay are 100% and 99.90% respectively, compared with 100% and 99.6% for the Abbott IgG assay (Center for Devices and Radiological Health, 2021). Serum samples with cut-off indices (COI) ≥ 1.0 on the Siemens IgG assay or ≥ 1.4 on the Abbott IgG assay were considered as positive for IgG antibodies against SARS-CoV-2. One hundred and fifty positive serum samples and 150 negative serum samples for each assay were retested for quality control purposes.

Statistical analysis

The characteristics of study participants are described as percentage, mean and standard deviation (SD). The reported occupations were categorized as high risk and low risk on the basis of the potential risk of exposure to a known or unknown COVID-19 case. For example, occupations such as HCWs, police or security personnel, shopkeepers, bus or taxi drivers, and bank employees were considered as high-risk occupations; and farmers, retired employees, students, information technology professionals and homemakers were considered as low-risk occupations (Murhekar et al., 2021). The weighted seroprevalence of IgG antibodies against the N protein and the S1-RBD protein were estimated separately, along with 95% CI, using a random-effects model to account for cluster sampling. Sampling weights were calculated as the product of the inverse of the sampling fraction for the selection of districts and the selection of villages or wards from each district. Weighted seroprevalence was further adjusted for the sensitivity and specificity of the respective assays (Sempos and Tian, 2021). Overall seroprevalence in the general population was estimated by considering serum samples positive on any of the assays. Weighted overall seroprevalence was adjusted for joint sensitivity and specificity of the two assays (Sempos and Tian, 2021). Seroprevalence among HCWs was considered on the basis of the anti-S1 assay alone. In addition, overall seroprevalence was calculated by age group, sex, area of residence and COVID-19-related characteristics of the study participants.

The first serosurvey was conducted among adults alone, whereas individuals aged ≥ 10 years were surveyed in the second and third surveys. The serum samples in the second serosurvey were tested only for IgG antibodies against the N protein using the Abbott assay. For comparison of seroprevalence in the three surveys, one adult per household was selected at random from the survey database, and adjusted seroprevalence of IgG antibodies against the N protein was estimated among these adults.

Overall adjusted seroprevalence in the general population aged ≥ 10 years was applied to the total population of the entire country aged ≥ 10 years to estimate the total number of cases of SARS-CoV-2 infection. Studies indicate that IgG antibodies start appearing between 7 and 14 days after symptom onset and reverse transcriptase polymerase chain reaction (RT-PCR) positivity (Long et al., 2020). The infection to case ratio was estimated by dividing the estimated number of SARS-CoV-2 infections by the number of reported COVID-19 cases detected by RT-PCR or rapid antigen test 1 week (19 December 2020) and 2 weeks (12 December 2020) before the median survey date (26 December 2020).

Sensitivity analysis

IgG antibodies against SARS-CoV-2 infection decline over time (Ripperger et al., 2020; Bolotin et al., 2021). The COI for different assays specified by manufacturers are based on ≥ 14 days convalescent sera. Lowering the COIs could improve the sensitivity of the assays used for population-based serosurveys (Bolotin et al.,

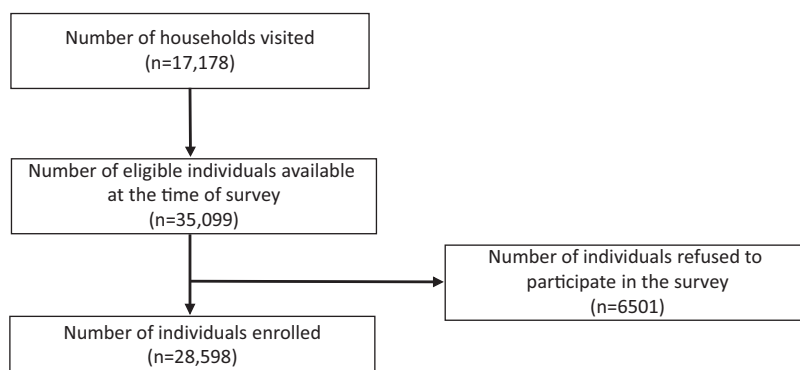

Figure 1. Flowchart of participant enrollment.

2021). In this study, seroprevalence was also calculated using lower COI of >0.54 for the Abbott assay and 0.32 for the Siemens IgG assay, as suggested by Irsara et al. (2021). In addition, seroprevalence was estimated using the lowest values of sensitivity (90.8% for the Abbott assay and 78.8% for the Siemens assay) and specificity (99.3% for Abbott assay and 100% for the Siemens assay) estimated through external validation studies (see online Supplementary material).

Protection of human participants

Written informed consent was obtained from individuals aged ≥ 18 years, and assent was obtained from children aged between 10 and 17 years, with written informed consent from their parents or guardians, before the survey (Indian Council of Medical Research, 2017). The Institutional Human Ethics Committee of ICMR National Institute of Epidemiology, Chennai approved the study protocol.

Results

Seroprevalence among the general population

In total, 17,178 households from 700 clusters in 70 districts were visited. Of the 35,099 individuals who were available at the time of the visit of the survey teams, 28,598 (81.5%) consented to participate (Figure 1).

The mean age of the study participants was 38.2 (SD 16.4) years. Nearly three-quarters of the participants ($n = 21,187$, 74.1%) were residing in rural areas, 51.6% ($n = 14,763$) were female, and 15.2% ($n = 4333$) had an occupation with a higher risk of exposure to potentially infected persons. Of the 1889 (6.6%) participants who reported history of COVID-19 symptoms since March 2020, 474 (25.1%) reported seeking medical care. The main symptoms reported by participants were cough (63.7%), fever (52.4%), tiredness/fatigue (13%), sore throat (12.4%), shortness of breath (11.2%), new loss of smell (4.2%) and new loss of taste (3.5%) (see online Supplementary material). In total, 3232 (11.4%) individuals reported having been tested for SARS-CoV-2 by RT-PCR or rapid antigen test in the past, of whom 287 (8.9%) reported a positive result (Table 1).

Of the 28,598 individuals tested, 4585 (16%) had IgG antibodies against the N protein and 6647 (23.2%) had IgG antibodies against the S1-RBD protein. Weighted and assay-characteristic-adjusted seroprevalence of IgG antibodies against the N and S1-RBD proteins were 14.3% (95% CI 13.6–15.0%) and 21.5% (95% CI 20.4–22.6%), respectively. Overall, 7436 individuals had IgG antibodies against either the N protein or the S1-RBD protein, with weighted and assay-characteristic-adjusted seroprevalence of 24.1% (95% CI

23.0–25.3%) (Table 2). Seroprevalence in districts ranged between 4.9% (20/407) in Mahisagar (Gujarat) and 44.4% (176/396) in Bijapur (Chhattisgarh) (see online Supplementary material).

Overall seroprevalence did not differ by sex (males 23.2%, 95% CI 22.1–24.5%; females 24.9%, 95% CI 23.7–26.3%). Seroprevalence was lowest among individuals aged 18–44 years and was similar among other age groups. Individuals residing in rural areas had significantly lower seroprevalence (21.4%, 95% CI 20.3–22.6%) compared with those living in urban non-slum areas (29.5%, 95% CI 27.0–32.1%) and urban slum areas (34.7%, 95% CI 31.2–38.5%) (Table 3, see online Supplementary material).

Seropositivity was higher among individuals who reported COVID-19-related symptoms (28.7%, 95% CI 26.1–31.4%), and had contact with COVID-19 cases, either within (42.5%, 95% CI 36.7–48.3%) or outside (24.9%, 95% CI 20.0–30.6) the household.

Of the 287 individuals who reported COVID-19 infection by rapid antigen test or RT-PCR, 178 (63.6%, 95% CI 57.2–69.4%) were seropositive (Table 3). Seroprevalence had a positive non-linear correlation with the cumulative incidence of reported COVID-19 cases in the 70 districts (correlation coefficient 0.352) (see online Supplementary material).

Seroprevalence among adults

In order to compare seroprevalence among adults between the three serosurveys, 16,565 adults, one per household, were selected at random from the database. Of these, 2657 had IgG antibodies against the N protein with weighted and adjusted seroprevalence of 14.3% (95% CI 13.5–15.1%). The weighted seroprevalence of IgG antibodies against either the N protein or the S-RBD protein was 24.3% (95% CI 23.1–25.6%).

Burden of SARS-CoV-2 infection in December 2020

Applying the overall seroprevalence to the population aged ≥ 10 years, it was estimated that 271,404,207 (95% CI 259,016,464–284,918,110) individuals in India had been infected by December 2020. With 10,027,311 and 10,181,165 COVID-19 cases reported by 12 December and 19 December 2020, respectively, it was estimated that there were 27.1 (95% CI 25.8–28.4) and 26.7 (95% CI 25.4–28.0) infections per reported case of COVID-19 (Table 4).

Sensitivity analysis

Using the lower cut-off values, the overall seroprevalence of SARS-CoV-2 infection was 37.4% (95% CI 35.9–38.8) (see online Supplementary material). Considering the lowest values of

Table 1
Characteristics of study participants.

Characteristics	General population <i>n</i> (%)	Healthcare workers <i>n</i> (%)

sensitivity and specificity obtained from external validation studies, the overall seroprevalence was 24.5% (95% CI 23.4–25.7).

Seroprevalence among HCWs

In total, 7385 individuals working in 199 subdistrict-level public health facilities in 70 districts were included in the survey. Their mean age was 38 (SD 10.2) years and 4206 (56.9%) were female. Approximately one third (*n* = 2684, 36.4%) were

paramedical workers and 27.3% (*n* = 2014) were doctors/nurses (Table 1). Overall, 1066 (14.4%) reported a history of COVID-19 symptoms since March 2020, and 3441 (46.7%) reported exposure to a case of COVID-19. In all, 664 (14.1%) of the 4700 individuals who reported COVID-19 testing by rapid antigen testing or RT-PCR were positive (Table 1).

Test-performance-adjusted seroprevalence of IgG antibodies against SARS-CoV-2 infection was 25.7% (95% CI 23.7–27.9) (Table 2). Seroprevalence did not differ between different HCW

categories. Seroprevalence did not differ by age and sex. Seroprevalence was higher among HCW who reported COVID-19 symptoms in the past, those who reported contact with a COVID-19 case within the household, and those who reported a positive result on rapid antigen testing or RT-PCR (Table 3).

Discussion

The findings of the third serosurvey indicate that nearly 24% of India's population aged ≥ 10 years had been exposed to SARS-CoV-2 infection by December 2020, with an estimated 271 million infections. Seroprevalence did not differ by sex, but was lower among adults aged 18–44 years and in rural areas compared with urban areas. The results also indicate that approximately one-quarter of HCWs working in the peripheral public sector health facilities were positive for IgG antibodies.

Antibody assays were used to detect IgG against the N and S1-RBD proteins of SARS-CoV-2 in this survey. N-protein assays are reported to be more sensitive than S1 assays for the detection of antibodies in mildly infected patients that are reported to show absent or delayed, and lower SARS-CoV-2 antibody responses (Özçürümez et al., 2020; van Tol et al., 2020). It has been shown that the anti-N antibodies appear earlier than the S antibodies, and may therefore increase the clinical sensitivity of the assay if samples are drawn early (Rikhtegaran Tehrani et al., 2020). In the third serosurvey, 800 individuals were reactive for the N-protein but negative for the S1-RBD protein, possibly suggesting early infections. The IgG antibody response against different viral antigens is heterogeneous in nature and the results do not always correlate with each other (McAndrews et al., 2020). Therefore, the detection of antibodies against two different antigens, with high sensitivity and specificity, is needed to confirm the findings and avoid false-negative results in surveillance studies (Irsara et al., 2021).

Seroprevalence studies provide information about the extent of transmission in the past, and help predict the future course of the pandemic (World Health Organization, 2020a; Chen et al., 2021). Seroprevalence of IgG antibodies against SARS-CoV-2 among individuals aged ≥ 10 years in India increased from 6.6% in August 2020 to 24.1% in December 2020. The prevalence of IgG antibodies against the N protein between the two serosurveys increased at least 2.2-fold. Serum samples from the previous serosurvey were not tested for anti-S1-RBD IgG antibodies. During the same period, the reported number of COVID-19 cases in India has increased 3.5-fold. Anti-N antibody seropositivity has decreased in 15 of the 70 survey districts by 10.7% to 63.4%, with the steepest decline in Vizianagaram (Andhra Pradesh), Chennai (Tamil Nadu) and Ganjam (Odisha) districts. In the remaining 55 districts, seropositivity to anti-N antibodies has increased 1.04–76-fold (see online Supplementary material). This increase in seroprevalence is consistent with the increase in the number of COVID-19 cases reported between August and December 2020 in these districts (see online Supplementary material).

In the third serosurvey, seroprevalence was significantly lower in the 18–44 years age group, whereas in the second serosurvey, prevalence was similar across age groups. Between August and December 2020, the age-specific seroprevalence of anti-N antibodies increased 1.8-fold among individuals aged 18–44 years and 2.6–3.1-fold in the remaining age groups (see online Supplementary material).

Lower seroprevalence in the active and productive age group compared with other age groups is not consistent with the transmission pattern of COVID-19. This age group was exposed to infection early in the pandemic, as reflected by the relatively high incidence of COVID-19 among this age group between January and April 2020 (ICMR COVID Study Group, 2020). Therefore, the lower seroprevalence found in this age group could be due to relatively higher waning of IgG antibodies compared with other age groups. It is noteworthy that 81% of individuals with RT-PCR-confirmed infection were seropositive during the second survey, compared with 63% during the third serosurvey.

Higher seroprevalence of SARS-CoV-2 infection was found in urban areas compared with rural areas in the third serosurvey. Although this pattern was similar to the second serosurvey in August 2020, seroprevalence did not differ between slum and non-slum urban areas, as was observed in August 2020. Between August and December 2020, the increase in seroprevalence was highest in rural areas (2.5-fold), followed by urban non-slum areas (1.93-fold) and urban slum areas (1.07-fold), reflecting the varied distribution of susceptible populations in these areas. The declining trend in the reported number of COVID-19 cases in India from mid-September 2020 points to a reduction in transmission, which could be attributed to higher seroprevalence in urban slum and non-slum areas, considering these locations to be the drivers of the epidemic in the country (Malani et al., 2021b). The findings of the third serosurvey also indicate that a large proportion of individuals in rural areas remain susceptible to SARS-CoV-2 infection. A similar finding was observed in the recent serosurvey conducted in Karnataka and Tamil Nadu (Malani et al., 2021a; Mohanan et al., 2021).

In India, several cities and states have conducted serosurveys. Metropolitan cities such as Delhi, Mumbai, Pune, Chennai, Ahmedabad and Hyderabad have reported seroprevalence ranging between 17.6% and 56% at different timepoints (see online Supplementary material). Tamil Nadu and Kerala conducted serosurveys covering all districts in October–November 2020 and February 2021, respectively. Seroprevalence reported in Chennai, Coimbatore and Tiruvannamalai districts of Tamil Nadu were comparable to the present survey. The higher seroprevalence in Palakkad, Ernakulam and Thrissur districts of Kerala found in the present survey compared with the Kerala serosurvey could be due to the use of assays for antibodies against the N-protein alone in the Kerala serosurvey.

Seroprevalence among HCWs (25.6%) observed in this study was much higher compared with the 8.7% prevalence estimated in a systematic review and meta-analysis among HCWs (Galanis et al.,

2021). Comparable seroprevalence among clinical, paramedical, field and administrative workers in health facilities and by place of contact with known COVID-19 case suggests widespread transmission of SARS-CoV-2 in the survey areas.

This study has several limitations. First, the participation of children aged 10–17 years in this survey was lower than the census-based age distribution in India ([Office of the Registrar General and Census Commissioner, New Delhi and Government of India, 2011](#)). According to the 2011 census, approximately 21% of the population were aged 10–17 years, whereas 8% of the study population were aged 10–17 years (see online Supplementary material). The under-representation of children and over-representation of adults in the survey could lead to underestimation of the true seroprevalence if one expects a real difference in the risk of exposure to SARS-CoV-2 across age groups. Further, 26% of the study clusters in the present survey were from urban areas, whereas, according to the 2011 census, 31% of the population of India reside in urban areas. Although the proportion of clusters from urban areas in this survey was slightly lower than the national average, this survey was representative of India overall. Approximately 18.5% of eligible individuals declined to participate in this survey. If this non-response was not at random, this could introduce selection bias. Second, different assays were used to measure IgG antibodies in the three serosurveys. In the first serosurvey, a laboratory assay which detected IgG antibodies against the whole cell antigen was used, and positive sera were retested with an assay which detected antibodies against the S1 domain of the S protein of SARS-CoV-2 ([Murhekar et al., 2020](#)). In the second serosurvey, a laboratory assay which detected IgG antibodies against the N protein of SARS-CoV-2 was used ([Murhekar et al., 2021](#)). As antibodies against the N protein of SARS-CoV-2 have been shown to decline faster over a period of time, the actual seroprevalence may have been under-estimated, and thereby the actual number of infections ([Ripperger et al., 2020](#); [Bolotin et al., 2021](#)). In order to overcome these limitations, the serum samples were tested with both anti-N and anti-S1 assays in the third survey. Third, the infection to case ratio was estimated based on the reported number of cases of COVID-19. The completeness of reporting of COVID-19 cases could vary between Indian states.

In conclusion, the findings of the third nationwide serosurvey indicate that nearly one in four individuals aged ≥ 10 years from the general population as well as HCWs had been exposed to SARS-CoV-2 by December 2020 in India. Seroprevalence increased between August and December 2020, and the decline in the number of COVID-19 cases seen in India since mid-September could be on account of higher seroprevalence in urban areas. As three-quarters of the population are still susceptible, it is necessary to continue ongoing surveillance for COVID-19 cases, especially in rural areas. It is also necessary to continue implementation of non-pharmaceutical interventions, such as physical distancing, use of face masks and hand hygiene. The Government of India has initiated COVID-19 vaccination since January 2021, targeting healthcare and frontline workers in the first phase and individuals aged >60 years in the second phase ([Ministry of Health and Family Welfare, Government of India, 2020](#)). As a higher proportion of rural residents are susceptible to infection, and considering limited healthcare facilities in rural areas, especially oxygen beds ([Kumar et al., 2020](#)), elderly populations in rural areas may be prioritized for COVID-19 vaccination.

Author contributions

MVM, TB, JWVT, MSaK, KR, DCSR, SP and BB undertook the study design. TB, MSaK, JWVT, SSe, RSa, AT, SA, RB, SDB, AKB, VC,

Summary

The SARS-CoV-2 lineage B.1.1.28 has been evolving in Brazil since February 2020, but the recent emergence of sub-lineages with convergent mutations in the spike (S) protein raises

concern about the potential impact on viral infectivity and immune escape. The lineage P.1 (alias of B.1.1.28.1) is an emerging variant that harbours several amino acid mutations including S:K417T, S:E484K, and S:N501Y. This report describes the first confirmed case of reinfection with the P.1 lineage in a 29-years-old female resident in the Amazonas state, Brazil, previously infected with a B.1 lineage virus.

Keywords: COVID-19; SARS-CoV-2; reinfection; secondary infection; S:E484K; lineage B.1.1.28.P.1, Amazonas, Brazil

Introduction

Since the emergence of the coronavirus disease 2019 (COVID-19), a few cases of reinfection with phylogenetically distinct variants of SARS-CoV-2 have been reported **(1)**. These reinfection cases might be the consequence of a limited and transitory protective immunity induced by the primo-infection or might reflect the reinfecting virus's ability to evade the previous immune responses. The rapid spread in the United Kingdom (UK) and South Africa of emerging SARS-CoV-2 variants carrying several mutations in the receptor-binding domain (RBD) of the spike (S) protein **(2,3)** granting them the title of Variants of Concern (VOC). Among these mutations, E484K and N501Y are of particular concern since they potentially reduce antibody neutralization and increase affinity for ACE2 receptor **(4-10)**. Of note, the first official record of a reinfection case with the emerging VOC B.1.1.7 circulating in the UK **(11)** was recently published.

The SARS-CoV-2 lineage B.1.1.28 has been circulating in Brazil since February 2020 without accumulating notable amino acid changes in the S protein **(12,13)**. Nevertheless, recent genomic surveillance studies reported the emergence of two B.1.1.28 sub-clades with convergent mutations in the RBD of the S protein common to those detected in the UK and South African variants. One sub-clade, designated P.2 (alias for B.1.1.28.2), was first detected in Rio de Janeiro harboring the mutation S:E484K **(14)**. The second sub-clade, designated P.1 (alias of B.1.1.28.1), was first detected in Japanese travelers returning from the Amazonas state **(15)** and due to the presence of several important mutations in the RBD (K417T, E484K, and N501Y) was also classified as a VOC. It is currently unclear to what extent the B.1.1.28 emerging lineages are disseminating in Brazil. However, two recent reports described the first documented cases of reinfection with the emerging P.2 lineage in individuals from the Brazilian Northeast region that were primo-infected by B.1.1.33 lineage variants **(16,17)**.

In this study, we report the first documented case of reinfection with the newly emerging P.1 lineage in a 29-years-old individual from Amazonas, a Brazilian state that was severely hit by COVID-19 at the first epidemic wave between March and July, and is currently facing a spiraling surge of deaths since November 2020. The current case report here raises questions about the role of reinfections caused by this new VOC in the Amazonas's second epidemic wave.

Case description

A 29-years-old woman resident in Manaus, Amazonas, Brazil, with no history of immunosuppression, presented two clinical episodes of COVID-19 infection with a gap interval of nine months **(Figure 1)**. In the first episode on March 16th, the patient presented long-term fever and myalgia, cough, sore throat, nausea, and back pain. The patient was classified as having mild COVID-19 with no complications regarding these clinical manifestations and imaging exams. On December 19th, the patient reported participating in an end-of-year celebration with ten other

people after testing positive in an IgG rapid test (Medlevensohn, RJ, Brazil). One of the meeting participants was RT-PCR confirmed for SARS-CoV-2 **(18)** infection on December 24th, and the patient exhibited the second symptomatic COVID-19 episode on December 27th, with fever, cough, sore throat, diarrhea, anosmia, ageusia, headache, runny nose, and resting pulse oximetry of 97%. Patient samples from the nasopharyngeal and pharyngeal swabs (NPS) were obtained on March 24th and December 30th, 2020. This study was approved by the UEA Ethics Committee CAAE: 25430719.6.0000.5016.

Figure 1. Timeline indicating the epidemiological, clinical, and laboratory events regarding the P.1 (alias of B.1.1.28.1) reinfection case in Manaus, Amazonas, Brazil. Mutation highlighted in pink indicates a new potential N-glycosylation site, and orange mutations indicate changes at the RBD.

Diagnostic Laboratory findings

The first and second NPS samples (e.g., March 24th and December 30th) were processed for diagnosis at Fiocruz Amazônia (Fiocruz/ILMD), which is part of the official network of the Ministry of Health for diagnostics and surveillance of the SARS-CoV-2 in the Amazonas state, Brazil. Briefly, total nucleic acid was extracted from the NPS specimens with Maxwell® RSC Viral Total Nucleic Acid Purification Kit (Promega, Madison, WI) and then immediately submitted to RT-qPCR detection of the SARS-CoV-2 RNA using the protocol developed by the US CDC, targeting the viral N gene, and human RNase P as the internal control **(18)**. Both RT-PCR results were positive

(mean Ct 27.5 - 1st sample; 20.5 - 2nd sample, **Figure 1**). Additionally, these samples were also positive for the DPP SARS-CoV-2 Antigen test system (Chembio Diagnostics, Medford, NY).

Genomic findings

We recovered high-quality SARS-CoV-2 whole-genomes from the two positive NPS samples from the suspected reinfection case (EPI_ISL_811148 and EPI_ISL_811149) and from other 10 subjects from Manaus that were also tested positive in December 2020 (EPI_ISL_833131 to EPI_ISL_833140). The whole-genome amplicons were generated as previously described (**19**) with a PCR scheme with nine overlapping amplicons ([Supplemental File.pdf](#)). NGS libraries were produced with Nextera XT and sequenced with MiSeq Reagent Micro Kit v2 (300-cycles). The FASTQ reads were obtained following the Illumina pipeline on BaseSpace, imported into Geneious v10.2.6, trimmed (BBduk 37.25), and mapped (BBMap 37.25) against the reference sequence EPI_ISL_402124 available in EpiCoV database from GISAID (<https://www.gisaid.org/>). Consensus sequences with a mean coverage of 3,283x and 4,663x were generated for the first infection and reinfection case, respectively, excluding duplicate reads. Sequences were genotyped with the Pangolin software v2.1.7 (**20**) that indicate the presence of two different SARS-CoV-2 lineages in each COVID-19 episode: a B.1 lineage in the primo-infection and a P.1 lineage at reinfection.

To confirm the presence of two phylogenetically different SARS-CoV-2 lineages, sequences from the suspected reinfection case were aligned with all high quality (<2% of N) SARS-CoV-2 whole-genomes (>29 kb) from Brazil available in the EpiCoV database in GISAID by January 10th, 2021. Additionally, we also selected the four Japanese whole-genomes as the first representatives of the new P.1 lineage (EPI_ISL_792680 to EPI_ISL_792683). The ML phylogenetic analysis performed with IQ-TREE v2.1.2 (**21**) confirmed that the SARS-CoV-2 sequence from primo-infection branched in a small sub-clade together with three B.1 sequences from other Brazilian states (aLRT = 79%), while the sequence from the reinfection branched together with P.1 sequences isolated in Japan in 2021 along with five new sequences isolated in Manaus in December 2020 (aLRT = 100%) (**Figure 2A**). The P.1 reinfecting virus carried all 21 lineage-defining mutations (Supplementary Table 1) and displayed 11 amino acid changes in the S protein relative to the primo-infecting B.1 virus (**Figure 1**).

To further investigate the temporal scale of the novel P.1 lineage emergence and the viral strain associated with the reinfection case, we conducted a Bayesian analysis of all 10 SARS-CoV-2 sequences that branched within such clade. The time-scaled tree was estimated using a strict molecular clock model with a uniform substitution rate prior ($8-10 \times 10^{-4}$ substitutions/site/year), the HKY nucleotide substitution model, and the Bayesian skyline coalescent prior as implemented in BEAST 1.10 (**22**). Bayesian reconstructions traced the origin of the emerging P.1 lineage to December 1st (95% High Posterior Density [HPD]: November 15th – December 4th) and the most recent common ancestor of the reinfecting virus and the closest P.1 viruses to December 23th (95% HPD: December 12th – December 29th) (**Figure 2B**). This time frame confidently excludes the possibility of long-term persistence of the P.1 virus since primo-infection and traced the second infection a few days earlier before the onset of reinfection symptoms (December 27th).

Figure 2. Evolutionary analysis of the SARS-CoV-2 genomic sequences from the reinfection case. **A.** ML phylogenetic tree of all SARS-CoV-2 whole-genome sequences from Brazil. Branches and tips were colored based on the lineage and sampling location, respectively, following the legend's color code. Branch supports (aLRT) are presented at key nodes. The first (R1) and the second (R2) genomes obtained from the reinfection case are indicated. The scale of the phylogenetic branches is given as substitutions per nucleotide site. **B.** Time-scaled Bayesian MCC tree of SARS-CoV-2 P.1 lineage. Tips are colored according to the sampling location. Colored diamonds indicate the key ancestral nodes representing the MRCA of the P.1 clade (green) and the MRCA of the reinfecting virus, and the closest P.1 sequences (purple).

Discussion

This study described the first case of reinfection with the emerging P.1 lineage (carrying mutations S:K417T, S:E484K and S:N501Y) in a young, immunocompetent woman infected with a B.1 lineage virus nine months before. Notably, the patient had equal moderate symptomatic infections during both episodes and higher viral load (SARS-CoV-2 RT-PCR Ct value) in nasopharyngeal and pharyngeal samples obtained at reinfection compared with those from primo-infection. Although samples at primo-infection were collected later relative to symptom onset compared with samples at reinfection, these findings support that natural infections do not necessarily prevent reinfection or mitigate disease at subsequent infections (11,23). Furthermore, the low Ct values (< 25) detected at reinfection suggests that the subject may have been infectious and contributed to the onward transmission of the virus in the population (24).

A recent longitudinal study in health care workers suggests that post-infection anti-SARS-CoV-2 IgG antibodies are associated with protection from reinfection for most people for at least six months (25). We may speculate that the patient here described developed a transient protective immunity after primo-infection, but the anti-SARS-CoV-2 antibodies substantially decayed by the time of reinfection nine months later (26). However, the positive IgG rapid test obtained only eight days before the onset of symptoms in the second episode suggests that reinfection probably occurred in the face of pre-existing anti-SARS-CoV-2 antibodies. Another hypothesis is that the analyzed COVID-19 convalescent individual produced total IgG antibodies with low neutralizing potency and was thus susceptible to reinfection with new viral variants (27). Finally, the cases of reinfection with the B.1.1.28-derived emerging lineages (i.e P.1 and P.2) detected here and in previous reports (16,17) might also reflect the ability of S:K484 viruses to escape from anti-SARS-CoV-2 neutralizing antibodies induced during primo-infection with S:E484 variants that predominated during the “first-wave” epidemic in Brazil (4-7).

Urgent studies are necessary to determine whether reinfection with newly emerging lineages harboring the mutation S:E484K is a widespread phenomenon or is limited to a few sporadic cases. It will also be crucial to understand the extent to which reinfection contributes to the forward transmission of SARS-CoV-2 in previously exposed populations and the rising number of SARS-CoV-2 cases observed in Amazonas and other Brazilian states during December 2020 - January 2021.

Hi Paola,

Rather than using the Japanese genomes which are, to my knowledge, unpublished why not use the recently released P.1 genomes from Manaus described in this post: [Genomic characterisation of an emergent SARS-CoV-2 lineage in Manaus: preliminary findings](#)

It might help put the reinfection in better context.

Andrew

paola

Jan 19

Hi Andrew,

Thank you for your comments!

The decision to not include those sequences in our reference dataset was based on the following reasons:

1. We decided to analyze genomes with high quality (>29kb) and coverage (<2% N) because this is a new lineage and all sites may be important to classify it, especially in the context of the reinfection case. The genomes deposited by the CADDE do not fulfill these criteria.

2. We also noted, however, that high quality and coverage genomes from some of the same samples were also sequenced by the Instituto Adolfo Lutz (IAL) - SP and are currently available in GISAID. We recognize the value of these genomes generated by the CADDE and IAL-SP groups as the first evidence of the circulation of the P.1 lineage in the Amazonas, but those sequences were not published yet and their inclusion in our work (that will be submitted to publication) might affect the originality of the manuscripts eventually produced by those groups. We believe it is important that groups that generated and rapidly share the primary sequences with the scientific community will be the first to publish their own data. We also modified the text to properly cite the post in the final version of our manuscript.
3. Regarding the Japanese reference sequences (which are also not published yet), we are in contact with the group that generates the sequences and they agree to be coauthors of our manuscript.
4. Because all P.1 sequences detected so far were nearly identical, the inclusion of a large number of sequences from this clade will not add much temporal information to the context of the reinfection case analyzed in our study.

Best regards,
Paola

nuno_faria

Jan 19

Hi Paola,

We are of course happy for you to use our P.1 genomes from Manaus to help to contextualize your findings regarding reinfection in Manaus. Seven of our P.1 genomes on GISAID have $\geq 95\%$ coverage so hopefully they could provide some useful context. If you do use them, just cite our virological post for now (happy to share preprint/paper citation later too).

Abstract: Influenza viruses are a threat to global public health resulting in ~500,000 deaths each year. Despite an intensive vaccination program, influenza infections remain a recurrent, yet unsolved public health problem. Secondary bacterial infections frequently complicate influenza infections during seasonal outbreaks and pandemics, resulting in increased morbidity and mortality. *Staphylococcus aureus*, including methicillin-resistant *S. aureus* (MRSA), is frequently associated with these co-infections, including the 2009 influenza pandemic. Damage to alveolar epithelium is a major contributor to severe influenza-bacterial co-infections and can result in gas exchange abnormalities, fluid leakage, and respiratory insufficiency. These deleterious manifestations likely involve both pathogen- and host-mediated mechanisms. However, there is a paucity of information regarding the mechanisms (pathogen- and/or host-mediated) underlying influenza-bacterial co-infection pathogenesis. To address this, we characterized the contributions of viral-, bacterial-, and host-mediated factors to the altered structure and function of alveolar epithelial cells during co-infection with a focus on the 2009 pandemic influenza (pdm2009) and MRSA. Here, we characterized pdm2009 and MRSA replication kinetics, temporal host kinome responses, modulation of MRSA virulence factors, and disruption of alveolar barrier integrity in response to pdm2009-MRSA co-infection. Our results suggest that alveolar barrier disruption during co-infection is mediated primarily through host response dysregulation, resulting in loss of alveolar barrier integrity.

1. Introduction

Influenza A viruses (IAV) have posed a persistent threat to global public health for centuries, through both recurrent seasonal epidemics and sporadic pandemic outbreaks [1]. Approximately 10% of the global population is infected with an influenza virus annually, resulting in an estimated 3–5 million severe infections and 300,000–500,000 deaths [1–3]. Initial signs and symptoms include

acute onset of high fever, headache, cough, myalgias, and fatigue [4,5]. IAV is a self-limiting infection in most healthy adults, predominantly affecting the upper respiratory tract, and typically resolves within seven days of symptom onset [4,5]. However, severe infections progress to the lower respiratory tract, resulting in increased risk of respiratory failure and death. Populations at increased risk of severe influenza infection include infants, the elderly, pregnant women, and individuals with pre-existing respiratory, cardiac, neurological, or immunosuppressive conditions [5,6].

There is an increasing appreciation that a large percentage of severe or fatal influenza infections is associated with secondary bacterial infections [7]. The contribution of bacterial infection to influenza morbidity and mortality was well documented throughout the 1918 “Spanish” influenza pandemic and in all subsequent influenza pandemics over the past century [8]. Modern analyses of lung tissue and review of historical autopsy data from fatal 1918 influenza infections demonstrated that 95% of lethal cases were complicated by bacterial co-infection, primarily due to *Streptococcus pneumoniae* and *Staphylococcus aureus* [9–11]. During the 1957 and 1968 influenza pandemics, secondary bacterial pneumonia also caused significant morbidity and mortality, with *S. aureus* and *S. pneumoniae* being the predominant bacterial pathogens [9,12–16]. During the 2009 influenza pandemic, up to 34% of severe influenza infections managed in intensive care units and up to 55% of fatal cases were complicated by bacterial co-infections [17–20]. It is estimated that approximately 65,000 influenza- and pneumonia-related deaths occur in the U.S. each year [17]. *S. aureus*, including methicillin-resistant *S. aureus* (MRSA), is highly prevalent in severe IAV-bacterial co-infection in adults and infants [21–24].

Host and pathogen molecular mechanisms that contribute to severe influenza-bacterial infections in the lower respiratory tract are poorly understood. Excessive mucus production and impaired mucociliary clearance in response to IAV infection facilitates bacterial colonization of the lower respiratory tract, and respiratory epithelial cell barrier breakdown predisposes to bacterial invasion [7,17,21,25]. Influenza infection may also enhance bacterial adhesion to cells through the incorporation of hemagglutinin into the host cell membrane, promoting bacterial cell attachment [25,26]. These events, in conjunction with respiratory epithelial cell barrier breakdown, are likely critical to the development of secondary bacterial infections [25]. Type I and type II alveolar epithelial cells, responsible for physiology gas-exchange and surfactant production, respectively, become infected by influenza viruses, and altered alveolar-capillary membrane function results in impaired oxygen exchange and lung injury [27,28]. However, molecular mechanisms contributing to (1) bacterial replication, (2) bacterial virulence factor expression, and (3) host cell signaling in the context of IAV co-infection to epithelial cell barrier breakdown have not been fully elucidated [25]. Understanding the contribution of these factors to co-infection pathogenesis may yield novel therapeutic targets for treatment of IAV and bacterial co-infection.

As the pathophysiology of severe influenza-bacterial co-infections is primarily associated with the lower respiratory tract, we sought to characterize the contributions of viral-, bacterial-, and host-mediated factors to alveolar cell dysfunction. For this analysis, we employed human adenocarcinoma A549 alveolar epithelial cells to characterize host- and pathogen contributions directly in a relevant and well-characterized alveolar epithelial cell line. Further, A549 cells have been used extensively for the analysis of host responses to influenza virus infection [29–33]. We studied (1) the impact of IAV-infection on MRSA replication kinetics in A549 cell culture, (2) the host cell response to IAV, MRSA, or co-infection by analyzing temporal intracellular kinome responses, (3) the modulation of MRSA virulence factors related to adhesion and invasion in the presence or absence of IAV co-infection by RT-qPCR, and (4) alveolar epithelial barrier function and integrity during IAV, MRSA, or co-infection using electric cell-substrate impedance sensing (ECIS).

2. Materials and Methods

2.1. Virus, Bacteria, and Cell Conditions

The 2009 pandemic H1N1 Influenza A/Mexico/4108/09 (pdm2009) was kindly provided by Dr. Kevin Coombs (University of Manitoba, Canada). Virus stocks were grown in Madin–Darby canine kidney cells and concentrated following ultracentrifugation on a 35% sucrose cushion, kept at -80°C . Viral titers were determined via plaque assay [34]. MRSA USA300 (herein referred to as MRSA) was kindly provided by Dr. George Zhanel (University of Manitoba, Canada). MRSA inocula were generated following growth to mid-log phase in tryptic soy broth (TSB; Hardy Diagnostics, Santa Maria, CA, USA). Human A549 adenocarcinomic alveolar basal epithelial cells were grown in DMEM (Gibco, Grand Island, NY, USA) supplemented with 10% fetal bovine serum (Gibco, Grand Island, NY, USA) and 1% penicillin-streptomycin (HyClone Laboratories, South Logan, UT, USA) at 37°C and 5% CO_2 . Normal human bronchial epithelial cells infected with human telomerase and CDK4-expressing retrovirus (HBEC-3KT) were kindly provided by Dr. Neeloffer Mookherjee (University of Manitoba, Canada). Cells were grown in Airway Epithelial Basal Cell Medium fully supplemented with the Bronchial Epithelial Cells Growth Kit (ATCC).

2.2. Viral and Bacterial Infection of Alveolar Epithelial Cells

For infectious assays, alveolar epithelial cells were seeded at ~95% confluence in DMEM supplemented with 2% FBS 1 day prior to infection. Cells were infected with pdm2009 at a multiplicity of infection (MOI) of 0.01 or mock-infected with DMEM supplemented with 2% FBS for 1 h with gentle rocking every 15 min. Following infection, viral inocula were aspirated from cells and replenished with fresh DMEM supplemented with 2% FBS. Cells were rested for 24 h post-pdm2009 infection. Cells were then infected with mid-log phase MRSA USA300 or mock-infected 24 h post-pdm2009 addition (DMEM supplemented with 2% FBS) for 1 h with gentle rocking every 15 min to ensure equal distribution of bacteria. Bacterial MOIs of 0.1 and 0.01 were used in this investigation and were achieved by serial dilution of mid-log phase culture in DMEM supplemented with 2% FBS. Bacterial inocula were aspirated from cells and replaced with fresh DMEM supplemented with 2% FBS. Cells were harvested at 0, 1, 4, 8, 12, 16, 20, and 24 h post-MRSA infection for further investigation of bacterial replication kinetics, bacterial virulence factors' expression, and kinome analysis. Infections of HBEC-3KT cells (kindly provided by the Mookherjee laboratory) utilized the same conditions with the exception that cells were maintained in Airway Epithelial Basal Cell Medium supplemented with 6 mM L-glutamine.

2.3. Quantification of Bacterial and Viral Replication Kinetics

Enumeration of the total number of adherent and internalized bacteria was determined at 0, 1, 4, 8, 12, 16, 20, and 24 h post-MRSA infection. Media was aspirated from wells, and cells were washed at least $2\times$ with PBS prior to harvest for bacterial enumeration. Alveolar epithelial cells were lysed with 0.025% TritonX-100 (VWR Life Science, Solon, OH, USA). Cell lysates (incl. intact bacteria) were collected, and MRSA colony forming units were enumerated by standard bacterial plating on tryptic soy agar (TSA; MP Biomedicals, LLC, Solon, OH, USA). Viral replication was quantified by RT-qPCR in supernatant samples from pdm2009-MRSA-infected A549 cells. Total RNA was extracted from the supernatants with the PureLink Viral RNA/DNA Mini Kit (Life Technologies, Burlington, ON, USA) according to the manufacturer's instructions. Reverse transcription of total RNA was performed with primers specific for the pdm2009 H1N1 HA sequence using the Superscript IV first-strand cDNA synthesis kit (Life Technologies, Burlington, ON, USA). RT-qPCR was performed on an Applied Biosystems QuantStudio 6 Flex Real-Time PCR System, and each sample was run in duplicate with the PowerUp SYBR Green PCR master mix (Life Technologies, Burlington, ON, USA). Quantification of viral copy number was accomplished by comparison of RT-qPCR results to an established external standard of viral copy number.

2.4. Kinome Peptide Array Analysis

Kinome peptide array analysis was performed as previously described [35,36]. Briefly, IAV-, MRSA-, IAV-MRSA-, and mock-infected alveolar epithelial cells were scraped and pelleted by gentle centrifugation at 4, 8, 12, 16, 20, and 24 h post-MRSA addition. Cell pellets were treated with kinome lysis buffer (20 mM Tris-HCl, pH 7.5, 150 mM NaCl, 1 mM EDTA, 1 mM EGTA, 1% Triton X-100, 2.5 mM sodium pyrophosphate, 1 mM Na₃VO₄, 1 mM NaF, 1 µg/mL leupeptin, 1 µg/mL aprotinin, 1 mM phenylmethylsulfonyl fluoride) and incubated on ice for 10 min. Cell lysates were clarified by centrifugation at 14,000 rpm. Cell lysates were transferred to fresh microcentrifuge tubes, and the total protein concentrations were measured using the Pierce BCA Protein Assay Kit. Activation mix (50% glycerol, 50 µM ATP, 60 mM MgCl₂, 0.05% Brij 35, 0.25 mg/mL bovine serum albumin) was added to the equivalent amounts of total protein (100 µg) for each sample, and total sample volumes were matched by the addition of kinome lysis buffer. Samples were spotted onto kinome peptide arrays (JPT Peptide Technologies GmbH, Berlin, Germany) and incubated for 2 h at 37 °C and 5% CO₂. Following incubation, arrays were washed once with PBS containing 1% Triton X-100, followed by a single wash in deionized H₂O. Arrays were stained with PRO-Q Diamond phosphoprotein stain (Invitrogen, Carlsbad, CA, USA) for 1 h with gentle agitation. Arrays were subsequently destained (20% acetonitrile, 50 mM sodium acetate, pH 4.0) 3 times × 10 min each with the addition of fresh destain each time. A final 10 min wash was performed with deionized H₂O. Arrays were dried by gentle centrifugation. Array images were acquired using a PowerScanner microarray scanner (Tecan, Morrisville, NC, USA) with a 580-nm filter to detect dye fluorescence. Signal intensity values were collected using Array-Pro Analyzer version 6.3 software (Media Cybernetics, Rockville, MD, USA). Kinome data analysis was performed using the Platform for Integrated, Intelligent Kinome Analysis 2 (PIIKA2) software (available online: <http://saphire.usask.ca/saphire/piika>), as described previously [37]. Additional heatmaps were derived using the Heatmapper software suite [38]. Phosphorylation fold changes were validated using the Proteome Profiler Human Phospho-Kinase Array Kit according to the manufacturer's instructions (R&D Systems, Minneapolis, MN, USA).

2.5. Pathway Overrepresentation and Gene Ontology Analysis

Pathway overrepresentation and gene ontology analyses of differentially-phosphorylated proteins were performed using InnateDB software as described previously [35,36,39]. Input data were limited to peptides that demonstrated statistically-significant changes in expression as compared to their respective time-matched mock-infected controls, as described previously [40]. Protein identifiers, phosphorylation fold change values (>1), and *p*-values (<0.05) were uploaded to InnateDB.

2.6. RNA Extraction, cDNA Synthesis, and Quantitative qPCR

At each time point, samples were collected to determine the modification of bacterial virulence factors. Three biological replicates were collected per sample. Media was aspirated from the wells, and the cell monolayers were gently scraped, then pelleted via centrifugation for 10 min at 1200 rpm. The cell pellets were stored at −80 °C until RNA extraction. Bacterial RNA extraction was performed via standard TRIzol-chloroform extraction (Ambion, Carlsbad, CA, USA). Equivalent amounts of RNA from each biological replicate were used for cDNA synthesis using the QuantiNova reverse transcription kit (Qiagen, Hilden, Germany) with random primers. RT-qPCR was performed on the Applied Biosystems QuantStudio 6 Flex Real-Time PCR system (Life Technologies, Burlington, Ontario) using PowerUp SYBR Green Master Mix (Applied Biosystems, Austin, TX, USA) as a detection method. Each biological replicate was run in at least technical duplicate, and non-template controls were included during each run. Melt curve analysis was performed to ensure amplification specificity. Bacterial gene expression was quantified through comparison to the MRSA housekeeping gene 16S [41], and relative fold change in expression was calculated using the 2^{−ΔΔCT} method. Relative fold change

values represent pdm2009-MRSA (normalized to 16S)/MRSA-alone (normalized to 16S). Primer sequences are presented in Table S1.

2.7. Barrier Integrity Determination

The ECIS Z0, 96W Array Station and 96W20idf PET plates (Applied BioPhysics, Troy, NY, USA) were employed to quantify changes in the barrier integrity of alveolar epithelial cells during pdm2009-MRSA co-infection. A549 cells were seeded in 96W20idf PET plates at a concentration of 50,000 cells/mL and were rested in the 96W Array Station (Applied BioPhysics, Troy, NY, USA) for 24 h at 37 °C with 5% CO₂ prior to pdm2009 infection. Cells were subsequently infected with pdm2009 (MOI of 3.0 or 0.1) or mock-infected (DMEM supplemented with 2% FBS) followed by resting for 24 h. Viral- and mock-infected cells were subsequently infected with mid-log phase MRSA USA300 (MOI of 0.1 or 0.01) or mock-infected (DMEM supplemented with 2% FBS) 24 h post-pdm2009 infection. Resistance measurements were acquired during the duration of the entire experiment (72 h). Control conditions included: (i) cells infected with pdm2009-alone (MOI of 3.0, 0.1, or 0.01); (ii) cells infected with MRSA-alone (MOI of 0.01); (iii) mock-infected cells (background barrier resistance); and (iv) cells treated with 1% Triton-X100 (positive control for barrier dysfunction).

3. Results

3.1. MRSA Replication Kinetics Are Similar during Bacterial Infection-Alone and pdm2009-MRSA Infection

We first sought to characterize bacterial replication kinetics in human lung epithelial cells during IAV co-infection. Although IAV-bacterial co-infections can result in increased lung pathology in humans and nonhuman primates [42–44], there is little information available regarding the relation of bacterial replication kinetics to increased disease severity. To address this, we temporally-enumerated MRSA replication in alveolar epithelial cells during MRSA and pdm2009-MRSA infections. MRSA was added to mock-infected or pdm2009-infected cells 18 h post-infection. Timing was based on observational data from human patients with influenza-bacterial co-infections during the 2009 H1N1 pandemic where bacterial co-infection commonly occurred during the peak of viral infection [17]. The total number of adherent and internalized bacteria in alveolar epithelial cells was enumerated through standard bacterial plating. Although there was a trend towards faster bacterial replication in MRSA-alone infection as compared to pdm2009-MRSA infection at 4 h and 8 h post-MRSA infection, there were no statistically-significant differences in MRSA replication between the two conditions at any time point (Figure 1). Cells infected with MRSA-alone entered the exponential growth phase at 1 h post-infection and the stationary phase at 16 h post-infection. This was largely mirrored in the pdm2009-MRSA-infected cells. Bacterial colony counts began increasing exponentially at 4 h post-infection and entered the stationary phase beginning at 16 h post-infection. A similar pattern of MRSA replication in the presence or absence of pdm2009 co-infection was also found in HBEC-3KT cells (Figure S1). This suggests that bacterial replication kinetics are not impacted during influenza co-infection in anatomically- and physiologically-distinct regions of the lungs. To confirm that A549 cells were productively infected by pdm2009, supernatants were harvested from the pdm2009-MRSA-infected cells at the same time points as those used for CFU determination. Influenza virus gradually decreased throughout the course of co-infection (Figure 1B).

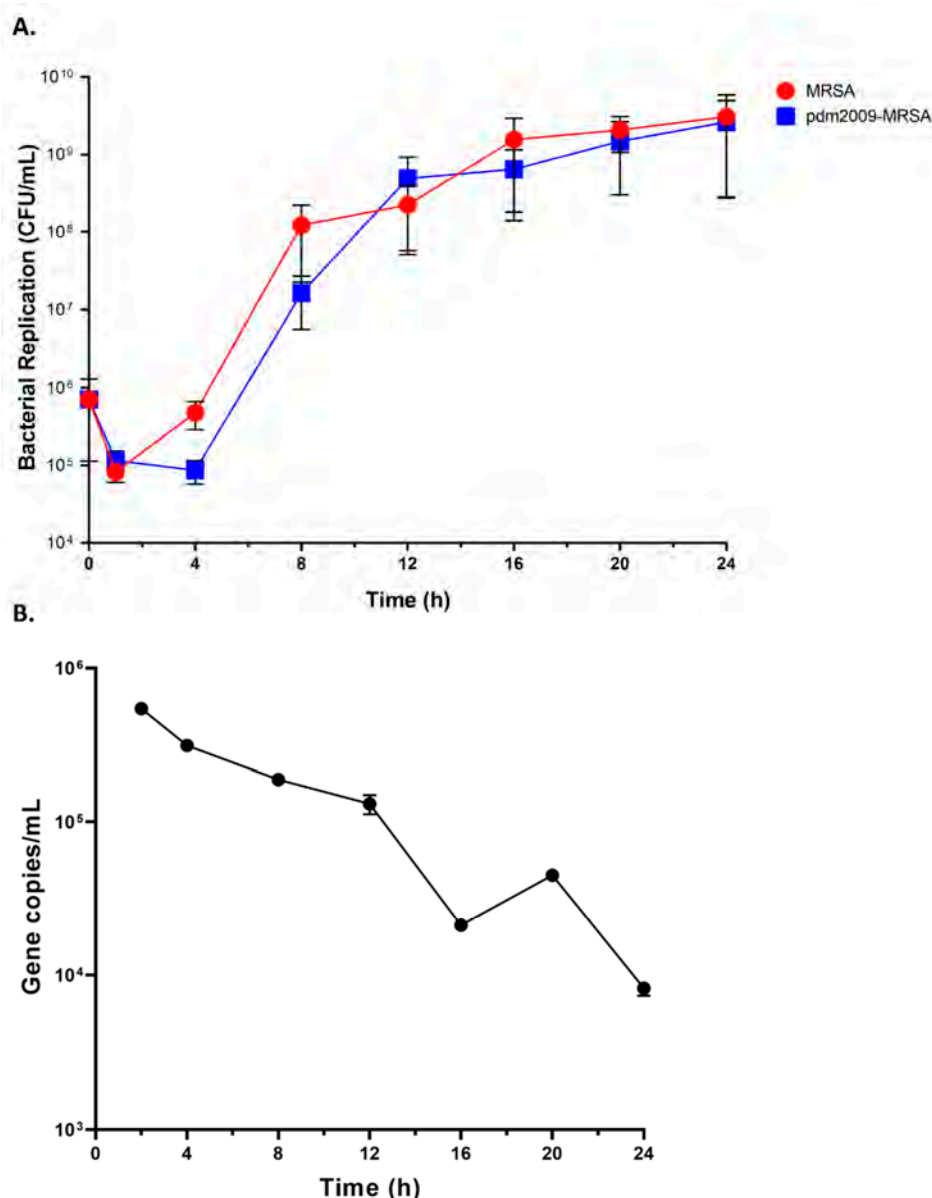

Figure 1. Pathogen replication kinetics during bacterial infection and influenza-bacterial co-infection. A549 cells were infected with 2009 pandemic influenza (pdm2009) and mock-infected, followed by MRSA infection 24 h later (MCR2009) or pdm2009-MRSA infection 24 h later (MCR2009-MRSA). Alternatively, cells were selectively infected with MRSA or pdm2009-MRSA. (A) Alveolar epithelial cells were harvested at the indicated time points, and CFU were quantified by standard bacterial plating. (B) Supernatants were harvested for isolation of viral RNA prior to quantification by RT-qPCR. Error bars represent SEM calculated from at least three biological replicates. Error bars for some of the time points are not visible due to the y-axis scale. No significant differences were found between groups as assessed by two-way ANOVA and significance testing by Tukey's test.

3.2. Temporal Analysis of Host Kinome Responses During pdm2009-MRSA Infection

As bacterial replication rates were virtually identical between the MRSA-alone infection and pdm2009-MRSA infection, we next sought to address whether aberrant cell-mediated immune responses may contribute to viral and bacterial co-infection pathogenesis. We performed temporal kinome analysis of pdm2009-, MRSA-, and pdm2009-MRSA-infected alveolar epithelial cells. We postulated that the activation state of host cell signaling responses or individual cellular kinases could provide insight into differential cellular responses found within co-infected cells as compared to pdm2009- or MRSA-alone. Time-matched mock-infected control cells served as controls. Naive

kinome analysis of pdm2009-, MRSA-, and pdm2009-MRSA-infected alveolar epithelial cells. We postulated that the activation state of host cell signaling responses or individual cellular kinases could provide insight into differential cellular responses found within co-infected cells as compared to pdm2009- or MRSA-alone. Time-matched mock-infected control cells served as controls. Naive A549 cells were initially infected with pdm2009 (MOI 0.1) or mock-infected and rested for 24 h prior to bacterial infection. MRSA addition to MRSA-infected and pdm2009-MRSA co-infected cells was designated as Time 0. Cells were harvested at various post-MRSA infection time points ranging from 4 h post-MRSA addition to 24 h post-infection. Both pdm2009-alone infected cells and mock-infected control cells were treated with MRSA-free infection inoculum at Time 0 to normalize cellular responses that may have been induced through the physical stress of the inoculum addition. Time-matched pdm2009-, MRSA-, and mock-infected control cells were collected throughout the duration of the experiment. Cell lysates were subsequently probed to quantitate host kinome responses by kinome peptide arrays. This analysis relies on the phosphorylation of specific kinase targets (immobilized peptides) on the arrays by active kinases in a cell lysate [45,46]. Data from our arrays, comprised of 309 unique kinase recognition sequences related to a broad spectrum of cell signaling pathways and processes, was analyzed using the Platform for Intelligent, Integrated Kinome Analysis 2 (PIIKA 2) software tool [37]. Hierarchical clustering analysis of the kinome data is presented in Figure 2. Overall, the kinome datasets clustered into three major clusters, which were primarily grouped based on post-MRSA infection time points. From left to right, the first cluster consisted of the 16, 20, and 24 h post-infection MRSA-alone and pdm2009-MRSA co-infection datasets (denoted as A). The second major cluster was comprised of the 4 h and 12 h MRSA-, pdm2009-, and pdm2009-MRSA-infected samples as well as the 8 h MRSA- and pdm2009-MRSA-infected samples (denoted as B). In the third cluster, all of the mock-infected datasets clustered together along with the 8, 16, 20, and 24 h post-infection pdm2009-alone infected datasets (denoted as C). Clusters B and C were more similar to each other than to the samples from Cluster A. These data suggested that the host kinome responses of the MRSA- and pdm2009-MRSA-infected samples from 16 h onwards were highly conserved between the two conditions and differentiated strongly from all other infection conditions and post-infection time points.

Figure 2. Hierarchical clustering of temporal kinome responses of pdm2009, MRSA, and pdm2009 MRSA-infections in alveolar epithelial cells. Cells were plated 24 h prior to initial infection with MRSA-infections in alveolar epithelial cells. Cells were plated 24 h prior to initial infection with pdm2009. Cells were infected or mock-infected with pdm2009 (MOI 0.1). Twenty four h post-pdm2009 infection, MRSA was added to cells at an MOI of 0.1. Cells were harvested for kinome analysis at the indicated time points. MRSA-alone-, pdm2009-alone-, and mock-infected time-matched samples were also collected at the indicated time points. A–C designate the three major dataset clusters as identified following hierarchical clustering.

To gain further insight into the similarities and/or differences in host kinome responses during pdm2009-MRSA co-infection as compared to infection by either pathogen alone, we performed biological subtraction of the time-matched mock-infected kinome datasets from their respective infected counterparts. Respective hierarchical clustering analysis of phosphorylation fold changes following mock-infected background subtraction is presented in Figure 3. Notably, the 16–24 h MRSA- and pdm2009-MRSA-infected datasets grouped together independent of the time-matched pdm2009-infected datasets. In contrast, at 4 h post-MRSA infection, the pdm2009-MRSA and pdm2009-alone datasets clustered together independent of the time-matched MRSA-alone dataset. However, from 8–12 h post-MRSA infection, the MRSA-alone, pdm2009-alone, and pdm2009-MRSA datasets clustered together. These data suggested that a transition phase occurred in the host cellular response from an IAV-dominated to a MRSA-dominated response. To provide additional validation of the kinome data, we performed phospho-Western blot analysis with Phospho-kinase Proteome Profiler Arrays (R&D Systems). Phosphorylation events that were conserved between the upregulated phosphorylation on the arrays (fold change ≥ 1.5 , p -value < 0.05) and the phospho-Western blots are presented in Table 1.

Figure 3. Background-subtracted temporal kinome responses of pdm2009, MRSA, and pdm2009-MRSA infection. Mock-infected kinome responses were subtracted from the time-matched infected samples. Fold change phosphorylation values are plotted for all kinase recognition sequences on the kinome peptide arrays. Clustering analysis was performed with the Heatmapper software suite. Z-score values represent fold change differences in phosphorylation as computed to the time-matched mock-infected control cells.

In addition, we also performed gene ontology (GO) analysis to identify biological processes that were overrepresented within our pdm2009-MRSA kinome data during the 8–12-h transition period (Table S4). While the majority of the biological processes identified mirrored those found in the pathway analysis (i.e., apoptosis- and IFN-related cellular responses) or were directly related to cellular damage responses (e.g., ATP catabolism, unfolded protein response, DNA damage), IL6- and IL8-related cellular responses were also identified, suggesting a potential role of these immune

Table 1. Conservation of phosphorylation status between kinome analysis and phospho-Western blots. pdm2009-MRSA-infected A549 cell lysates 8 h post-MRSA infection were assessed by phospho-Western blot and by peptide kinome arrays.

We next sought to identify host cell signaling responses or biological networks in the pdm2009-MRSA-infected alveolar cells that were selectively modulated during the 8–12 h post-MRSA infection transition phase (Figure 3). Pathway over-representation analysis at 8-h post-MRSA infection resulted in the identification of numerous pathways that were selectively upregulated as compared to the mock-infected cells (Table S2). Multiple apoptosis-related pathways were identified to be activated at this time point including p75(NTR)-, NRAGE-, NRIF-, NADE-, Tsp-1- and BH3-mediated signaling events. In addition, signaling pathways directly related to cell-cell contacts were also identified including alpha 6-beta 4 integrin-, and ephrin-mediated signaling events. Viral infection-related signaling pathways were also identified (incl. type I interferon (IFN) and inflammatory response-related signaling events). At the 12-h post-MRSA infection time point, the host response was dominated by NOTCH-related signaling and antiviral response-mediated events (incl. TRAF6-mediated IRF7 activation and IFN-related responses). As predicted from our hierarchical clustering analyses, there were strong similarities in the overrepresented signaling pathways found between the pdm2009-MRSA co-infection and MRSA-alone infection samples from 16–24 h post-MRSA addition. Upregulated pathways were primarily related to pro-apoptotic (e.g., p53- and caspase-mediated responses), cytokine signaling (e.g., TNF α ; IL1; NF κ B), innate immune response (e.g., TLR signaling; IFN β), and wound healing (e.g., TGF β -mediated signaling). In contrast, the pdm2009-alone infection samples were dominated by IFN-, JAK/STAT-, and IL4-mediated signaling during this time frame with p53-mediated signaling only being overrepresented at the 24-h time point. To provide additional clarity regarding potential differences in host responses between MRSA-alone and pdm2009-MRSA infection during the 8–12-h transition period, we directly compared the pdm2009-MRSA kinome responses to MRSA-alone responses (Table S3). At the 8-h time point, apoptosis-related signaling pathways were over-represented in pdm2009-MRSA-infected cells as compared to cells infected with MRSA-alone, suggesting that co-infection may result in an earlier activation of apoptosis in alveolar epithelial cells as compared to MRSA. At 12 h post-infection, there were fewer total differentially-upregulated pathways between the two infection conditions. Pathways related to TRAF6-, p75NTR, and apoptosis were differentially upregulated during pdm2009-MRSA infection; however, there was no clear over-representation of a particular biological response (e.g., apoptosis).

In addition, we also performed gene ontology (GO) analysis to identify biological processes that were overrepresented within our pdm2009-MRSA kinome data during the 8–12-h transition period (Table S4). While the majority of the biological processes identified mirrored those found in the pathway analysis (i.e., apoptosis- and IFN-related cellular responses) or were directly related to cellular damage

responses (e.g., ATP catabolism, unfolded protein response, DNA damage), IL6- and IL8-related cellular responses were also identified, suggesting a potential role of these immune mediators in the host response to IAV bacterial co-infections. The greatest number of significantly-modulated signaling pathways was identified at 24 h post-MRSA infection. Many of the identified pathways were related to pro-inflammatory responses (incl. TNF- and IL1-mediated signaling), general innate immune responses (incl. NF- κ B, TLR, and RIG-I/MDA5-mediated signaling), apoptosis, wound healing (e.g., TGF β signaling), and cell-cell contacts (e.g., integrin, cadherin, and gap junction signaling). Collectively, our host kinome response data demonstrated that pdm2009-MRSA infection resulted in the selective activation of host cell signaling events largely related to apoptosis, cell-cell contacts and innate immune responses. While the overall represented cell signaling pathways in the pdm2009-MRSA-infected samples resembled those found in both the pdm2009- and MRSA-alone infections during the 8–12-h time period, the cell signaling responses in the co-infections strongly resembled those of the MRSA-alone infections from 16 h onwards.

3.3. Bacterial Invasion- and Attachment-Related Virulence Factor Expression Patterns Are Modulated Early during pdm2009-MRSA Infection

As our prior analysis had focused on the potential role of selective host response modulation in IAV bacterial co-infection pathogenesis, we next sought to characterize the potential role of selective modulation of bacterial virulence factors to pathogenesis. We employed RT-qPCR to examine differential modulation of MRSA virulence factor gene expression in the presence or absence of pre-existing influenza virus infection in alveolar epithelial cells. We focused on MRSA virulence factor genes related to host-cell adhesion and invasion for our analysis. Overall, the expression of virulence factors in the pdm2009-MRSA-infected cells was largely repressed (<1) relative to MRSA-alone from 8 h onwards (Figure 4). In contrast, the expression of *hla*, *spa*, and *fmbB* was highly upregulated in the co-infected A549 cells relative to MRSA-alone at 1 h post-MRSA addition. The expression of *spa* and *fmbB* remained upregulated in the co-infected cells at 4 h post-infection, while the expression of *hla* was similar to MRSA-alone. This pattern of differential gene expression coincided with the early exponential phase of MRSA replication in infected cells (Figure 1). Taken together, our data suggest that MRSA virulence factors may contribute to pdm2009-MRSA co-infection pathogenesis during the early phase of bacterial attachment and entry in alveolar epithelial cells.

Our host kinome data suggested that pdm2009-MRSA co-infection-mediated modulation of host signaling responses shifted to a more dominant response during the exponential phase of MRSA replication in infected cells (Figure 1). Taken together, our data suggest that MRSA virulence factors may contribute to pdm2009-MRSA co-infection pathogenesis during the early phase of bacterial attachment and entry in alveolar epithelial cells. We focused on MRSA virulence factor genes related to host-cell adhesion and invasion for our analysis. Overall, the expression of virulence factors in the pdm2009-MRSA-infected cells was largely repressed (<1) relative to MRSA-alone from 8 h onwards (Figure 4). In contrast, the expression of *hla*, *spa*, and *fmbB* was highly upregulated in the co-infected A549 cells relative to MRSA-alone at 1 h post-MRSA addition. The expression of *spa* and *fmbB* remained upregulated in the co-infected cells at 4 h post-infection, while the expression of *hla* was similar to MRSA-alone. This pattern of differential gene expression coincided with the early exponential phase of MRSA replication in infected cells (Figure 1). Taken together, our data suggest that MRSA virulence factors may contribute to pdm2009-MRSA co-infection pathogenesis during the early phase of bacterial attachment and entry in alveolar epithelial cells. We focused on MRSA virulence factor genes related to host-cell adhesion and invasion for our analysis. Overall, the expression of virulence factors in the pdm2009-MRSA-infected cells was largely repressed (<1) relative to MRSA-alone from 8 h onwards (Figure 4). In contrast, the expression of *hla*, *spa*, and *fmbB* was highly upregulated in the co-infected A549 cells relative to MRSA-alone at 1 h post-MRSA addition. The expression of *spa* and *fmbB* remained upregulated in the co-infected cells at 4 h post-infection, while the expression of *hla* was similar to MRSA-alone. This pattern of differential gene expression coincided with the early exponential phase of MRSA replication in infected cells (Figure 1). Taken together, our data suggest that MRSA virulence factors may contribute to pdm2009-MRSA co-infection pathogenesis during the early phase of bacterial attachment and entry in alveolar epithelial cells.

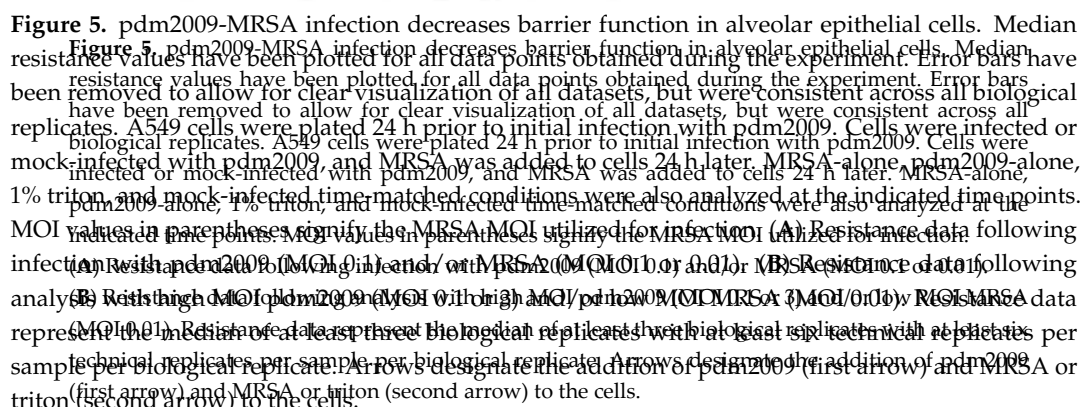

Figure 4. pdm2009-MRSA co-infection alters bacterial virulence factor expression in alveolar epithelial cells as compared to MRSA infection alone. MRSA virulence factor expression fold change values for co-infected samples relative to MRSA-alone-infected cells. Error bars represent SEM calculated from at least three biological replicates. Relative expression fold changes represent pdm2009-MRSA vs MRSA infection alone and were calculated by the $2^{-\Delta\Delta CT}$ method. Comparison between groups was assessed by two-way ANOVA and significance testing by Tukey's test, * $p < 0.05$.

3.4. MRSA-Alone and pdm2009-MRSA Infection Result in Alveolar Epithelial Cell Barrier Dysfunction

Our host kinome data suggested that pdm2009-MRSA co-infection-mediated modulation of host cell signaling responses shifted to a MRSA-dominated response during the 8–12-h post-MRSA addition period. Thus, we next examined whether the MRSA-dominated host response observed in the kinome data also dominated barrier function disruption. To assess this, we incorporated ECIS to characterize alveolar epithelial cell barrier function in response to pdm2009-MRSA infection by measuring temporal changes in resistance [47].

Alveolar epithelial cells were initially plated and rested overnight prior to pdm2009 infection (0 h). Following the overnight rest, cells were infected with pdm2009 (first arrow; Figure 5). Mock-infected control cells were treated with media alone. IAV- and mock-infected cells were subsequently infected with mid-log phase MRSA or mock-infected with media alone (second arrow; Figure 5), and resistance was continually monitored for the duration of the experiment. A summary of the data is presented in Figure 5, beginning just prior to the initial infection with pdm2009 (20 h). Mock-infected cells were left untreated throughout the duration of the experiment (negative control).

Infection of alveolar epithelial cells with pdm2009-alone at a MOI of 0.1 resulted in no changes to resistance during the first 24 h of infection. Only a small loss in resistance was found following the addition of mock-infected inoculum at 43 h (Figure 5A). The addition of MRSA (MOI 0.1) to mock-infected alveolar epithelial cells at 43 h resulted in the loss of resistance of the alveolar epithelial monolayer beginning at 57 h. Infection with pdm2009-MRSA (MOI 0.1) resulted in a nearly identical loss in resistance across the alveolar epithelial cells as that for infection with MRSA-alone. We also examined how a lower MOI of MRSA would affect the trends in resistance across our alveolar epithelial cells. Losses in resistance across the alveolar epithelial monolayers were similar between the two MOIs of MRSA tested (0.1 and 0.01). In contrast, the trend in resistance measurements differed slightly between the two MOIs of MRSA during co-infection. As these results suggested that pdm2009-MRSA co-infection-mediated disruption of alveolar epithelial barrier function largely resembled that of MRSA infection alone, we sought to expand on these observations. We examined pdm2009-MRSA co-infection using higher MOI pdm2009 and/or lower MOI MRSA inocula (Figure 5B). Infection with pdm2009-MRSA (MOI 0.1; MOI 0.01) resulted in a nearly identical loss in resistance across the alveolar epithelial cells as that for infection with MRSA-alone. We also examined how a higher MOI of pdm2009 would affect the trends in resistance across our alveolar epithelial cells. By 9 h post-pdm2009 infection (31 h; MOI 3), the resistance measurements began to decrease from the mock-infected condition and remained under 300 ohms for the duration of the experiment. Following the addition of MRSA (MOI 0.01) to the high MOI pdm2009-infected cells, resistance values across the alveolar epithelial cells began to decrease at the same time as in MRSA-alone and MOI 0.1 pdm2009-MRSA infections. However, the high MOI pdm2009-MRSA infections resulted in losses to resistance equivalent to those of the 1% triton-treated cells much more rapidly than the other infection conditions. To examine the effect of pdm2009-MRSA co-infection on distal regions of the respiratory tract, we investigated the effects of co-infection on HBEC-3KT human bronchial epithelial cells (Figure S2). The trends in loss of resistance during MRSA-alone- and pdm2009-MRSA-co-infection were largely similar to those found in A549 cells. Collectively, these data suggested that the increased damage imparted to respiratory epithelial cells by high MOI pdm2009 results in exacerbated MRSA-mediated cytotoxicity during co-infection, even at low MOIs of bacteria.

Secondary bacterial infections can complicate both seasonal and pandemic influenza virus infections, resulting in increased morbidity and mortality [7]. During the 1918 influenza pandemic, >90% of lethal infections were complicated by bacterial co-infections and were primarily associated with *S. pneumoniae* and *S. aureus* [10]. More recently, *S. aureus*, including MRSA, has been commonly associated with influenza-bacterial co-infections, including during the 2009 pandemic, where 55% of fatal cases were associated with secondary bacterial infections [18–20]. Bacteria have the ability to sense and adapt to their surrounding environment, including during infection. This includes the modulation of replication kinetics and the synthesis of virulence factors or toxins, which can enhance both adhesive and invasive properties [48]. Here, we sought to assess the roles of host and bacterial factors directly

in influenza-bacterial co-infection-mediated alveolar epithelial cell barrier dysfunction. Of note, pathophysiology associated with co-infection is thought to occur mainly in the lower respiratory tract [17]. Thus, we utilized the well-characterized alveolar epithelial adenocarcinoma A549 cells for our investigation. While it is appreciated that the potential biological implications of immortalized cell host response data must be interpreted cautiously, A549 cells provide the opportunity to assess alveolar epithelial cell responses directly in a well-characterized cell line. We have also demonstrated that the bacterial replication kinetic trends were nearly identical in the presence or absence of pdm2009 co-infection between A549 cells and HBEC-3KT cells, a normal human bronchial cell line. Further, barrier dysfunction analysis by ECIS demonstrated similar trends in loss of barrier integrity during MRSA infection alone or in conjunction with pdm2009. Future investigations will also address potential differences between non-differentiated versus differentiated/polarized A549 or primary alveolar cells.

Although we had hypothesized that pre-existing pdm2009 infection may enhance MRSA replication due to the exposure of additional bacterial binding sites on infected cells, this was not observed. Virtually identical bacterial replication kinetics were observed with no significant differences in replication at any time point. This would suggest that MRSA fitness is not altered by cellular damage or host molecule secretion (e.g., cytokines) resulting from pre-existing pdm2009 infection. This also suggests that the increased disease severity associated with influenza-bacterial co-infections is not simply due to increased bacterial burden within the lungs during co-infection.

In contrast to our replication kinetics data, the expression of MRSA virulence factors related to adhesion and invasion were selectively upregulated during the early stages of infection in pdm2009-MRSA co-infected cells as compared to bacterial infection alone. Statistical analysis demonstrated that *hla* and *spA* expression was significantly greater than all of the other virulence factors examined at 1 h post-MRSA infection; however, there were no statistically-significant differences in expression between virulence factors from 4 h onwards. Increased expression of virulence factors during pdm2009-MRSA infection as compared to MRSA-alone was inversed, as virulence factor expression in the co-infected samples was repressed as compared to MRSA-alone. This is perhaps unsurprising given that we focused on virulence factors related to bacterial adhesion and invasion. The MRSA *hla* gene codes for α -hemolysin, which forms pores in the cytoplasmic membrane of infected cells, resulting in lysis [49]. Expression of *hla* was ≥ 16 -fold higher at 1 h post-infection, but rapidly declined by the 4-h time point. This may suggest a critical role for *hla* in the immediate stages of secondary MRSA infection pathogenesis and may contribute to co-infection pathogenesis, as α -hemolysin is related to clinical pneumonia [24,50]. Similarly, *fnbB* and *spA*, which are both involved in cell adhesion, were upregulated in the co-infected cells as compared to MRSA-alone from 1–4 h post-infection. Fibronectin-binding protein B, encoded by *fnbB*, is able to bind fibronectin, fibrinogen, and elastin in order to mediate adhesion to cells, specifically for internalization of MRSA [51,52]. Protein A, the product of *spA*, mediates binding and adhesion to airway epithelial cells, while also being able to repress innate and adaptive immune responses [53]. Our data suggest that pdm2009 infection of alveolar epithelial cells results in cellular damage and subsequent exposure of host molecules (e.g., fibrinogen, elastin, and fibronectin) in the extracellular matrix and plasma membrane, resulting in the upregulation of MRSA binding factors, including FnbB and SpA. In contrast, the relative expressions of *icaA*, *ebpS*, and *clfB* were all repressed as compared to infection with MRSA-alone throughout the course of our investigation. The *ica* locus is involved in intracellular adhesion and encodes N-acetylglucosaminyltransferase [54,55]. The *ebpS* gene is able to bind elastin in injured tissues, facilitating bacterial colonization [56], and *clfB* mediates fibrinogen [57]. Our data suggest that specific bacterial adhesion and invasion factors may provide an advantage for bacterial entry into influenza-infected cells. Future investigations of the relation between targeted inhibition of *fnbB*, *hla*, and *spA* and co-infection pathogenesis in alveolar epithelial cells are warranted and may provide important information regarding novel antimicrobial therapeutic targets. However, our data also suggest that there is likely no competitive advantage for expression of adherence and invasion-related bacterial virulence factors post-entry between pdm2009-MRSA infection and MRSA-alone infection.

Further analyses of additional bacterial toxins and virulence factors may provide evidence for bacterial molecules that are related to post-bacterial adhesion/invasion co-infection pathogenesis.

Although our data suggested that the role of bacterial virulence factors in pdm2009-MRSA infection is likely important for early bacterial attachment and entry events alone, our host kinome response data suggested that host response dysregulation plays an integral role in co-infection pathogenesis. We examined this by characterizing the temporal host kinome response of alveolar epithelial cells in response to co-infection. Interestingly, the host response of co-infected cells clustered most strongly with those from pdm2009-alone infections during the early stage of infection. This was perhaps surprising, as the greatest difference in relative expression of bacterial virulence factors, including those with immunomodulatory activities (e.g., SpA), occurred early during the course of co-infection. A previous investigation by Kumar et al. demonstrated that stimulation of epithelial cells with SpA resulted in the induction of TNF α and IL8 secretion and activation of NF κ B signaling [58]. While the host response in our co-infected cells was dominated by antiviral-related signaling responses during the early course of infection, GO analysis demonstrated that IL6-, IL8-, TNF α -, and NF κ B-mediated signaling events were overrepresented in the co-infected samples, although absent in our MRSA-alone and pdm2009-alone infected cells. The upregulation of these signaling events corresponds with the upregulation of *spA* expression in the co-infected samples as compared to MRSA infection alone. This suggests that while the early host response during co-infection is largely dominated by the induction of antiviral responses, the upregulation of bacterial virulence factors might have an underlying influence on the induction of host cell cytotoxic responses. Interestingly, direct comparison of host kinome responses during pdm2009-MRSA infection to those from cells infected with MRSA-alone suggest that a stronger apoptotic response is found in co-infected cells as compared to bacteria-alone during the 8–12 h transition phase. This comparison supports the postulate that influenza-bacterial co-infections specifically alter host cellular responses as compared to either pathogen alone. Focused in vivo and in vitro investigations of the contributions of host response dysregulation, and in particular modulation of alveolar epithelial cell apoptosis, may provide important clues to the molecular mechanisms underlying the pathophysiology of influenza-bacterial co-infections. Future investigations will explore potential roles for the modulation of IFN-mediated cell signaling responses to pdm2009-MRSA infection pathophysiology. In particular, does modulation of the secretion of soluble host factors during pdm2009 infection impact downstream virulence factor expression patterns in MRSA?

In contrast, the kinome data (following background subtraction of the mock-infected samples) from co-infected cells clustered strongly with those derived from MRSA-alone infections from 16 h post-MRSA addition onwards, and this was reflected in strong upregulation of cell death responses (e.g., apoptosis-related pathways) in both infection conditions. From 8–12 h post-MRSA infection, host kinome data from the three different infection conditions clustered together. Taken together, our clustering data suggest that the host response transitions from an influenza- to bacterial-centric response during infection. Importantly, this transition phase in the host response corresponded with mid- to late-exponential MRSA growth. These data largely overlapped with the observations from our ECIS analysis of pdm2009-MRSA co-infection. The addition of pdm2009-alone to the alveolar epithelial cells at a low MOI of 0.1 did not result in a significant decrease in resistance, nor any negative repercussions in regards to barrier integrity and cell morphology. This reflects the majority of influenza infections in healthy adults, which do not generally result in severe disease [4–6]. However, the addition of high MOI pdm2009 resulted in significantly decreased barrier integrity and may reflect a relation between exacerbated disease and infectious titer of the exposure. In contrast, the addition of MRSA resulted in significant decreases in resistance and eventual loss of alveolar epithelial barrier integrity across all tested MOIs. Clinically, MRSA colonization is known to occur in healthy, young adults and may lead to overt infections, such as pneumonia [59,60]. Additionally, the development of bacterial pneumonia is known to result in inflammation of the lungs and hypoxemia, a direct result of cell barrier failure [61]. Resistance measurement trends were nearly identical between the

MRSA-alone and pdm2009-MRSA infections following the addition of MRSA. These data suggest that while pdm2009, and potentially other influenza A viruses, may provide for increased adhesion and/or attachment of bacteria to the surfaces of infected epithelial cells, disruption of alveolar epithelial cell barrier function appears highly dependent on the induction of bacterial- or host cell-mediated cytotoxicity. Although the host kinome data suggest a major host-response effect, we do not exclude the possibility that bacterial-mediated cytotoxicity may still play a direct role in alveolar epithelial cell barrier dysfunction. Future investigations will focus on comparisons of host responses between these two regions of the respiratory tract during influenza-bacterial co-infection. Although our ECIS data suggest that the differential expression of bacterial virulence factors did not augment alveolar epithelial cell barrier disruption, the roles of these virulence factors in additional post-infection processes in the lung remain to be determined. These include damage to the underlying endothelium at the alveolar-capillary barrier and the disruption or attenuation of host leukocyte recruitment and immune responses within the lung.

5. Conclusions

Although bacterial co-infections can exacerbate influenza virus infections and result in severe or fatal disease, there is a paucity of information regarding the molecular mechanisms underlying the pathogenesis of co-infections. Our data demonstrated that while bacterial replication kinetics were similar in MRSA- and pdm2009-MRSA-infected cells, the expression of bacterial virulence factors related to adhesion and invasion were significantly upregulated during the early course of co-infection. Further, our analysis of temporal host kinome responses demonstrated that host cell signaling responses shifted from viral- to bacterial-centric throughout the course of co-infection with a transition phase in the response from 8–12 h post-MRSA addition to pdm2009 infected cells. This related well to the loss of alveolar epithelial barrier function and integrity during IAV, MRSA, or co-infection as demonstrated by ECIS.

Supplementary Materials: The following are available online at <http://www.mdpi.com/1999-4915/11/2/116/s1>. Figure S1: MRSA replication kinetics during bacterial infection and influenza-bacterial co-infection in HBEC-3KT cells. Figure S2: pdm2009-MRSA infection decreases barrier function in bronchial epithelial cells. Table S1: MRSA RT-qPCR primer sequences; Table S2: Pathway overrepresentation analysis of host kinome responses in infected samples (8–12 h post-MRSA infection); Table S3: Pathway overrepresentation analysis of differentially-upregulated host kinome responses in pdm2009-MRSA infected cells vs. MRSA infection alone (8–12 h post-MRSA infection). Table S4: GO analysis of host kinome responses in infected samples (8–12 h post-MRSA infection).

Author Contributions: J.K. and D.S.C. conceived of the ideas presented herein. M.E.N., J.C., and S.D.F. performed the described experiments. M.E.N., J.C., S.D.F., D.S.C., and J.K. analyzed the data. M.E.N., J.C., S.D.F., D.S.C., and J.K. performed the drafting and revising of the manuscript.

Funding: M.E.N. is funded by a Research Manitoba Master's Studentship Award. J.K. is funded by a Tier 2 Canada Research Chair in the Molecular Pathogenesis of Emerging and Re-Emerging Viruses provided by the Canadian Institutes of Health Research (Grant No. 950-231498) and a Research Manitoba New Investigator Operating Grant (Grant No. 3531).

Conflicts of Interest: The authors declare no conflict of interest.

A year of terror and a century of reflection: perspectives on the great influenza pandemic of 1918–1919

Michaela E. Nickol and Jason Kindrachuk^{*}

Abstract

Background: In the spring of 1918, the “War to End All Wars”, which would ultimately claim more than 37 million lives, had entered into its final year and would change the global political and economic landscape forever. At the same time, a new global threat was emerging and would become one of the most devastating global health crises in recorded history.

Main text: The 1918 H1N1 pandemic virus spread across Europe, North America, and Asia over a 12-month period resulting in an estimated 500 million infections and 50–100 million deaths worldwide, of which ~ 50% of these occurred within the fall of 1918 (*Emerg Infect Dis* 12:15–22, 2006, *Bull Hist Med* 76:105–115, 2002). However, the molecular factors that contributed to the emergence of, and subsequent public health catastrophe associated with, the 1918 pandemic virus remained largely unknown until 2005, when the characterization of the reconstructed pandemic virus was announced heralding a new era of advanced molecular investigations (*Science* 310:77–80, 2005). In the century following the emergence of the 1918 pandemic virus we have landed on the Moon, developed the electronic computer (and a global internet), and have eradicated smallpox. In contrast, we have a largely remedial knowledge and understanding of one of the greatest scourges in recorded history.

Conclusion: Here, we reflect on the 1918 influenza pandemic, including its emergence and subsequent rapid global spread. In addition, we discuss the pathophysiology associated with the 1918 virus and its predilection for the young and healthy, the rise of influenza therapeutic research following the pandemic, and, finally, our level of preparedness for future pandemics.

Keywords: Influenza, Pandemic, Pneumonia, Therapeutics, Preparedness, 1918 Spanish flu

Background

Influenza viruses have posed a continual threat to global public health since at least as early as the Middle Ages, resulting in an estimated 3–5 million cases of severe illness and 291,243–645,832 deaths annually worldwide, according to a recent estimate [1]. Regional influenza epidemics occur on an annual basis, resulting in millions of illnesses and hospitalizations despite intensive vaccination and awareness programs [2, 3]. Moreover, influenza pandemics arise sporadically due to the introduction of an antigenically-distinct influenza A virus within a population, which can result in devastating effects on global

public health and healthcare networks. The emergence of influenza subtype H1N1 in 1918, which ultimately resulted in an estimated 50–100 million deaths worldwide, would forever change the course of human history and will be discussed in detail in the following sections [4–6]. The aims of this short review are to discuss: i) the emergence and spread of the 1918 virus; ii) the unique severity of disease in young, healthy individuals; and iii) the subsequent influence of the pandemic on influenza virus therapeutic and future preparedness.

Main text

General influenza epidemiology

It is postulated that 10% of the worldwide population is infected by an influenza virus each year, resulting in a total economic burden of \$87.1 billion USD [7, 8]. As a

testament to the significant toll posed by influenza on public health and healthcare systems, the US Centers for Disease Control and Prevention (CDC) estimated that from 2010 to 2015, influenza infections resulted in 9.23–35.6 million illnesses and 139,000–707,000 hospitalizations annually in the US alone [9]. It has been suggested that children are likely the primary transmitters of influenza [10]. Lethal influenza infections are primarily associated with high risk populations, including infants (< 1 year), the elderly (> 65 years), and individuals with pre-existing comorbidities, including chronic respiratory abnormalities, cardiac disease, immunodeficiency, and pregnancy [11, 12]. Mortality in children and young adults is generally low [3]. Symptoms manifest as a sudden high fever, headache, pharyngitis, cough, myalgia, nausea, vomiting, and fatigue, which generally resolve within 7 days in healthy adults [11, 13]. Severe and/or lethal disease is typically associated with viral pneumonia or secondary bacterial infections in the lower respiratory tract [3].

A history of influenza pandemics

To be considered a pandemic, an influenza virus must: i) spread globally from a distinct location with high rates of infectivity resulting in increased mortality; and ii) the hemagglutinin (HA) cannot be related to influenza strains circulating prior to the outbreak nor have resulted from mutation [14, 15]. It should also be appreciated that prior to the first isolation of a human influenza virus in 1933, the cause of influenza outbreaks and pandemics could only be inferred based on physiological symptoms of disease, along with the speed and breadth at which illness was spread [15].

As early as 412 BC, Hippocrates, the father of modern medicine, described the first known account of an influenza-like illness in his sixth “Book of Epidemics” [16, 17]. Here, he recounted an annual recurring upper respiratory tract infection characterized by pharyngitis, coryza, and myalgia which peaked around the winter solstice [18]. This seasonal epidemic occurred in Perinthus, a northern port town located in what is now Turkey, and is referred to as the “Cough of Perinthus” [16]. It has been suggested that potential pandemics may have occurred in 1510 and 1557; however, it is unanimously agreed that the first documented influenza pandemic occurred in 1580, resulting in high morbidity [15, 19]. The virus originated in Asia, before spreading to Africa, and then simultaneously spreading from both continents to Europe. It reportedly spread across the entire European continent within 6 months, before eventually reaching the Americas [19, 20]. Two pandemics were recorded in the eighteenth century. The first began in Russia in 1729, eventually moving across the entirety of Europe within 6 months and, ultimately, across the known world

over the following 3 years [20–23]. The second pandemic began in China in 1781, before spreading to Russia and, subsequently, across all of Europe. Interestingly, this second pandemic had a high proclivity for young adults [24]. Two major pandemics also occurred throughout the nineteenth century. The first began in 1830 in China, with subsequent spread to Southeast Asia, Russia, Europe, and North America and had a low overall mortality rate [15, 19, 20, 23]. A second pandemic emerged in Russia in 1889 and spread rapidly to Europe and North America, circumnavigating the globe in just 4 months [25, 26]. The virus, suggested to be of subtype H3N8, reappeared at least 3 more times in successive years resulting in an estimated 1 million global fatalities [20, 23, 26, 27].

Four influenza pandemics have occurred over the past century (Fig. 1). The 1918–1919 Spanish flu pandemic, subtype H1N1, resulted in an estimated 50–100 million deaths worldwide and will be discussed in detail in the following sections. The 1957–1958 Asian flu pandemic, subtype H2N2, originated in China in February 1957 and spread throughout Asia and then globally by the summer. Case fatality rates were approximately 0.67% with 1–2 million deaths worldwide [20, 28–31]. Just a decade later, the 1968–1970 Hong Kong flu pandemic, subtype H3N2, emerged in China in July 1968 and spread throughout Europe, North America, and Australia by early 1969 [25]. Although mortality rates were low, the pandemic would ultimately claim between 500,000 and 2 million lives [25]. In April 2009, the 2009–2010 swine flu pandemic, subtype H1N1, began with nearly simultaneous outbreaks in Mexico and the US, before spreading globally over the next 6 weeks. While the 2009–2010 pandemic had a low associated case fatality rate, resulting in 284,000 deaths worldwide, it had devastating effects on global economies and healthcare networks [25, 32]. Conventionally, influenza pandemics result in the extinction of previously circulating virus strains; however, this view was complicated by events in 1977. Although H1N1 was replaced by H2N2 as the circulating strain following the 1957–1958 Asian flu pandemic, a descendant of the 1918 virus “re-emerged” suspiciously in 1977, likely as a result of a man-made event, and established itself as a co-circulating strain, along with the reassortant H3N2 virus (following the 1968–1970 Hong Kong flu pandemic) [4, 33]. The suspicious “re-emergence” of a descendant of the 1918 virus in 1977 has been postulated to have been the result of a man-made event. This hypothesis has gained traction, as both the HA and NA of the re-emerged virus show incredible similarity to a 1950 reference virus, and it is unlikely that this strain was maintained in an animal reservoir for almost two decades without having undergone detectable mutation [33]. In 2009, a triple

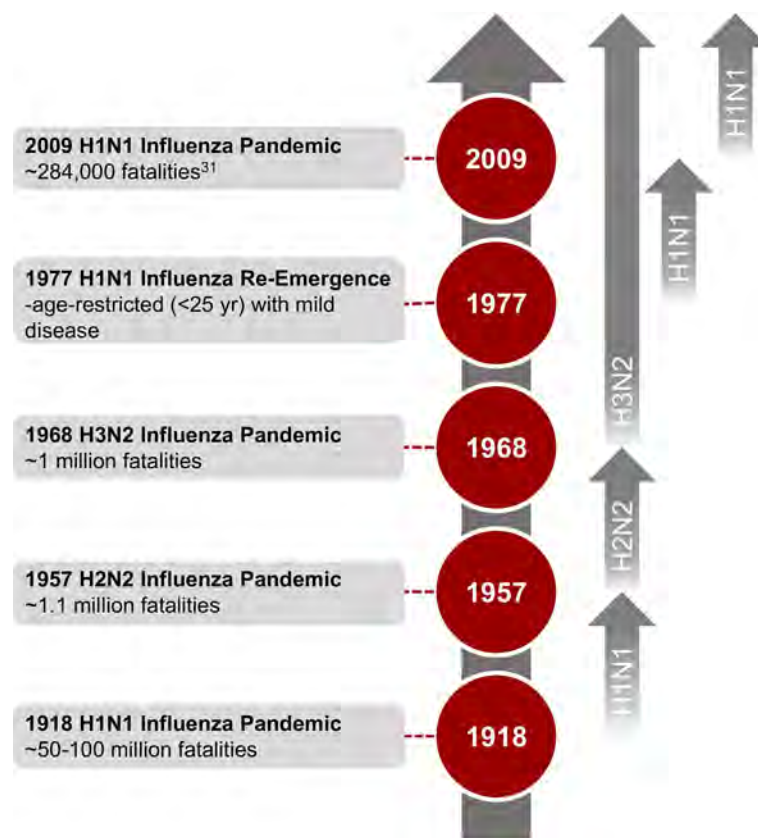

Fig. 1 Timeline of Influenza Pandemics from 1918 Onwards. Four pandemics have occurred over the last century (1918, 1957, 1968 and 2009). Circulation of H1N1 was reinitiated in 1977 and has therefore been added to this timeline. Grey arrows designate the circulating or co-circulating strains during the inter-pandemic periods

reassortment (made up of avian, swine, and human influenza genes) pandemic H1N1 jumped from pigs to humans, resulting in the co-circulation of three influenza strains [34].

The first wave of the 1918 pandemic

One hundred years following its emergence, the origin of the 1918 pandemic influenza virus remains shrouded in mystery. The 1918 pandemic began early in the final year of the First World War. Whereas prior pandemics had spread largely along trade routes, the global context of the war enabled greater viral spread facilitated by the mass mobilisation of military personnel and civilians [25, 35]. This was further augmented by the poor health and sanitation conditions found within trenches along the frontlines of the War, facilitating disease transmission [36]. Public knowledge regarding the severity of the pandemic was hindered, as many news agencies were barred from writing about the global health threat, instead reporting solely on morale boosting subjects [37]. However, as Spain was a neutral party in the War, newspapers were able to report on the devastating effects that the 1918 pandemic virus was exhibiting in Spain. Thus, it was

generally perceived that this devastating illness originated in Spain, resulting in the pandemic being incorrectly labeled as “the Spanish flu” [37].

A century following its emergence, there remains a relative paucity of knowledge regarding the ancestry and regional origin of the 1918 virus. Sequence analysis suggests that the virus was derived from an avian-like influenza virus and that all eight gene segments likely evolved in parallel [34, 38]. Analyses of influenza virus genome sequences also suggest that the initial entry of the 1918 precursor virus into human circulation began in 1915 and did not appear to have jumped directly from an avian source [4, 38, 39]. However, improved understanding regarding the emergence of the 1918 virus, as well as factors (biological, social, environmental) that contributed to viral transmission and pathogenesis, have been vital to the development of current epidemic and pandemic influenza outbreak response efforts. Descendants of the 1918 pandemic influenza virus strain have been the cause of almost every seasonal influenza A infection worldwide over the past century [4]. Additionally, each of the pandemics occurring in 1957, 1968, and 2009 were caused by descendants of the 1918 pandemic

influenza virus strain, earning the 1918 viral strain the nickname “The Mother of all Pandemics” [4].

Investigations concerning the origins of the first wave of the pandemic, beginning in March 1918, have primarily focused on the US and China, though recently it has been suggested that the origin may have been an outbreak of a respiratory disease misidentified as pneumonic plague in China [15, 36, 40]. Humphries suggests that the dissemination of labourers from China to assist Allied war efforts during this outbreak resulted in the inadvertent spread of the virus to Europe [36]. From 1916 to 1918, the route of travel to Europe for the labourers included checkpoints in Singapore, Durban, Cape Town, North Africa, and Canada. Additional reports of the first wave of the virus in the spring of 1918 suggest that the pandemic originated with Chinese workers at Camp Funston, Kansas, where the workers began suffering from 2 to 3 day fevers, gastrointestinal symptoms, and general weakness [37, 41]. Within 3 weeks 1100 soldiers had been hospitalized, and thousands more had received out-patient treatment [41]. The illness was able to spread to other military camps within the US, before traversing the Atlantic Ocean via soldiers supporting Allied operations in Europe. The US Army reported that from March–May 1918, 11.8% of US soldiers were

hospitalized due to this unidentified respiratory illness [41]. While illness rates were high during this initial wave, mortality rates were largely similar to seasonal outbreaks of influenza. Spain reported that the mortality rates for pneumonia and influenza was only 0.065% [37]. Although there was some acceptance that this new illness was indeed influenza, this was not generally accepted [37]. Radusin reported that although the physiological symptoms were similar to influenza, the illness was too mild and short-lasting with minimal complications for it to be influenza [37]. Infections began to subside in many regions by the early summer [41]. The generally accepted lines of spread of the first and second waves of the 1918 virus are provided in Fig. 2.

The second and third waves of the pandemic

In mid-August of 1918, reports suggesting a second wave of this severe illness began to surface [35]. In some regions, primarily Northern Europe, the period between the end of the first wave and the beginning of the second wave was incredibly short, making the two waves almost indistinguishable [4, 42]. This second wave, occurring from September–November 1918, was responsible for the majority of illnesses and fatalities associated with the pandemic. Although the origins of the first wave

Fig. 2 The First and Second Waves of the 1918–1919 Pandemic. First outbreaks and foci of second waves of the pandemic are labeled as red and purple circles, respectively. The lines of spread of the first and second waves of the pandemic are labeled as purple dashed lines and red solid lines, respectively. Map images were derived and/or modified from Servier Medical Arts under a Creative Commons Attribution 3.0 Unported License. Adapted from Nicholson et al. [80]

continue to be debated, the origin of the second wave is generally agreed to be the harbour town of Plymouth in Southern England, which allowed the pandemic influenza virus strain to easily spread to the rest of the world [25]. Ships from Plymouth were dispatched to Freetown, Sierra Leone in August 1918, which allowed the virus to spread across the African continent [25]. New Zealand soldiers, who stopped in Freetown on their way to and from the war front in Europe, facilitated transfer of the pandemic virus to New Zealand [25]. From Plymouth, the virus also spread to Boston, from which it was able to disseminate across the rest of North America resulting in >1 million fatalities over the ensuing four months [5, 25]. This second wave spread globally throughout the fall of 1918 with illness seen first amongst military personnel and, subsequently, within the general population [25, 35].

The second wave of the 1918 pandemic differed from the first in that much higher morbidity and mortality rates were reported, with the majority of all fatalities associated with the pandemic occurring during this wave [4]. Ultimately, the pandemic would result in an estimated 500 million infections worldwide (~1/3 of the world's population at the time) and a case fatality rate >2.5%, more than 25 times higher than any other pandemic [4, 37]. As a testament to the severity of this second wave, during the fall of 1918, the first 4–5 pages of Spanish newspapers were filled with obituaries of those who had succumbed to the pandemic virus [35]. Further, reports from Philadelphia, Pennsylvania stated that across 31 hospitals in the city, every hospital bed was occupied by patients with influenza [35]. The pandemic was especially problematic in highly isolated communities where many individuals had limited contact with prior influenza strains, thus lacking any pre-existing immunity. For example, some Inuit settlements reported case mortality rates as high as 70%, while certain communities in Africa were completely decimated [35]. Interestingly, individuals who had been infected throughout the first wave seemed to be protected against this secondary wave, and recent analyses have suggested that these individuals had up to 94% protection throughout the fall wave [4, 41].

A third and final wave of the pandemic appeared in most of the world in the early months of 1919 [4, 5, 35]. This final wave generally overlapped the first wave in terms of regional distribution; however, it seemed to spare areas where the second wave had been especially severe. Overall, morbidity rates were lower throughout this final influenza wave; however, mortality rates are believed to have been just as severe as the second wave [4, 35]. Three successive annual winter post-pandemic

recurrences occurred following the third wave of the pandemic with continually decreasing mortality rates, in particular within those 20–40 years of age [43].

Pathophysiology of the 1918 pandemic influenza virus

Classically, fatal influenza infections are primarily associated with the very young (<5 years) and the elderly (>65 years) resulting in a characteristic “U”-shaped mortality curve (Fig. 3). Interestingly, however, the 1918–1919 H1N1 influenza pandemic mortality curve exhibits a “W”-shape due to excess mortality in young adults 20–40 years of age due to influenza-related illness. It has been postulated that the increased disease severity in young adults was likely associated with immune status due to the lack of pre-existing immunity in this population [44]. Further, more than 99% of fatal infections occurred in those <65 years of age and nearly 50% of all influenza-related deaths during the 1918 pandemic were in those aged 20–40 years [4]. Influenza and pneumonia fatality rates in those aged 15–34 years were more than 20 times higher than in previous years and absolute risk of influenza-related death was higher in those <65 years of age than those >65 years old [4]. It is still not fully understood why this occurred, but it is possible that an antigenically similar influenza strain circulated prior to 1889, providing a level of protection against the novel H1N1 pandemic strain to those born prior to 1889 [4]. Additionally, archaerological and epidemiological evidence have shown that an H3 subtype influenza virus may have been responsible for the 1889 influenza pandemic, which circulated until the emergence of the 1918 pandemic virus, leaving those individuals who had not been exposed to an H1 subtype virus highly susceptible to the pandemic virus [34]. It has also been suggested that the generation of an excessive inflammatory response (“cytokine storm”) in healthy, young adults infected with the 1918 virus may have contributed to the excess mortality seen within this age group [34]. Recent in vivo studies with the 1918 virus have shown a marked upregulation of inflammatory cytokines, along with the suppression of important antiviral immune responses [34, 45]. In addition, other influenza strains, such as fatal H5N1 infections in humans, have also been associated with the deleterious consequences of an excessive inflammatory response [46]. Ultimately, the case fatality rate was so severe in young adults during the 1918–1919 pandemic that the average life expectancy rate in the US dropped by ~12 years [47].

Physiological symptoms of the 1918 pandemic virus generally lasted for 7 days and were described as feeling cold, shivering, high fever, weakness, nausea, loss of appetite, pharyngitis, cough, and bloodshot eyes [35]. In some patients, a short “rebound” to normal health would occur that was followed by an aggressive recrudescence

Fig. 3 Association of Age with Influenza Mortality Prior to and During the 1918–1919 pandemic. Influenza- and pneumonia-specific mortality in the United States is plotted for 1911–1917 (blue line) and for 1918 (red line) [81, 82]. Means with standard deviations are presented for the pre-pandemic mortality curve. Adapted from Taubenberger and Morens [4]

of disease and, ultimately, death [35]. Similar to the 1889 pandemic, the majority of fatal infections resulted from respiratory complications. However, it has also been demonstrated that excess influenza fatalities during the 1918–1919 pandemic were associated with an acute aggressive bronchopneumonia (including epithelial and vascular necrosis, hemorrhage, edema, and bacterial-associated variant pathology within the lungs) and a severe acute respiratory distress-like syndrome associated with severe facial cyanosis [43].

Autopsies performed on preserved lung tissues in the modern era have revealed acute pulmonary hemorrhage and secondary bacterial infections associated with pulmonary lesions in nearly all the fatal cases examined [41, 43, 47]. *Streptococcus pneumoniae* was present in many cases; however, *Staphylococcus aureus*, *Haemophilus influenzae*, and *Streptococcus pyogenes* also appeared to complicate fatal cases [48, 49]. Neutrophilic pulmonary infiltration was seen in cases of pneumococcal pneumonia, while cases of staphylococcal pneumonia were marked by multiple microabscesses infiltrated by neutrophils [48]. However, alveolar cell damage was seen in each case along with pulmonary repair and remodelling [48]. Tissues from each of the fatal cases examined had similar pathologic presentation, independent of which pandemic wave they were associated with. Despite the difference in mortality rates, each wave showed similar cellular tropism, infecting both type I and type II pneumocytes, as well as the bronchiolar respiratory epithelium [48].

The rise of vaccines and antivirals following the 1918–1919 pandemic

A multitude of scientific and technological advances have occurred over the past century, allowing for a greater understanding of the dynamic relationship between the host and influenza viruses during infection. These advances, along with access to autopsy samples and the reconstitution of the 1918 pandemic virus, have facilitated a greater understanding of how the pandemic virus differs from other seasonal and pandemic influenza virus strains. Moreover, technological advancements following the 1918–1919 influenza pandemic virus have facilitated the development of preventative measures, including vaccines and antivirals, to limit widespread illness due to influenza infections.

The determination of the genomic sequence of the 1918 pandemic virus, and the subsequent reconstruction of the virus, has provided us with the opportunity to decipher the viral- and host-specific properties that contributed to the severity of the 1918–1919 pandemic. It has been demonstrated that in contrast to other influenza viruses, the 1918 pandemic virus is highly virulent and pathogenic in multiple animal species without prior adaptation [45, 50]. While obvious knowledge gaps remain, in particular with respect to the origin of the virus and the molecular mechanisms (host and/or viral) underlying differential pathogenesis as compared to other influenza viruses, there have been considerable advances in our understanding of the 1918 pandemic virus.

Since the isolation of the first human influenza virus in 1933, researchers have worked to develop an effective influenza vaccine [16]. Current influenza vaccines are reformulated seasonally and provide protection against circulating influenza A and B viruses [13]. The World Health Organization conducts worldwide surveillance studies throughout the year on currently circulating influenza strains, and thus recommends which strains should be included in each influenza vaccine [13]. While the seasonal influenza vaccine is approximately 60% effective, this protection is dependent on the characteristics of the individual being vaccinated, including age and overall health, as well as the match between the strains included in the vaccine formulation and currently circulating strains [13]. Individuals who have been vaccinated are generally protected from illness and provide a measure of protection for those who are not able to be vaccinated due to their age or other health issues through herd immunity [13]. There has also been increasing interest in the development of “universal” influenza vaccines designed to provide protection against a wide range of antigenically-distinct influenza viruses, including those currently in circulation and those that may emerge in the future [51]. These will not be discussed in detail as recent reviews have provided excellent discussions of this topic [51–57].

Two major classes of antivirals have emerged for therapeutic treatment of severe influenza virus infections. Adamantane antivirals target the matrix-2 (M2) surface protein, while neuraminidase (NA) inhibitors target the NA viral surface protein. Adamantane compounds were the first licensed influenza antivirals and block the M2 ion channel protein from properly functioning, thus effectively blocking membrane fusion [58, 59]. Unfortunately, adamantane antivirals are only able to target influenza A viruses limiting their application for influenza B virus infections [58]. Further, more than 90% of influenza A viruses are resistant to this class of drugs due to the high mutation rate of the virus [58, 60]. Thus, the use of NA inhibitors is recommended [60]. NA inhibitors block the NA surface protein and prevent the release of progeny virus and infection of additional cells [60]. While resistance to NA inhibitors has been observed in some influenza virus strains, they are still highly effective in the majority of patients [60]. Studies have shown that both adamantane antivirals and NA inhibitors provide protection against the 1918 virus [50].

Although outside the auspice of this commentary, it should be mentioned that advances in mechanical ventilation modalities, including non-invasive positive pressure ventilation, from the 1950s onwards, have provided an additional support mechanism for treatment of severely ill patients [34]. The routine clinical use of antibiotics in the early twentieth century also heralded a new

era for combating influenza viruses. As a testament to this, excess influenza mortality declined significantly from 1942 to 1951 onwards [61–63]. However, the widespread general administration of antibiotics has resulted in an escalating public health crisis due to multi-drug resistance. This has impacted the treatment of severe influenza infections, as methicillin-resistant *S. aureus* (MRSA) is the most frequently isolated bacteria from patients with severe influenza-bacterial co-infections in the US [64, 65] and complicated up to 55% of fatalities during the 2009 pandemic [66–69].

Influenza preparedness and lessons for the future

Although it has now been a century since the start of the Spanish flu pandemic, lessons from this global health catastrophe continue to inform modern-day pandemic preparedness. Investigations of the pandemic, including those with the reconstructed virus, have allowed researchers, as well as the global public, to understand the mechanisms that underlie pandemic emergence and escalation to public health crisis. It also allows researchers to predict the potential public health risks which may be caused by new pandemic viruses. For example, sequencing of the 1918 pandemic virus revealed similarities in the H1 protein of the 2009 pandemic virus, allowing researchers to predict that a lack of protection, and thus a high mortality rate may be seen in healthy, young adults throughout the 2009 H1N1 pandemic [45]. Thus, when vaccines were limited during the early stages of the 2009 pandemic, young adults were prioritized over the elderly, who demonstrated some degree of protection to this influenza strain, resulting in a lower mortality rate in young, healthy adults [45]. The average age for laboratory-confirmed fatalities during the 2009 pandemic was 37 years in the US, supporting this vaccine prioritization initiative [70]. Additionally, the awareness of the complications caused by secondary bacterial co-infections from the 1918 pandemic ensured that the medical community was aware of this threat throughout the 2009 pandemic, likely resulting in a reduced mortality rate due to severe influenza infections with complications [45].

However, the 2009 pandemic, albeit milder than previous pandemics in terms of overall mortality, resulted in significant strains on global healthcare networks and economies [25]. In Canada, direct healthcare costs (including hospitalizations, outpatient visits, and therapeutics) related to the 2009 pandemic have been estimated at \$2 billion CAD, with \$250 million CAD related directly to hospital care [71]. A computational modeling study by Smith and colleagues suggested that direct costs related to illness would be between 0.5–4.3% of GDP in the UK for pandemics ranging from low to extreme [72]. Further, the 2002–2004 severe acute

respiratory syndrome outbreak resulted in ~\$1 billion total GDP loss in Toronto alone [73]. This highlights the importance of pandemic preparedness beyond a healthcare-centric approach to one that also includes downstream economic effects.

The 1918–1919 pandemic resulted in incredible improvements to public health as well as scientific advances. However, our current understanding of influenza viruses, and their ability to cause illness in humans is still in its infancy in many aspects, and further underlines our inherent need for continued influenza research. The identification of key molecular determinants involved in the pathophysiology of severe influenza infections will also assist drug discovery and development strategies, including insights on appropriate timing for administration of antivirals and/or antibiotics. The development of efficacious broader-spectrum or “universal” influenza vaccines is also of incredible importance. The emergence of novel highly pathogenic avian influenza (HPAI) viruses, including H5 and H7 subtypes, are of particular concern due to their pandemic potential. Circulating HPAI viruses are of potential concern to global public health [74]. Asian lineage avian influenza A (H5N1), which circulates in fowl, is rarely found in humans but has resulted in life-threatening cases when able to establish stable lineages [74] and H7N9 has resulted in sporadic human infections in China resulting in > 1500 infections with an estimated 39% case fatality rate since 2013 [75]. Because HPAI viruses can arise from previously known low-pathogenicity viruses with only minor mutations, it is important to be vigilant concerning these potential pandemic viruses [76, 77].

Conclusions

In spite of the public health advancements in the 100 years following the 1918–1919 pandemic, including widespread access in the developed world to an efficacious influenza vaccine, influenza viruses remain a global public health threat. This past year, there were > 55,000 reported influenza infections, 5155 influenza-associated hospitalizations, and 303 deaths across Canada [78]. Further, during the 2016–2017 influenza season, vaccination rates in those 18–64 years of age was only 37 and 69% in those ≥65, both below the national vaccination target of 80% [79]. These data suggest that our continued vigilance against influenza must not only include a “research”-driven focus but also include public outreach and awareness campaigns that increase the general understanding of the healthcare burden associated with influenza infections.

Abstract

Variants of SARS-CoV-2 are evolving under a combination of immune selective pressure in infected hosts and natural genetic drift, raising a global alarm regarding the durability of COVID-19 vaccines. Here, we conducted longitudinal analysis over 1.8 million SARS-CoV-2 genomes from 183 countries or territories to capture vaccination-associated viral evolutionary patterns. To augment this macroscale analysis, we performed viral genome sequencing in 23 vaccine breakthrough COVID-19 patients and 30 unvaccinated COVID-19 patients for whom we also conducted machine-augmented curation of the electronic health records (EHRs). Strikingly, we find the diversity of the SARS-CoV-2 lineages is declining at the country-level with increased rate of mass vaccination ($n = 25$ countries, mean correlation coefficient = -0.72, S.D. = 0.20). Given that the COVID-19 vaccines leverage B-cell and T-cell epitopes, analysis of mutation rates shows neutralizing B-cell epitopes to be particularly more mutated than comparable amino acid clusters (4.3-fold, $p < 0.001$). Prospective validation of these macroscale evolutionary patterns using clinically annotated SARS-CoV-2 whole genome sequences confirms that vaccine breakthrough patients indeed harbor viruses with significantly lower diversity in known B cell epitopes compared to unvaccinated COVID-19 patients (2.3-fold, 95% C.I. 1.4-3.7). Incidentally, in these study cohorts, vaccinated breakthrough patients also displayed fewer COVID-associated complications and pre-existing conditions relative to unvaccinated COVID-19 patients. This study presents the first known evidence that COVID-19 vaccines are fundamentally restricting the evolutionary and antigenic escape pathways accessible to SARS-CoV-2. The societal benefit of mass vaccination may consequently go far beyond the widely reported mitigation of SARS-CoV-2 infection risk and amelioration of community transmission, to include stemming of rampant viral evolution.

Introduction

To date, over 175 million individuals have been infected with SARS-CoV-2 worldwide, and over 2.2 million deaths have been attributed to COVID-19. More than a year and half since the first known case of SARS-CoV-2 infection, the virus continues to evolve in different parts of the

world resulting in emerging variants of concern¹ (e.g. delta variant) with increased transmissibility. Host immune response is a key selective pressure that influences the emergence of novel strains of the SARS-CoV-2 virus in different parts of the world. Understanding the longitudinal trends of SARS-CoV-2 evolution and mapping the mutational landscape of the antigen is imperative to comprehensively combat the ongoing pandemic and future outbreaks²⁻⁴.

Accelerated development of COVID-19 vaccines and mass vaccination rollouts has led to the immunization of over 10% of the world's population (over 800 million individuals fully vaccinated⁵). Sudden immunization of a large fraction of the population at the height of the ongoing pandemic could significantly increase evolutionary pressure on the SARS-CoV-2 virus. However, to date there has been no comprehensive study on the impact of the global vaccination efforts on SARS-CoV-2 evolution. The main axes of the host immune response that have been examined in SARS-CoV-2 infection are the innate immunity⁶, the cell-mediated (i.e. T cell) and humoral or antibody-mediated responses (through B cells)⁷. B cells and T cells are two specialized cell types that undergo junctional recombination somatic hypermutation in antigen receptor genes during their differentiation, which generates extensive diversity within the immune receptor repertoire. B cells can recognize virtually any molecule (proteins, sugars, non-organic, etc.), without antigen presentation, but are largely restricted to exposed surfaces of molecules, a feature that pathogens utilize as an escape mechanism. T cells on the other hand, can generate immunity against epitopes that are buried within the antigen, but are limited to small peptides presented by complex HLA molecules. They are however essential for optimizing neutralizing antibodies through somatic hypermutation and antibody class switching in B cells during an immune response.

Since the beginning of the pandemic concerted global data sharing efforts have led to the rapid development of large-scale genomic COVID-19 resources. Over 1.8 million SARS-CoV-2 genomes from 183 countries and territories have been deposited in the GISAID database⁸. Based on this data, we and others reported that deletion mutations are enriched in the Spike protein N-terminal domain^{3,4}. Similarly, concerted efforts have led to the development of a rich immunological resource of 1.04 million peptide epitopes from over 22,000 studies⁹. Using this data we previously identified epitopes that are identical between the SARS-CoV-2 and the human proteome¹⁰. The availability of genomic and immunological data provides a timely opportunity to systematically characterize the antigenic mutational landscape of SARS-CoV-2.

In this immuno-epidemiology and clinical genomics study, we systematically analyzed the mutational burden of the known B cell and T cell epitopes and found that the prevalence of mutations in neutralizing, conformational B cell epitopes is higher than in neutralizing T cell epitopes. These results demonstrate that the SARS-CoV-2 Spike protein is presently undergoing strong B cell-driven selection pressure, with the variants of concern (particularly Beta and Gamma variants) displaying the most significant recent increases in mutations to known B-cell epitopes. Given that the Spike protein is a key antigen for COVID-19 vaccine-induced protection, as well as the emerging evidence of reasonable distinctions in B cell versus T cell activation by different COVID-19 vaccines¹¹, we prospectively conducted clinico-genomic sequencing of SARS-CoV-2 genomes from vaccinated "breakthrough infections" (n = 26) as well as unvaccinated COVID-19 patients (n = 36). We report that unvaccinated patients share significantly more genomic mutational similarity (particularly B-cell epitope mutations) to the

variants of concern than the breakthrough infection patients. This study demonstrates that mass vaccination may serve as an antigenic impediment to the evolution of fitter and more transmissible SARS-CoV-2 variants, emphasizing the urgent need to stem vaccine hesitancy as a key step to mitigate the global burden of COVID-19.

Results

Diversity of the SARS-CoV-2 lineages is declining significantly with increased rate of mass vaccination

Analysis of the 1.8 million SARS-CoV-2 genomes deposited from 183 countries and territories between Dec. 2019 and May 2021 in the GISAID database⁸ revealed a total of 1296 lineages. We quantified the monthly diversity in SARS-CoV-2 lineages within the GISAID data using Shannon entropy of the lineage probability distribution within 1-month time windows (see **Methods**). The diversity of SARS-CoV-2 lineages has declined globally (**Figure 1a, b**) and this decline appears to coincide with the onset of mass vaccination in the countries (**Figure 1b**). In order to understand the relationship between lineage diversity and mass vaccination, we compared the lineage entropy and vaccination rates, focusing on countries that had at least 25% of their population fully vaccinated, this analysis included 25 countries that had at least 100 SARS-CoV-2 genomes deposited per month for at least four different months. Analysing the relationship between vaccination rates and lineage entropy, we found that the declining diversity of SARS-CoV-2 lineages is indeed negatively correlated with increased rate of mass vaccination across the countries analyzed (**Figure 1c,d**; mean correlation coefficient = -0.72, S.D. = 0.20). Furthermore, the decline in the lineage diversity is coupled with the increased dominance of Variants of Concern: the B.1.1.7/Alpha-variant (45%), B.1.1.617/Delta-variant (21%), P.1/Gamma-variant (10%)¹², suggesting that these variants may be “fitter strains” of SARS-CoV-2.

Neutralizing B-cell epitopes of Spike glycoprotein are enriched for mutations

In order to understand how the lineage diversity is shaped by immune selection pressure, we undertook a systematic characterisation of the mutational landscape of the Spike glycoprotein. We obtained all known neutralizing B cell epitopes and MHC-I and MHC-II T cell epitopes of the Spike protein from IEDB⁹. This included 220 B cell epitopes (involving 282 of 1,273 amino acids), 262 linear MHC class I T cell epitopes (involving 1,034 amino acids), and 140 linear MHC class II T cell epitopes (involving 999 amino acids) (**Figure 2, Methods**). Analysing the 1.8 million genome sequences, a total of 10,946 distinct Spike protein amino-acid mutations were found, occurring in at least 100 genomic sequences.

Comparing the prevalence of mutation per epitope residue (defined here as mutation away from the Wuhan-Hu-1 sequence; see **Methods**) in the known conformational B cell epitopes and a control set of randomly selected amino acids shows a 4.3-fold (3.0-6.1, 95% CI) enrichment of mutations (0.021 mutations per B cell epitope residue, compared to 0.005 mutations per random control residue, over all genomic sequences) (**Figure 2b**). Additional comparisons using randomly selected distance-constrained control sets of amino acids or randomly selected control sets of

amino acids with similar solvent accessibility as B cell epitopes, show comparable enrichment of mutations in the B cell epitopes (**Figure S1**). On the other hand, both MHC class I T cell epitopes (1.0-fold; 0.7-1.5, 95% CI) and MHC class II T cell epitopes (0.9-fold; 0.6-1.3, 95% CI) show no significant enrichment in mutations compared to random control residues (**Figure 2b**). This suggests that the antibody-interfacing antigenic sites are under a stronger selection pressure compared to the T cell binding epitopes.

The rate of B cell epitope mutations has sharply increased, starting December 2021, across all 1.8 million genomic sequences (**Figure 2c**). To ensure that the observed enrichment in B cell mutations is not solely reporting on events in the countries that report the majority of sequences in the GISAID database, we have also evaluated mutations within epitopes per country and territory; a rise in B cell epitope mutations and overall enrichment in mutations within B cell epitopes is observed globally (representative countries shown in **Figure S2**). The observed increase in B cell epitope mutations can be related to the recent dominance of variants of concern. Indeed, analysis of the mutations in the known B-cell epitopes shows that variants of concern have more mutations in B-cell epitopes than sequences that are not variants of concern (**Figure 2d**). The alpha variant (pango lineage B.1.1.7), which is the dominant variant of concern in the GISAID data (**Figure 2e**), shows a 4.3-fold (2.9-6.5, 95% CI) enrichment in mutations within B cell epitopes.

To investigate how increased prevalence of variants of concern relates to the global rise in mutations within B cell epitopes and reduced lineage entropy, we compare the B cell epitope mutation patterns observed in geographical regions over time to those of the variants of concern. A monthly country-level analysis, for the 55 countries with more than 1,000 total genomic sequences deposited to GISAID, shows increased mutation of known B-cell epitopes over time (**Figure 3**). Furthermore, the specific epitopes that are mutated correspond to those that are mutated in the variants of concern. This analysis shows that different SARS-CoV-2 variants have come to dominate in different geographical regions, and that their dominance globally results in increased mutation of antigenic sites.

Whole-genome sequencing of SARS-CoV-2 genomes from unvaccinated and vaccinated individuals reveals different mutational profiles

The immuno-epidemiology analysis presented above based on publicly accessible data has shown that the diversity of the SARS-CoV-2 lineages is declining and that neutralizing B-cell epitopes of Spike glycoprotein are enriched for mutations. However, the genome sequences deposited in publicly accessible databases (e.g. GISAID) lack any clinical or phenotypic data such as vaccination status or disease severity of the linked COVID-19 patients. To address this, we performed whole genome viral sequencing in non-duplicate positive upper respiratory tract specimens 53 SARS-CoV-2 infected patients at the Mayo Clinic health system. Of these, 23 cases were vaccine breakthrough infections, with the infected individuals having been fully vaccinated for COVID-19 at the time of their positive SARS-CoV-2 test (**Figure 4a**). We find that the known B-cell epitopes exhibit more mutational diversity in the unvaccinated individuals than in the vaccinated individuals (**Figure 4b,c**). Furthermore, a larger fraction of the vaccinated (82.6%) cohort had alpha variant compared to the unvaccinated cohort (60%) (**Table S1**). Availability of a

larger number of sequenced genomes in the future can help understand whether specific variants of concern are more likely to cause breakthrough infections.

Of the 53 SARS-CoV-2 infected patients, we have complete longitudinal health records and vaccination history of 47 patients. In **Table S2**, we present the clinical characteristics of the patients with SARS-CoV-2 genomes sequenced in the Mayo Clinic with EHR data available. In the overall cohort of 47 patients, we observe high rates of comorbidities (e.g. cancer: 48.9%, chronic kidney disease: 25.5%) and cardiovascular complications (e.g. cardiac arrhythmias: 40.4%, acute kidney injury: 29.8%, venous thromboembolism: 25.5%). Comparing the vaccinated and unvaccinated cohorts, we observe that vaccinated patients generally had lower rates of comorbidities and complications compared to the overall study population, while the unvaccinated patients generally had higher rates of both comorbidities and complications. Due to the large differences in the rates of comorbidities, we cannot draw any definitive conclusions comparing complications and other clinical outcomes in the vaccinated and unvaccinated cohorts. Considering the clinical data in combination with the genomic data, we do not observe any statistically significant associations between mutation count and rates of complications recorded in clinical notes (**Figure 5**). This preliminary data suggests that the number of mutations that a patient has in the Spike protein region of the SARS-CoV-2 genome does not translate to more or less severe clinical symptoms. As a result, although unvaccinated individuals harbor more viral mutations and also exhibit more COVID-19 complications, these two factors appear to be independent.

Discussion

In summary, our analysis of 1.8 million SARS-CoV-2 genomes shows that there is a 4.3-fold enrichment in mutational prevalence in 220 known neutralizing B cell epitopes. On the other hand, T cell epitopes did not appear statistically more mutated than by chance. This suggests that the antibody-interfacing antigenic sites are under a stronger selection pressure compared to the T cell binding peptide epitopes following vaccination or infection, implying breakthrough mutations and escape mutations have a higher likelihood of occurring in neutralizing antibody-binding residues on the Spike protein.

This result does not mean that T cell immunity is not critical against SARS-CoV-2. Indeed, durable T cell responses emerge following natural infections that are closely linked with antibody responses, reflecting the helper role of T cell help to mount better neutralizing antibodies¹³. Our findings are consistent with antibody and T cell responses to multiple SARS-CoV-2 variants following vaccination with the Ad26.COV2.S adenoviral vector vaccine. A recent study reported similar CD4 and CD8 T cell responses across strains, but reduced neutralizing antibody titers of virus-specific titers for B.1.1.7, CAL.20C, P1, and B.1.351 variants¹¹. Similarly, Geers et al. reported a 2-4 fold reduction in neutralization potential of BNT162b2 mRNA vaccine-induced antibodies against the B.1.351 variant, whereas CD4+ T cell responses elicited by the wild-type Spike protein were unaffected¹⁴. In one recent study, Agerer et al. reported that mutations in CD8 T cell epitopes result in reduced association of mutant peptides with HLA class I molecules *in vitro* leading to altered T cell immune responses¹⁵. While mutation of individual T cell epitopes may alter HLA-peptide interactions and antigen presentation, our data suggest that these mutations

do not represent a common route to viral immune escape, perhaps due to recognition of additional, non-mutated viral peptides and extensive genetic heterogeneity within the HLA genes¹⁶. In our data, we observed a relative paucity of enriched mutations in T cell epitopes, which suggests that T cell responses are likely able to recognize conserved viral sequences, which are less amenable to mutation. These results suggest a greater degree of degeneracy encoded into how the T cell epitopes buffer viral evolution, and suggest an ancient mechanism for immunosurveillance that exploits the inability of mutative viruses to escape such significant host HLA affinity to a fuzzy set of peptides beyond the wildtype peptides engaged on the pathogen. Targeted experimental validation is required, of course, to validate or nullify this speculative hypothesis on how T cell response may buffer viral evolution to durably protect the host species.

Our study has a number of key limitations. First, the list of B cell and T cell epitopes in the Spike (S) glycoprotein antigen studied here may not be exhaustive as they are based on curation of studies deposited in the immune epitope database (IEDB) as of June 10, 2021 (<https://www.iedb.org/>). The immunologic analysis presented in this study consequently has to be updated regularly as more evidence emerges regarding the exhaustive T cell and B cell epitopes presented by the SARS-CoV-2 pathogen and their neutralization potential in the human population. Similarly, the SARS-CoV-2 genomes analyzed herein were deposited in the global initiative on sharing avian influenza data (GISAID) initiative as of June 10, 2021 (<https://www.gisaid.org/>). Despite having over 1 million SARS-CoV-2 genomes at the time of this analysis, GISAID still represents less than 0.60% of the 175 million COVID-19 cases reported worldwide as of June 10, 2021, thus providing only a partial representation of the genomic evolution of SARS-CoV-2. Finally, we consider any mutation away from the wild-type genomic sequence of known immunogenic epitopes as deleterious to their immunogenicity. While it is possible that mutations in the Spike protein sequence result in new immunogenic epitopes, a scan of 469,649 unique mutated peptides identified from the SARS-CoV-2 genomes reveals that only 8 of these peptides match a previously defined T cell epitopes (from IEDB), from within the SARS-CoV and SARS-CoV-2 genomes (**Table S3**). Further work is needed to confirm if any of the novel peptides, resulting from epitope mutations, are also immunogenic.

Despite these limitations, this study presents the first holistic examination, to our knowledge, of the mutational landscape of the B cell versus the T cell epitopes derived from the SARS-CoV-2 S-protein antigen, by juxtaposing the genomic mutation patterns of the pathogen onto all the known neutralizing epitopes. Our finding that T cell epitopes are significantly less mutated than B cell epitopes suggests that vaccines that predominantly rely on T cell immunity would likely bestow a more durable protection against the many SARS-CoV-2 variants of concern that continue to emerge periodically across the globe. Understanding the immunologic basis of vaccine effectiveness and durability to the genomic variations and associated perturbations to antigenic cartography will be critical to reliably inform proactive vaccine design and rollout strategies, and also better inform important public health policy decisions.

A number of recent studies have performed bioinformatic prediction of SARS-CoV-2 epitopes¹⁷. While these studies have identified viral peptide sequences that are likely immunogenic, they generally fail to account for mutational diversity in SARS-CoV-2^{17,18}. Although our work does not directly predict variant neo-epitopes, it highlights the importance of epitopes that are recurrently mutated during viral evolution in response to immune pressure. In future work,

we will more thoroughly investigate strain-level epitopes for variants of concern within these hypermutated regions. We further plan to examine the immune selection pressure across the entire SARS-CoV-2 proteome. While we have focused on viral escape from adaptive immune responses, in future work we will expand on our analysis to consider the interplay between SARS-CoV-2 sequence variation and innate immune responses¹⁹.

Methods

Calculation of SARS-CoV-2 lineage entropy

To quantify the diversity in SARS-CoV-2 genomes over time and in different geographical regions, we have calculated the entropy of the Pango lineage²⁰ probability distribution (**Figure 1a-c**). Specifically, for a given time-period, t , and geographical region, c , the lineage entropy is defined as:

Lineage entropy

$$= - \sum_{l \in \text{all lineages}} \frac{\text{Number of sequences of lineage } l(t, c)}{\text{Total number of sequences}(t, c)} \log \left[\frac{\text{Number of sequences of lineage } l(t, c)}{\text{Total number of sequences}(t, c)} \right]$$

This quantity will be valued at 0 if all genomic sequences are classified as the same lineage, and has an upper-bound of 7.17 if all 1296 possible lineages are equally probable. SARS-CoV-2 lineage data was obtained from the GISAID database⁸. Error bars shown correspond to 95% confidence intervals, obtained by bootstrap sampling of the GISAID sequence data.

Data on country vaccination rates

The percentage of fully vaccinated individuals (**Figure 1c-d**) was obtained from the OWID database²¹. When multiple values for the percentages of fully vaccinated individuals are reported for a country in a month, we use the midpoint ($0.5 \cdot \text{min} + 0.5 \cdot \text{max}$).

Prevalence of mutations per epitope

Prevalence of mutations per epitope (**Figure 2c-e**) is defined as the average probability with which a residue within that epitope is mutated with respect to the Wuhan-Hu-1 sequence (UniProt identifier: P0DTC2). Specifically, we count the total number of mutations within all epitopes of that epitope type, across the 1,844,200 sequences from the GISAID database (**Figure 2c-d**) or only sequences corresponding to variants of concern (**Figure 2e**), and divide by the total number of amino-acid residues that were summed over.

Epitope mutation fraction

The epitope mutation fraction (**Figure 3**) is defined as the fraction of sequences in which a given epitope is mutated with respect to the Wuhan-Hu-1 sequence (UniProt identifier: P0DTC2). Specifically, it is the number of sequences in which an epitope exhibits at least one

mutation, divided by the total number of sequences summed over (i.e., all sequences from a given country in a given month).

Mutational burden on T cell and B cell epitopes of SARS-CoV-2 Spike (S) protein antigen

To assess the mutational burden on T cell and B cell epitopes we have determined the prevalence of mutations per epitope for known epitopes (from IEDB), as compared to various controls. The following controls were used: unrestrained randomly selected sets of amino-acid residues that match the size of the analyzed epitopes (separate size-matched controls for T cell and B cell epitopes, **Figure 2**), randomly selected sets of co-localized residues (**Figure S2**), and randomly selected sets of surface residues (**Figure S2**). For each epitope, a random control set with the same number of amino acids as that epitope is selected. Controls with restraints on localization were generated by measuring the largest pairwise C α -C α distance between residues within a B cell epitope (using a Spike protein homology model using SWISS-MODEL²², unresolved residues were excluded), D . We then selecting a control set of residues such that all residues in the control fall within a sphere of diameter, $D + 4\text{\AA}$. Where use of a 4 \AA buffer region was found to yield a comparable C α -C α distance distribution between epitopes and controls (**Figure S2a-b**). Controls restraint to surface residues were generated by calculating the solvent accessible surface area of each residue within the Spike protein (using the Biopython SASA module). We then match each residue in a B cell epitope to a control epitope with a SASA value within 10 \AA^2 . The resulting controls yield a comparable SASA distribution to that of the B cell epitopes (**Figure S2c-d**). Sufficient sampling of the possible sets of control residues, and 95% confidence intervals were obtained via bootstrap analysis.

Amplicon sequencing of SARS-CoV-2 genomes from vaccinated and unvaccinated patients

This is a retrospective study of individuals who underwent polymerase chain reaction (PCR) testing for suspected SARS-CoV-2 infection at the Mayo Clinic and Mayo Clinic Health System care facilities. This study was reviewed by the Mayo Clinic institutional review board and determined to be exempt from human subject research. Subjects were excluded if they did not have a research authorization on file.

SARS-CoV-2 RNA-positive upper respiratory tract swab specimens from patients with vaccine breakthrough infection or reinfection were subjected to next-generation sequencing, using the commercially available Ion AmpliSeq SARS-CoV-2 Research Panel (Life Technologies Corp., South San Francisco, CA) based on the "sequencing by synthesis" method. The assay amplifies 237 sequences ranging from 125 to 275 base pairs in length, covering 99% of the SARS-CoV-2 genome. Viral RNA was first manually extracted and purified from these clinical specimens using MagMAXTM Viral / Pathogen Nucleic Acid Isolation Kit (Life Technologies Corp.), followed by automated reverse transcription-PCR (RT-PCR) of viral sequences, DNA library preparation (including enzymatic shearing, adapter ligation, purification, normalization), DNA template preparation, and sequencing on the automated GenexusTM Integrated Sequencer (Life Technologies Corp.) with the GenexusTM Software version 6.2.1. A no-template control and a positive SARS-CoV-2 control were included in each assay run for quality control purposes. Viral sequence data were assembled using the Iterative Refinement Meta-Assembler (IRMA)

application (50% base substitution frequency threshold) to generate unamended plurality consensus sequences for analysis with the latest versions of the web-based application tools: Pangolin²³ for SARS-CoV-2 lineage assignment; Nextclade²⁴ for viral clade assignment, phylogenetic analysis, and S codon mutation calling, in comparison to the wild-type reference sequence of SARS-CoV-2 Wuhan-Hu-1 (lineage B, clade 19A).

Analysis of EHR data from patients with SARS-CoV-2 genome sequencing information

For the patients with SARS-CoV-2 genome sequencing data available, we analyzed their clinical covariates from the Mayo Clinic electronic health record (EHR) database. Demographic characteristics including age at time of sample collection, sex, race, and ethnicity were obtained from structured tables. Clinical phenotypes were obtained by applying natural language processing (NLP) methods to the unstructured clinical notes, using the phenotypes and following the methodology from previous studies^{25,26}. Comorbidities were determined from clinical notes in the 5 years leading up to the sample collection date. The following comorbidity phenotypes were considered: anemia, asthma, cancer, cardiomyopathy, chronic kidney disease, chronic obstructive pulmonary disease, coronary artery disease, heart failure, hyperglycemia, hypertension, liver disease, neurologic conditions, obstructive sleep apnea, type 1 diabetes mellitus, type 2 diabetes mellitus, and solid organ transplant. Similarly, complications were determined from the clinical notes in the time period +/- 30 days relative to the sample collection date. The following complication phenotypes were considered: acute respiratory distress syndrome / acute lung injury (ARDS/ALI), acute kidney injury, anemia, cardiac arrest, cardiac arrhythmias, disseminated intravascular coagulation, heart failure, hyperglycemia, hypertension, myocardial infarction, pleural effusion, pulmonary embolism, respiratory failure, sepsis, septic shock, stroke / cerebrovascular accident, venous thromboembolism, encephalopathy / delirium, and numbness.

Data Availability

After publication, the data will be made available to others upon reasonable requests to the corresponding author. A proposal with detailed description of study objectives and statistical analysis plan will be needed for evaluation of the reasonability of requests.

Declaration of Interests

nference collaborates with biotechnology, pharmaceutical, medical device, and diagnostics companies on data science initiatives unrelated to this study. These collaborations had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript. JCO receives personal fees from Elsevier and Bates College, and receives small grants from nference, Inc, outside the submitted work. ADB is a consultant for Abbvie and Flambeau diagnostics, is a paid member of the DSMB for Corvus pharmaceuticals, Equilibrium, and Excision biotherapeutics, has received fees for speaking for Reach MD, owns equity for scientific advisory board positions in nference and Zentalis, and is founder and President of Splissen therapeutics. JH, JCO, GJG, AWW, AV, MDS, and ADB are employees of the Mayo Clinic. The Mayo Clinic may stand to gain financially from the successful outcome of the research. nference and Mayo Clinic have filed a provisional patent application associated with this study. This research has been reviewed by the Mayo Clinic Conflict of Interest Review Board and is being conducted in compliance with Mayo Clinic Conflict of Interest policies.

a Estimating diversity of SARS-CoV-2 genomes using lineage entropy

b The diversity in SARS-CoV-2 lineages is declining across the world

c The diversity in SARS-CoV-2 lineages is declining at a country level

d Lineage diversity is negatively correlated with vaccination coverage

e Lineage diversity is negatively correlated with vaccination coverage

Figure 1. SARS-CoV-2 genomes show a global decline in sequence diversity coinciding with mass vaccination for COVID-19. (a) Schematic overview of estimating genomic diversity of SARS-CoV-2 (b-c) Diversity in SARS-CoV-2 lineages within the GISAID data, quantified using the entropy of the lineage probability distribution within 1-month time windows. Vertical dashed lines indicate the time at which countries reached a vaccine coverage of 1% of their total population. (d) Scatter plot showing the correlation between the country-level percentage of fully vaccinated individuals (from OWID²¹) and SARS-CoV-2 lineage entropy. (e) Distribution of the Pearson correlation coefficient between country-level percentage of fully vaccinated individuals and SARS-CoV-2 lineage entropy for all 25 countries with greater than 25% of their population fully vaccinated (as of June 26th, 2021) and at least 4-months with 100 or more sequences deposited to GISAID, after start of vaccination. The ISO 3166-1 alpha-3 code of included countries and their Pearson correlation are listed in the figure legend.

a Mapping B-cell and T-cell epitopes of SARS-CoV-2 Spike protein

b Prevalence of mutations per epitope

c Change in prevalence of mutations per epitope

d Mutations in Variants of Concern mapped to known B-cell epitopes

Figure 2. B cell epitopes are more mutated than CD8+ T cell epitopes across the Spike protein antigen. (a) We extracted known neutralizing epitopes of the reference SARS-CoV-2 Spike protein sequence from IEDB. Prevalence of mutations in these epitopes is determined for over 1.8 million viral genomes (GISAID). Specifically, we have quantified the average number of mutated amino acids for epitopes involved in distinct immune responses. (b) B cell epitopes (orange) show increased prevalence of mutations compared to size matched control, and T cell epitopes (blue, purple) do not show increased prevalence of mutations compared to size matched control. (c) Mutations in B cell epitopes are more prevalent and increase at a higher rate than for T cell epitopes, globally (see **Figure S3** for per country data). (d) Prevalence of mutations per B-cell epitope for SARS-CoV-2 genomic sequences of variants of concern; B.1.1.7 (alpha), B.1.531 (beta), P.1, and B.1.617.2, and Non-variant of concern sequences.

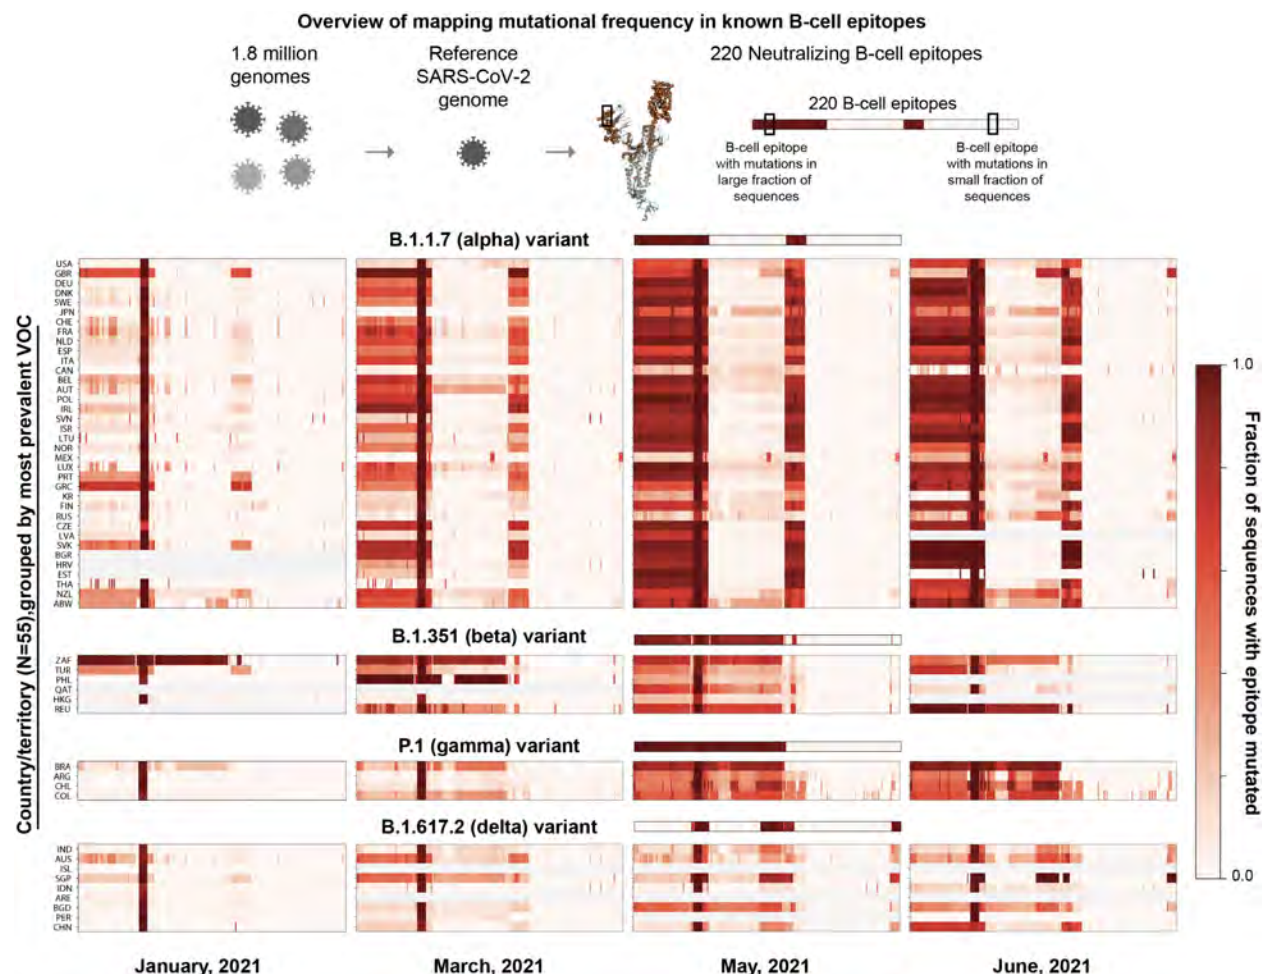

Figure 3: B-cell epitope mutation fractions for SARS-CoV-2 genomic sequences per country for 1-month time periods. Epitope mutation fractions for the variants of concern are shown as a visual guide and countries are grouped based on the most prevalent variant of concern; B.1.1.7 (alpha), B.1.531 (beta), P.1 (gamma), and B.1.617.2 (delta), in May 2021. Each row in a colormap corresponds to a country (ISO 1336-1 alpha-3 code, left; KR is South Korea) and each column corresponds to a B-cell epitope, ordering is conserved between the colormaps. Only countries with >1000 sequences deposited to GISAID are included. Rows in gray indicate countries for which no sequences were deposited in a given month.

b. Comparison of the distributions of the number of mutated positions among the vaccinated and unvaccinated individuals

c. Comparison of the mutational profiles of SARS-CoV-2 from vaccinated and unvaccinated individuals

Figure 4. (a) Whole genome sequencing of SARS-CoV-2 from vaccinated individuals (breakthrough) and unvaccinated individuals (b) Comparison of the distributions of the number of mutated positions among the vaccinated and unvaccinated individuals. (c) Comparison of the mutational profiles of SARS-CoV-2 from vaccinated and unvaccinated individuals.

Figure 5: Scatterplot of genomic mutations vs. clinical complications for all vaccinated and unvaccinated patients. Data points representing unvaccinated patients are shown in purple, and data points representing vaccinated patients are shown in green. X-axis: The number of Spike protein mutations in the patient's SARS-CoV-2 viral genome. Y-axis: The number of clinical notes +/- 30 days from the viral sample collection date which have a positive sentiment for at least one of the following complications: acute respiratory distress syndrome / acute lung injury (ARDS/ALI), acute kidney injury, anemia, cardiac arrest, cardiac arrhythmias, disseminated intravascular coagulation, heart failure, hyperglycemia, hypertension, myocardial infarction, pleural effusion, pulmonary embolism, respiratory failure, sepsis, septic shock, stroke / cerebrovascular accident, venous thromboembolism, encephalopathy / delirium, and numbness. In the legend, we show the average number of clinical notes per patient, Pearson's r correlation coefficient, and associated p-value for the following cohorts: all sequenced patients, unvaccinated sequenced patients, and vaccinated sequenced patients. Dotted lines represent the average number of clinical notes per patient in each cohort, and the black dotted line represents the population average number of clinical notes.

Supplementary Table S2: Clinical characteristics of patients with SARS-CoV-2 genomes sequenced in the Mayo Clinic database which have EHR data available. Comorbidities for each patient were determined from neural network models applied to the clinical notes over the past 5 years leading up to the first sample collection date. Similarly, complications for each patient were determined from neural network models applied to the clinical notes +/- 30 days relative to the first sample collection date. For continuous covariates such as age, mean and standard deviation are shown instead of patient counts and percentages. Clinical characteristics are shown for the following cohorts: (1) All sequenced patients, (2) Vaccinated patients: sequenced patients with SARS-CoV-2 infection post-vaccination, and (3) Unvaccinated patients: patients without COVID-19 vaccination or samples collected prior to vaccination date.

Clinical characteristic	All patients	Vaccinated patients	Unvaccinated patients
Total patient count	47	22	25
Age at time of sample collection (in years)			
- Mean	56.7	53.2	59.8
- Standard deviation	13.9	16.8	10.0
Sex			
- Female	34 (72.3%)	17 (77.3%)	17 (68.0%)

- Obstructive sleep apnea	12 (25.5%)	3 (13.6%)	9 (36.0%)
- Type 1 diabetes mellitus	4 (8.5%)	1 (4.5%)	3 (12.0%)
- Type 2 diabetes mellitus	11 (23.4%)	2 (9.1%)	9 (36.0%)

- Solid organ transplant	1 (2.1%)	0 (0%)	1 (4.0%)
Complications (+/- 30 days relative to sample collection date)			
- ARDS/ALI	9 (19.1%)	0 (0.0%)	9 (36.0%)
- Acute kidney injury	14 (29.8%)	2 (9.1%)	12 (48.0%)
- Anemia	13 (27.7%)	1 (4.5%)	12 (48.0%)
- Cardiac arrest	1 (2.1%)	0 (0%)	1 (4.0%)
- Cardiac arrhythmias	19 (40.4%)	3 (13.6%)	16 (64.0%)
- Disseminated intravascular coagulation	1 (2.1%)	0 (0%)	1 (4.0%)
- Heart failure	5 (10.6%)	1 (4.5%)	4 (16.0%)
- Hyperglycemia	5 (10.6%)	0 (0.0%)	5 (20.0%)
- Hypertension	23 (48.9%)	6 (27.3%)	17 (68.0%)
- Myocardial infarction	3 (6.4%)	2 (9.1%)	1 (4.0%)
- Pleural effusion	5 (10.6%)	0 (0%)	5 (20.0%)
- Pulmonary embolism	7 (14.9%)	2 (9.1%)	5 (20.0%)
- Respiratory failure	9 (19.1%)	0 (0%)	9 (36.0%)
- Sepsis	5 (10.6%)	0 (0%)	5 (20.0%)
- Septic shock	2 (4.3%)	0 (0%)	2 (8.0%)
- Stroke/cerebrovascular accident	0 (0.0%)	0 (0.0%)	0 (0.0%)
- Venous thromboembolism	12 (25.5%)	2 (9.1%)	10 (40.0%)
- Encephalopathy/delirium	7 (14.9%)	1 (4.5%)	6 (24.0%)
- Numbness	1 (2.1%)	0 (0.0%)	1 (4.0%)
Any complication	27 (57.4%)	6 (27.3%)	21 (84.0%)
Number of notes per patient			
- Average	23.6	5.0	39.9
- Standard deviation	38.6	13.0	46.0

Supplementary Table S3. Scanning unique mutated n-mer peptide sequences in SARS-CoV-2 genomes for potentially new epitopes.

nmer Length	Unique no. of mutated nmers	No. of unique mutated nmers associated with surge
8	74390	2183 (2.93%)
9	84071	2453 (2.92%)
10	93839	2723 (2.9%)
11	103700	2994 (2.89%)
12	113649	3265 (2.87%)

Supplementary Figure 1. Prevalence of Variants of Concern in the GISAID sequence increases over time.

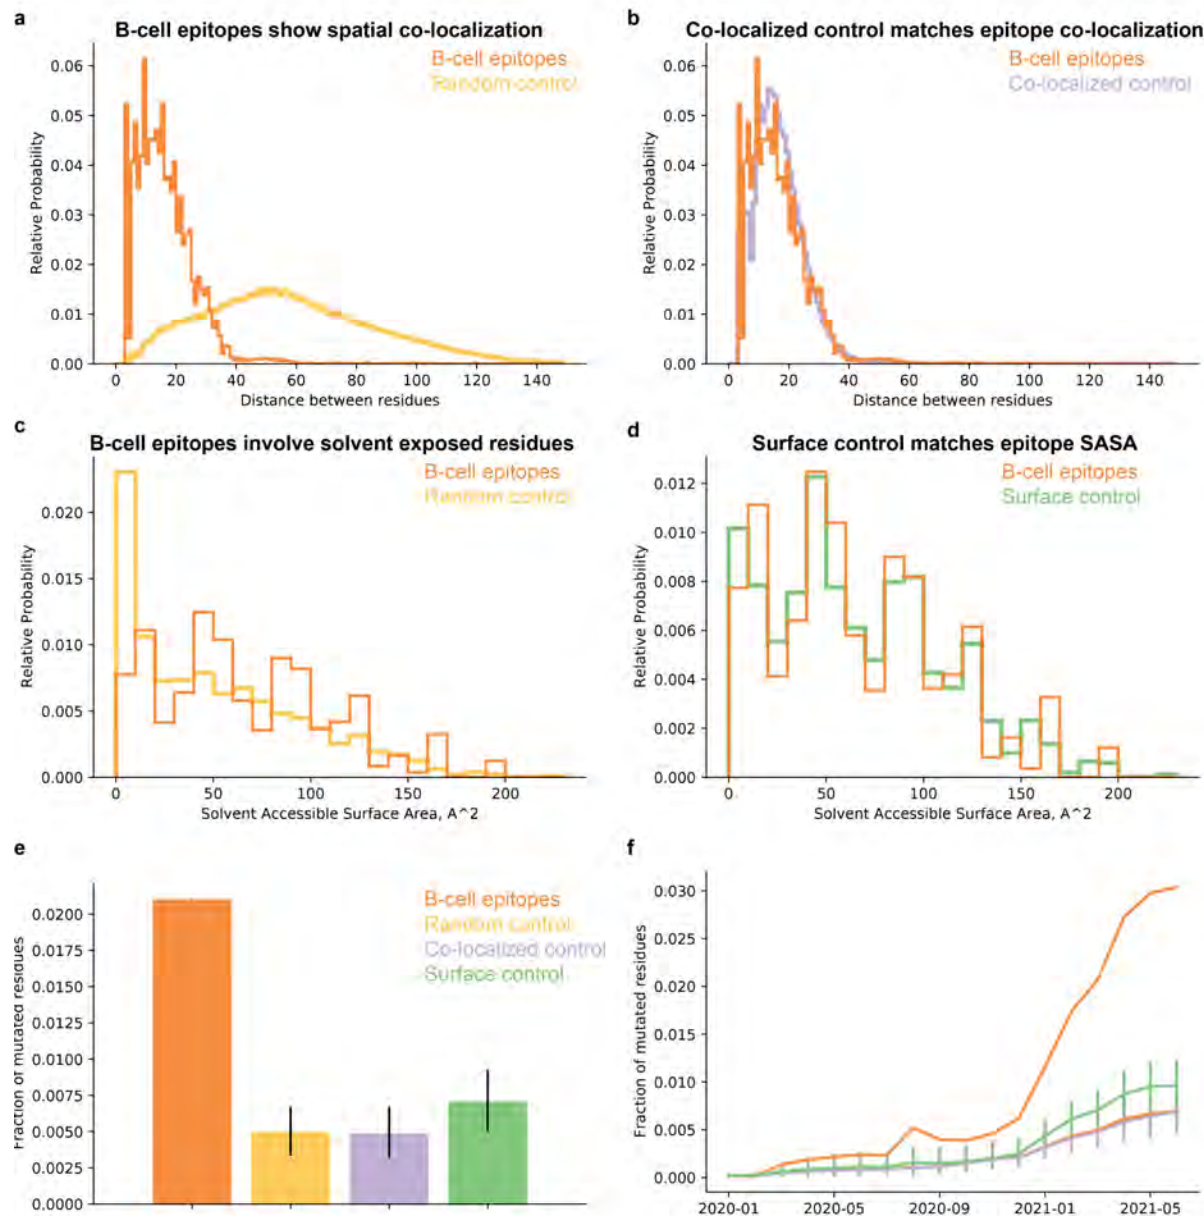

a B-cell epitope coverage of the Spike glycoprotein

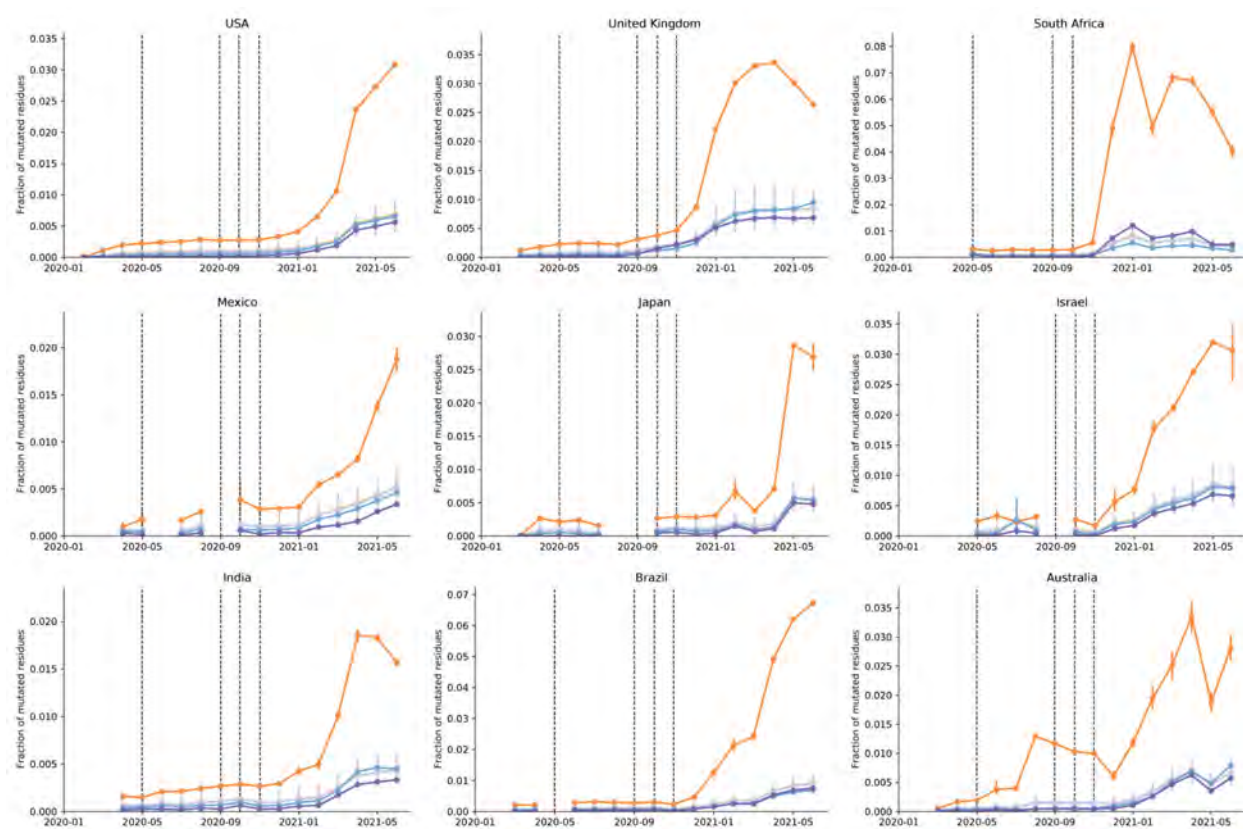

b T-cell epitope coverage of the Spike glycoprotein

Supplementary Figure 2. Neutralizing B cell and CD8⁺ T cell epitopes are unevenly distributed across the Spike protein. (a) The coverage of the Spike protein with known neutralizing B cell epitopes (from IEDB). Shown is the number of epitopes that each amino-acid residue is a part of, 280 residues are involved in at least one known B cell epitope. (b) The coverage of the Spike protein with known MHC class I T cell epitopes (from IEDB). Shown is the number of epitopes that each amino-acid residue is a part of. 1034 residues are involved in at least one known T cell epitope.

Supplementary Figure 3. B cell epitopes on the Spike antigen are more mutated than randomly selected 3-D/spatially co-localized residues and solvent-exposed surface residues. (a) Conformational B cell epitopes consist of co-localized residues, as is reflected by their low inter-residue distance distribution (orange), compared to the random control (yellow). **(b)** By selecting only residues with comparable inter-residue distance to the B cell epitopes, we have generated a co-localized residue control. **(c)** B cell epitopes consist of mainly surface residues, as is reflected by their increased solvent accessibility (orange), the random control also includes buried residues (yellow). **(d)** By selecting only residues with comparable solvent accessibility to matched residues from the B cell epitopes, we have generated a surface residue control. **(e-f)** Conformational neutralizing B cell epitopes (orange) show enhanced mutability compared both to the co-localized control (purple) and the surface residue control (green).

Supplementary Figure 4. Mutations in B cell epitopes are more prevalent and increase at a higher rate than for T cell epitopes.

Severe Acute Respiratory Syndrome: Temporal Lung Changes at Thin-Section CT in 30 Patients¹

PURPOSE: To evaluate lung abnormalities on serial thin-section computed tomographic (CT) scans in patients with severe acute respiratory syndrome (SARS) during acute and convalescent periods.

MATERIALS AND METHODS: Serial thin-section CT scans in 30 patients (17 men, aged 42.5 years \pm 12.2 [SD]) with SARS were reviewed by two radiologists together for predominant patterns of lung abnormalities: ground-glass opacities, ground-glass opacities with superimposed linear opacities, consolidation, reticular pattern, and mixed pattern (consolidation, ground-glass opacities, and reticular pattern). Scans were classified according to duration in weeks after symptom onset. Longitudinal changes of specific abnormalities were documented in 17 patients with serial scans obtained during 3 weeks. Each lung was divided into three zones; each zone was evaluated for percentage of lung involvement. Summation of scores from all six lung zones provided overall CT score (maximal CT score, 24).

RESULTS: Median CT scores increased from 1 in the 1st week to 12.5 in the 2nd week. Ground-glass opacities with or without smooth interlobular septal thickening and consolidation were predominant patterns found during the 1st week. Ground-glass opacities with superimposed irregular reticular opacities, mixed pattern, and reticular opacities were noted from the 2nd week and peaked at or after the 4th week. After the 4th week, 12 (55%) of 22 patients had irregular linear opacities with or without associated ground-glass opacities and CT scores greater than 5; five of these patients had bronchial dilatation. When specific opacities were analyzed in 17 patients, consolidation generally resolved completely ($n = 4$) or to minimal residual opacities; six (55%) of 11 patients with ground-glass opacities had substantial residual disease (CT scores > 5) on final scans.

CONCLUSION: There is a temporal pattern of lung abnormalities at thin-section CT in SARS. Predominant findings at presentation are ground-glass opacities and consolidation. Reticulation is evident after the 2nd week and persists in half of all patients evaluated after 4 weeks. Long-term follow-up is required to determine whether the reticulation represents irreversible fibrosis.

© RSNA, 2004

Severe acute respiratory syndrome (SARS) is a form of pneumonia that spread from east Asia to Toronto, Ontario, Canada, through international air travel from Hong Kong and China during February to May 2003 (1). A newly discovered SARS-associated coronavirus (SARS-CoV) has been implicated in the pathogenesis of SARS (2–4). The clinical features of this syndrome have been well documented as a respiratory illness with a prodrome that starts with fever (temperature $> 38^{\circ}\text{C}$ [100.4°F]) associated with malaise and chills followed by a dry nonproductive cough and dyspnea (5–7).

The computed tomographic (CT) findings at presentation usually include unilateral or bilateral ground-glass opacities or areas of consolidation (5,6,8,9). The utility of thin-section CT in the documentation of parenchymal abnormalities in SARS when chest radiographs appear normal or show only questionable abnormalities has also been established (8,9). In their initial description of the epidemiologic, clinical, and radiologic

features of the first 10 SARS patients, including the index case for Hong Kong, Tsang et al (5) alluded to radiologic features that suggest the development of fibrosis. Thin-section CT evidence of fibrosis has also recently been reported in SARS patients who have been discharged after treatment (9). The aim of this study, therefore, was to evaluate lung abnormalities on serial thin-section CT scans in patients with SARS during the acute and convalescent periods of the illness.

MATERIALS AND METHODS

Patients

All patients with clinically proved SARS who were admitted to Queen Mary Hospital, Hong Kong, China ($n = 28$), and Vancouver General Hospital, British Columbia, Canada ($n = 2$), and who underwent at least two serial thin-section CT evaluations of the thorax were included in this retrospective study. There were 30 patients (mean age, 42.5 years \pm

12.2 [SD]; median, 44 years; range, 24–72 years); 13 were women (mean age, 40.2 years \pm 10.2; median, 45 years; range, 24–56 years) and 17 were men (mean age, 43.2 years \pm 13; median, 43 years; range, 25–72 years). Diagnosis of SARS was established according to the Centers for Disease Control and Prevention and World Health Organization criteria (10,11), which included presence of high fever (temperature, $>38^{\circ}\text{C}$ [100.4°F]), respiratory symptoms (cough, shortness of

Figure 1. Line graph shows median thin-section CT scores at various time points in weeks after onset of symptoms. Scores peaked at 2nd week of illness, with a slow decline thereafter and substantial scores after the 4th week.

breath, and dyspnea), close contact within 10 days of onset of symptoms with a person who received a diagnosis of SARS, or travel within 10 days of onset of symptoms to an area with documented or suspected community transmission of SARS. Some of the researchers (J.C.M.H., B.L., S.N., K.W.T.T.) noted clinical parameters that included laboratory findings; date of onset of symptoms; indications for the scans; and presence of complications such as pneumomediastinum, pneumothorax, and superimposed infections. In the study, duration of disease refers to time in weeks from onset of symptoms. This study was conducted with institutional review board approval; patient informed consent was not required.

Thin-Section CT Scans

Thin-section CT scans were obtained with the patients in the supine position, and scanning was performed at end inspiration. One unit (HiSpeed Advantage; GE Medical Systems, Milwaukee, Wis) was used in 28 patients with the following parameters: 1.0-mm section thickness, 10-mm gap, 1- or 2-second scanning time per section, 120 kV, and 150 mA. Another unit (Lightspeed plus; GE Medical Systems) was used in one patient with the following parameters: 1.3-mm section thickness, 10-mm gap, 1-second scanning time per section, 120 kV, and 180 mA. A third unit (Toshiba Astreon; Toshiba, Tokyo, Japan) was used in one patient with the following parameters: 1.0-mm section thickness, 10-mm gap, 1-second scanning time per section, 120 kV, and 180 mA. All follow-up scans were obtained by using the same scanner as that used to obtain the initial scans. In the patient who underwent thin-section

CT with 1.3-mm section thickness, the initial scans were spiral. Spiral scans were obtained with the same scanner and the following parameters: 5-mm collimation, 120 kV, 181 mA, pitch of 0.75, scanning interval of 2.5 mm, and table feed of 11.25 mm. The thin-section CT findings at presentation in five patients in the current study were previously reported (9). In 14 of 30 patients, two CT scans were obtained; in 10 patients, three scans; in five patients, four scans; and in one patient, five scans. The images were photographed at lung (window width, 1,000–1,500 HU; window level, –700 HU) and mediastinal (window width, 350 HU; window level, 35–40 HU) settings.

Image Interpretation

Two experienced radiologists at each center (G.C.O. and P.L.K.; N.L.M. and S.N.) reviewed the thin-section CT images on hard copies and reached a decision in consensus. Three of these radiologists (N.L.M., G.C.O., S.N.) had 19, 8, and 6 years of experience in thoracic radiology, respectively, and one (P.L.K.) had 11 years of experience in radiology. The observers categorized the predominant pattern on CT scans as ground-glass opacification (hazy areas of increased attenuation without obscuration of the underlying vessels), consolidation (homogeneous opacification of the parenchyma with obscuration of the underlying vessels), reticular pattern, mixed pattern (combination of consolidation, ground glass opacities, and reticular opacities in the presence of architectural distortion), and honeycomb pattern. Presence of smooth interlobular septal thickening, intralobular lines (lacy pattern within the lobule), and irregular lines and interfaces with architectural distortion superimposed on ground-glass opacities were also noted. Reticular pattern consisted of either coarse linear or curvilinear opacities or fine subpleural reticulation without substantial ground-glass opacities. Presence of irregular or corkscrew bronchial or bronchiolar dilatation associated with any of the previously mentioned findings was noted. On the scans, presence of mediastinal lymphadenopathy (defined as a lymph node ≥ 1 cm in short-axis diameter), pneumothorax, pneumomediastinum, and pleural effusion was also noted.

The distribution of opacities was also noted as being predominantly subpleural (involving mainly the peripheral one-third of the lung), random (without predilection for subpleural or central regions), or diffuse

(continuous involvement without respect to lung segments). After evaluation, the scans were categorized according to the time between the date of onset of symptoms and the date on which the scan was obtained at 1, 2, 3, 4, and longer than 4 weeks after onset of symptoms. Patients with initial scans obtained during the first 2 weeks of the illness and with follow-up scans obtained after a minimum of 3 weeks were selected for further analysis to determine longitudinal changes of main lung abnormalities that were detected.

The extent of disease at thin-section CT was also evaluated. Each lung was divided into three lung zones: upper (above the carina), middle (below the carina up to the inferior pulmonary vein), and lower (below the inferior pulmonary vein) zones. Each lung zone (total of six lung zones) was assigned a score that was based on the following: score 0, 0% involvement; score 1, less than 25% involvement; score 2, 25% to less than 50% involvement; score 3, 50% to less than 75% involvement; and score 4, 75% or greater involvement. Summation of scores provided overall lung involvement (maximal CT score for both lungs was 24).

RESULTS

Clinical Parameters

Thin-section CT scans were obtained during a mean of 22.1 days \pm 10.7 (median, 22 days; range, 3–49 days). The indications for serial scans included clinical deterioration ($n = 7$) and requirement of a change in treatment, whether it included increased dosage of steroids ($n = 8$) or additional immunomodulation therapies ($n = 15$). In some patients, the initial thin-section CT scans were also obtained to confirm airspace disease when radiographs obtained at presentation were normal or slightly abnormal ($n = 10$). The condition in two of these patients deteriorated within 5 days after the initial thin-section CT scans were obtained, and a second thin-section CT scan was thus obtained. The mean time between the time the first and the last thin-section CT scans were obtained for the remaining 28 patients was 9.5 days \pm 2.9, 17.25 days \pm 2.05, 22.8 days \pm 1.3, and 33.4 days \pm 5.8 in four, eight, five, and 11 patients, respectively. Four patients developed pneumomediastinum, with three of them also having pneumothorax, during the 2nd and 3rd weeks of evaluation. Over the course of treatment in the 30 patients only, three patients

Figure 2. Stacked-bar graph shows distribution of different patterns of lung changes on thin-section CT scans at various time points from onset of symptoms. Dark gray = reticular pattern, white = mixed pattern, light gray = consolidation, black = ground-glass opacities, striped = normal.

developed oral candidiasis, one patient developed coagulase-negative staphylococcal septicemia, and another developed lower urinary tract infection.

Mean alanine aminotransferase and aspartate aminotransferase levels, total white blood cell count, and lymphocyte count at presentation for the 30 patients were $49.82 \text{ U/L} \pm 44.2$ (normal range, 6–53 U/L), $67.5 \text{ U/L} \pm 66.3$ (normal range, 13–33 U/L), $5.968 \times 10^9/\text{L} \pm 1.73$ (normal range, $4\text{--}11 \times 10^9/\text{L}$), and $0.70 \times 10^9/\text{L} \pm 0.3$ (normal range, $1.5\text{--}400.0 \times 10^9/\text{L}$), respectively. There was only one patient with a premorbid lung condition; this patient had childhood asthma. Four others had acute myelogenous leukemia treated with bone marrow transplantation, hypertension, resected renal cell carcinoma, and thyrotoxicosis controlled with medication. The other 25 patients were healthy and did not have a medical history of note prior to contraction of SARS. Coronavirus infection was confirmed in all patients from Hong Kong by means of a fourfold or greater increase in anti-SARS-CoV antibody ($n = 28$) and/or reverse transcriptase polymerase chain reaction positive for SARS-CoV RNA detected in nasopharyngeal aspirates and/or stool specimens ($n = 24$). In the two patients from Vancouver, coronavirus was isolated from respiratory secretions ($n = 1$) or fecal material ($n = 1$).

Thin-Section CT Findings

There was a marked increase in extent of disease during the 2nd week of illness, and the median CT score was 12.5 (range, 2–24). After that time, the extent decreased slowly to a median CT score of 8 (range, 0–24) during week 5, and this decrease reflected the presence of residual disease (Fig 1). The predominant patterns of abnormality changed over time (Fig 2). Within the 1st week after onset of symptoms, the main abnormalities included ground-glass opacities (10 [56%] of 18) and consolidation (eight [44%] of 18). The frequency of ground-glass opacities was highest in the 2nd week (10 [62%] of 16), and it decreased thereafter (Fig 2). Ground-glass opacities alone or with superimposed interlobular septal thickening were most commonly found in the 1st week after onset of symptoms (Figs 3, 4). At the 2nd week, smooth intralobular lines and other superimposed reticular opacities were noted in association with ground-glass opacities (Figs 3, 4). Three of 10 scans with ground-glass opacities in the 2nd week showed a combination of superimposed septal and reticular opacities. Irregular linear opacities and interfaces superimposed on ground-glass

Figure 3. Stacked-bar graph shows distribution of different types of ground-glass opacities on thin-section CT scans at various time points from onset of symptoms. Light gray = ground-glass opacities plus irregular linear opacities, dark gray = ground-glass opacities plus intralobular septal thickening, white = ground-glass opacities plus smooth interlobular septal thickening, black = ground-glass opacities.

opacities accounted for 90% (nine of 10) of all ground-glass opacification found after 4 weeks (Figs 3, 4). The prevalence of consolidation as the predominant abnormality was highest within the 1st week of symptoms and decreased thereafter (Fig 2).

Mixed and predominantly reticular patterns (Fig 4c) were noted from the 2nd week of illness and reached highest proportions on or after the 4th week on three (19%) of 16 and eight (32%) of 25 scans, respectively. There were no scans with a honeycomb pattern or mediastinal lymph nodes at any time point during the evaluation. Small bilateral effusions were present in one patient. Bronchial dilatation was noted on three, three, six, and 10 scans, respectively, at the 2nd, 3rd, 4th, and after the 4th week of illness. These were associated with ground-glass opacities with superimposed irregular linear opacities in nine, mixed pattern in seven, and reticular pattern in six scans. In three scans, the bronchial dilatation was reversed on follow-up scans. Opacities were mainly sited in the subpleural regions of the lungs in the 1st week of disease (13 [72%] of 18) and became more diffuse (five [50%] of

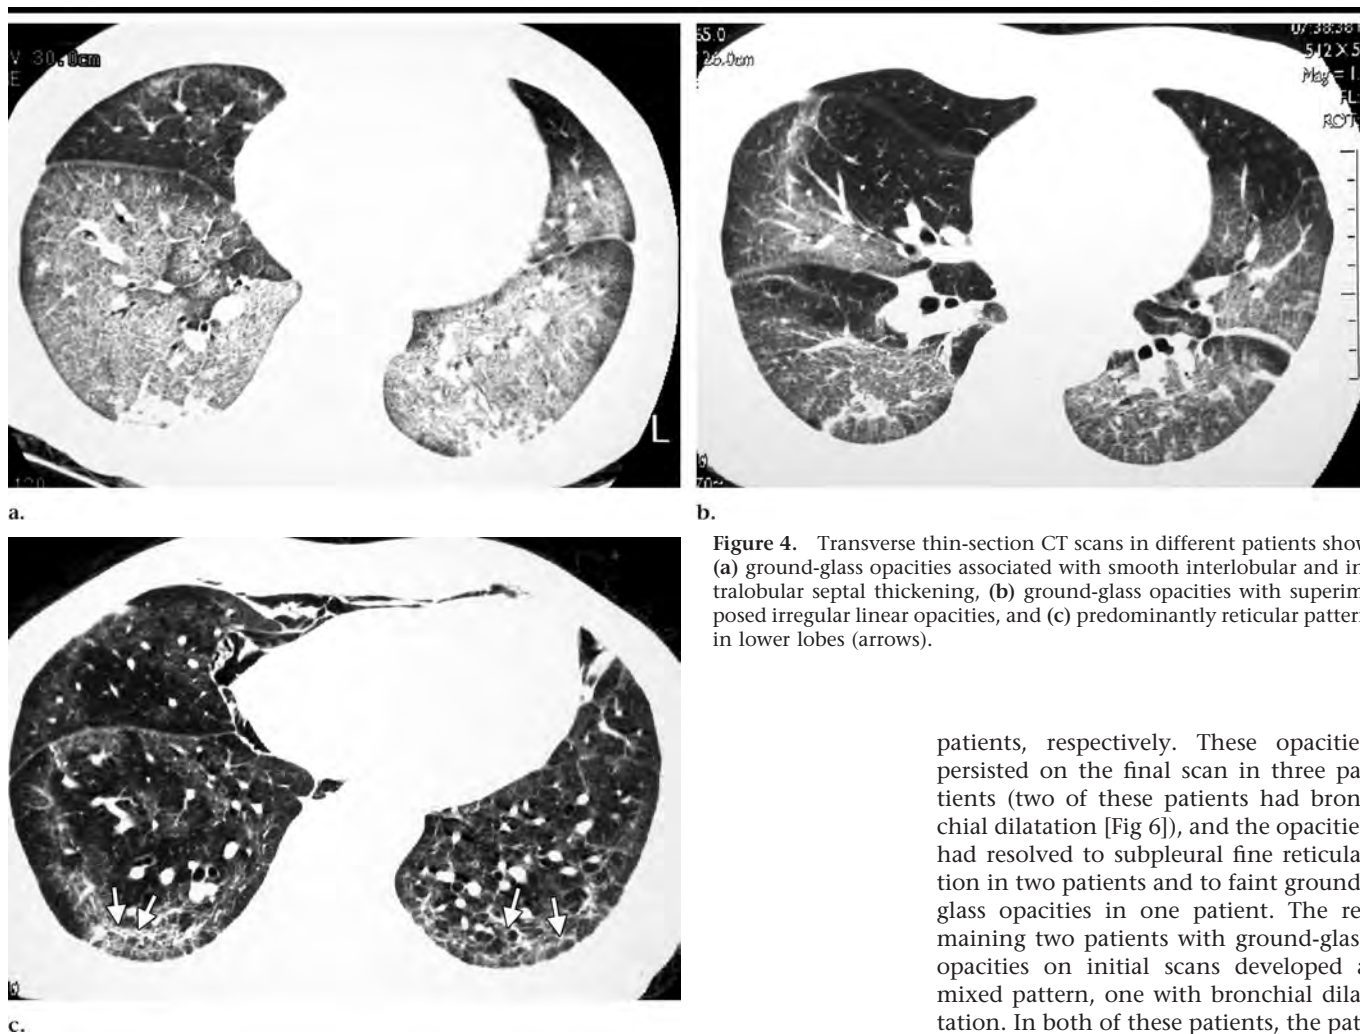

Figure 4. Transverse thin-section CT scans in different patients show (a) ground-glass opacities associated with smooth interlobular and intralobular septal thickening, (b) ground-glass opacities with superimposed irregular linear opacities, and (c) predominantly reticular pattern in lower lobes (arrows).

patients, respectively. These opacities persisted on the final scan in three patients (two of these patients had bronchial dilatation [Fig 6]), and the opacities had resolved to subpleural fine reticulation in two patients and to faint ground-glass opacities in one patient. The remaining two patients with ground-glass opacities on initial scans developed a mixed pattern, one with bronchial dilatation. In both of these patients, the pattern evolved to a reticular one, with reversal of bronchial dilatation observed on the final scans.

Of two patients with reticular opacities superimposed on ground-glass opacities on initial scans, complete resolution occurred in one, whereas a predominantly reticular pattern developed in the remaining patient and was associated with bronchial dilatation and architectural distortion (Fig 7).

In three of seven patients with predominant consolidation on the initial scans, the areas of consolidation resolved completely, although one of these patients developed extensive ground-glass opacities with reticulation in other areas of the lung. One of the seven patients developed a mixed pattern that comprised bandlike consolidation, parenchymal bands, curvilinear septal lines, and ground-glass opacities associated with architectural distortion and bronchial dilatation, and this patient had complete resolution of all features after 3 weeks (Fig 8). In two patients, the areas of consolidation were replaced by fine subpleural

10) at the 3rd week, after which opacities were sited either in the subpleural regions of the lungs or in both a diffuse and subpleural site.

In 24 patients, final thin-section CT scans were obtained at 4 weeks or longer after onset of symptoms. Of these patients, 12 had substantial residual disease (score > 5) and a mean score of 10.7 ± 5.4 (median, 9; range, 5–24), seven had minimal residual opacities (score ≤ 3) and a mean score of 2.21 ± 0.86 (median, 2.5; range, 1–3), and five had normal scans. In those with substantial residual disease, a reticular pattern was noted in five patients, a mixed pattern in two, consolidation in one, and ground-glass opacities with superimposed irregular linear opacities in four. Bronchial and/or bronchiolar dilatation was a feature in five patients. In the seven patients with minimal residual opacities, a subpleural reticular pattern was found in five patients, and small areas of ground-glass opacities with irregular linear opacities

were found in two patients. There was no zonal predominance in the distribution of the residual changes.

Longitudinal Changes of Specific Thin-Section CT Features

The Table summarizes the longitudinal changes in 17 patients in whom initial scans were obtained during the first 2 weeks of illness, and final scans were obtained at least 3 weeks later. In these patients, the initial CT scans demonstrated predominant ground-glass opacities without reticulation (eight scans), ground-glass opacities with reticulation (two scans), and consolidation (seven scans).

Serial thin-section CT scans obtained between the time that initial and final scans were obtained in the eight patients who had ground-glass opacities demonstrated that smooth interlobular septal thickening and irregular linear opacities (Figs 5, 6) had developed in the areas of ground-glass opacities in two and four

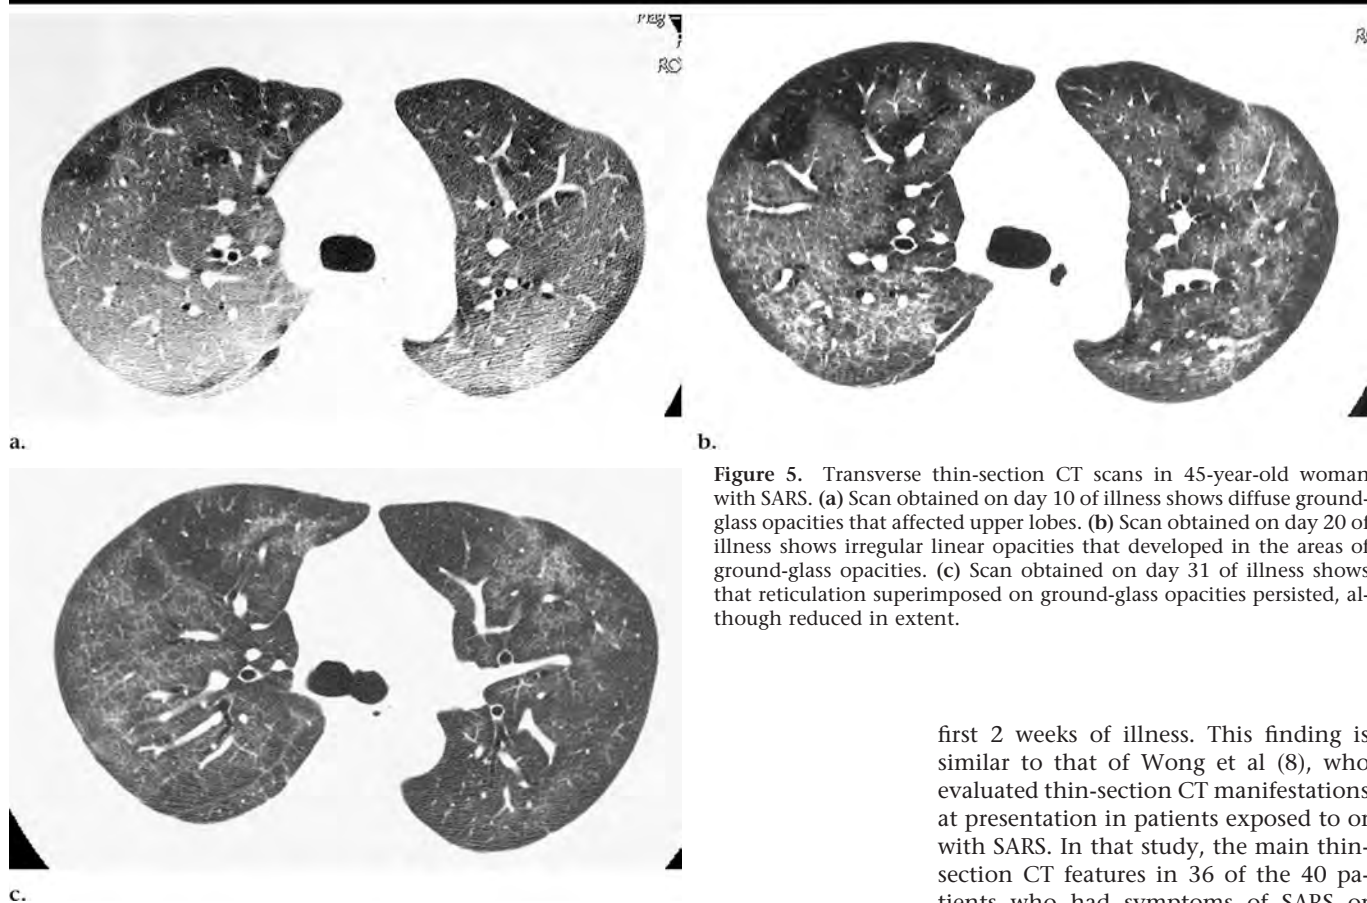

Figure 5. Transverse thin-section CT scans in 45-year-old woman with SARS. (a) Scan obtained on day 10 of illness shows diffuse ground-glass opacities that affected upper lobes. (b) Scan obtained on day 20 of illness shows irregular linear opacities that developed in the areas of ground-glass opacities. (c) Scan obtained on day 31 of illness shows that reticulation superimposed on ground-glass opacities persisted, although reduced in extent.

reticulation; in one patient, these areas were replaced by ground-glass opacities.

Consolidation in the seven patients generally resolved either completely ($n = 4$) or with minimal residual disease ($n = 3$), as denoted by scores of 3 or less. Ground-glass opacities in 11 patients (including patient 2 in whom ground-glass opacities developed in other areas of the lung at week 3) showed complete resolution in one patient, substantial residual opacities (scores > 5) in six patients, and minimal residual disease in four patients.

DISCUSSION

The serial scans obtained in our cohort provided an opportunity to study the longitudinal lung changes in SARS in the acute and convalescent periods. These scans were obtained to aid treatment and hence are heterogeneous in their timing and duration of follow-up. Nevertheless, the scans depict the lung abnormalities at specific time points in the course of the disease from onset of symptoms and allow description of temporal lung changes seen in a subgroup of patients in whom

longitudinal scans were obtained during a minimum of 3 weeks. To our knowledge, this is the first description of a longitudinal thin-section CT series in patients with clinically proved SARS in the acute and convalescent periods.

The extent of parenchymal abnormalities in our cohort of SARS patients increased markedly between the 1st and 2nd weeks after the onset of symptoms. This was followed by a slow decline in scores that reflected residual lung abnormalities at 4 weeks in 50% (12 of 24) of patients. In concordance with initial reports about lung changes in SARS, ground-glass opacities and consolidation were the predominant abnormalities found on thin-section CT scans in our cohort (5–8). These were predominantly subpleural (13 [72%] of 18) in the initial week of illness and became more diffuse (five [50%] of 10) at the 3rd week, after which opacities became distributed either in the subpleural regions of the lungs or were diffuse.

Ground-glass opacities with or without septal thickening or reticular opacities were the commonest pattern during the

first 2 weeks of illness. This finding is similar to that of Wong et al (8), who evaluated thin-section CT manifestations at presentation in patients exposed to or with SARS. In that study, the main thin-section CT features in 36 of the 40 patients who had symptoms of SARS or who were clinically suspected of having SARS were predominantly ground-glass opacities alone or in combination with consolidation. Interlobular septal thickening and intralobular lines were present in 22 and 26, respectively, of their 40 patients. In our study, the number of scans with ground-glass opacities was highest in the 2nd week (10 [63%] of 16) and decreased in the following 2 weeks, with a small upsurge in numbers after the 4th week. This upsurge was accounted for by an increase in ground-glass opacities with superimposed irregular linear opacities and interfaces.

A predominant pattern of consolidation was most common in the first 2 weeks of the illness and was not seen after the 4th week. The areas of consolidation generally either resolved completely or to small areas of fine reticulation. The reticular pattern associated with architectural distortion and bronchial or bronchiolar dilatation was noted to increase progressively from the 3rd week. In addition to this finding, 12 (50%) of 24 final scans obtained 4 weeks or longer after onset of symptoms showed substantial residual disease, consisting predominantly of a reticular pattern or of ground-glass opacities with a superim-

Figure 6. Transverse thin-section CT scans in 52-year-old man with SARS. (a) Scan obtained on day 12 of illness shows pneumomediastinum (arrows) and ground-glass opacities with superimposed irregular linear opacities in both lungs. (b) Follow-up scan obtained on day 37 of illness shows coarse reticular opacities with bronchial dilatation (arrow) and architectural distortion in the same areas.

Figure 7. Transverse thin-section CT scans in 32-year-old woman with SARS. (a) Scan obtained on day 8 of illness shows ground-glass opacities predominantly in right upper lobe. (b) Scan obtained on day 30 of illness shows coarse reticular opacities that developed in right upper lobe, with bronchial dilatation (arrows) and architectural distortion.

posed reticular pattern. Bronchial or bronchiolar dilatation was an associated feature in five (42%) of these 12 scans. When specific opacities in a subgroup of 17 patients were analyzed, consolidation in general either resolved completely or decreased to minimal areas of residual opacities. However, six (55%) of 11 scans with ground-glass opacities showed a substantial amount of residual disease after 3 weeks or longer.

These findings indicate that a proportion of patients develop persistent lung changes that may suggest the development of fibrosis, although ground-glass opacities are largely reversible in SARS

(12). Antonio et al (9) studied 24 SARS patients discharged from the hospital after treatment who had undergone thin-section CT; they observed that 15 (62%) of the patients had evidence of fibrosis. These were described to be parenchymal bands, traction bronchiectasis, and irregular interfaces. However, since the natural history of SARS is as yet uncharted, it may be too early to label the lung abnormalities found as irreversible fibrosis. Features that were reversible were bandlike consolidation and parenchymal bands, terms that generally described the mixed pattern found in our patients. The parenchymal bands probably represent subseg-

mental atelectasis that was reversed with resolution of inflammation with reexpansion of alveoli. Similarly, resolution of interstitial edema and cellular infiltration, particularly of interlobular septa, could also explain resolution of subpleural curvilinear lines noted.

In a recent publication (13) about post-mortem results in six fatal cases of SARS, with mean disease duration of 16.8 days \pm 5.3 (median, 17 days; range, 8–24 days), fibrosis was not observed in the lungs, although diffuse alveolar damage was noted in cases with duration of illness longer than 10 days. Macrophages, however, featured strongly as the main

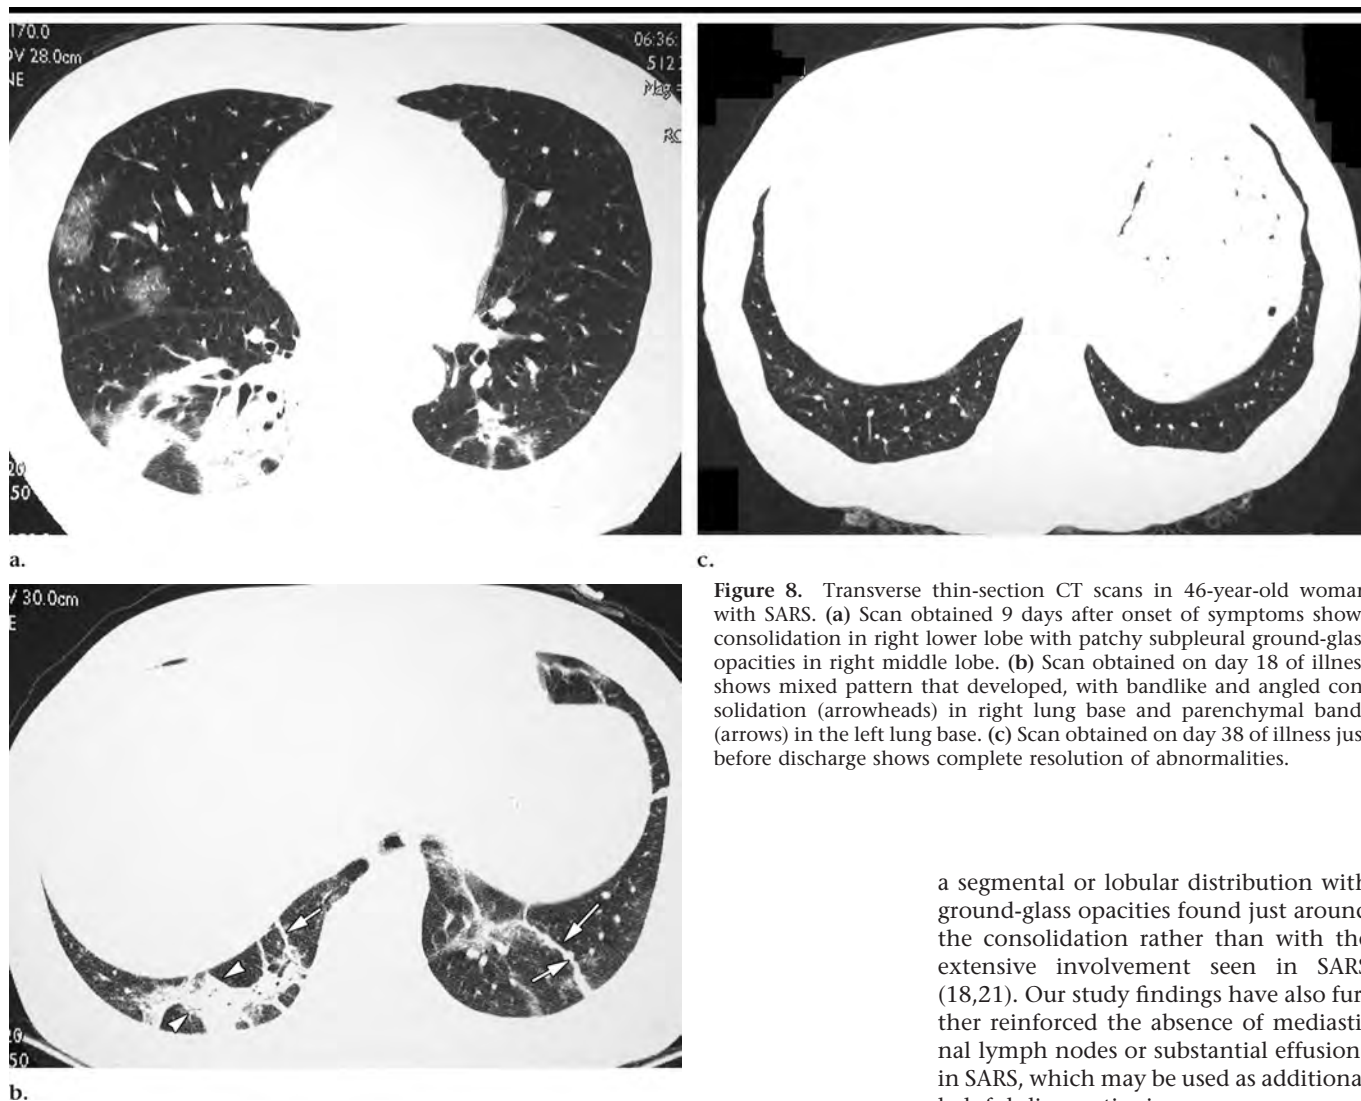

Figure 8. Transverse thin-section CT scans in 46-year-old woman with SARS. (a) Scan obtained 9 days after onset of symptoms shows consolidation in right lower lobe with patchy subpleural ground-glass opacities in right middle lobe. (b) Scan obtained on day 18 of illness shows mixed pattern that developed, with bandlike and angled consolidation (arrowheads) in right lung base and parenchymal bands (arrows) in the left lung base. (c) Scan obtained on day 38 of illness just before discharge shows complete resolution of abnormalities.

neutrophil infiltrate in the alveoli and interstitium of these fatal cases, even in those with early disease, which suggests that proinflammatory cytokines released by macrophages may underlie the pathogenesis of SARS (13). The macrophage and cellular infiltrates may also explain the predominant pattern of ground-glass opacities noted in the lungs at thin-section CT in our patients.

Thin-section CT features of SARS are not specific and could be found in other airspace diseases such as bronchiolitis obliterans organizing pneumonia, particularly in the initial phase of the illness when the ground-glass opacities and consolidation are primarily subpleural (14,15). When diffuse change develops in SARS, the thin-section CT and radiographic appearances may be indistinguishable from acute respiratory distress syndrome (5,16). Similarly the presence of smooth inter-

lobular septal thickening superimposed on extensive ground-glass opacities can also be found in other conditions—primarily alveolar proteinosis, pulmonary edema, and hemorrhage—and also in other types of bacterial or viral pneumonia, such as herpes simplex and cytomegalovirus infections (17–20).

There were no patients with peribronchiolar consolidation, bronchopneumonia, and nodules—particularly centrilobular and tree-in-bud opacities—in our cohort. The absence of these thin-section CT features may serve to distinguish SARS from other types of atypical pneumonia, particularly pneumonia of viral or *Mycoplasma* origins, and infectious bronchiolitis (17–21). The predominance of ground-glass opacities over consolidation may allow differentiation of SARS from bacterial pneumonia, which characteristically manifests as consolidation in

a segmental or lobular distribution with ground-glass opacities found just around the consolidation rather than with the extensive involvement seen in SARS (18,21). Our study findings have also further reinforced the absence of mediastinal lymph nodes or substantial effusions in SARS, which may be used as additional helpful diagnostic signs.

It should be noted, however, that our patients probably represent those at the severe end of the disease spectrum, primarily hospitalized patients, who also have developed appropriate indications or complications to justify serial evaluations with thin-section CT. Hence, natural selection bias may have been introduced into the study design. The absence of scans obtained in the prone position is another limitation of the study, particularly with reference to bandlike opacities in the lung bases, which could have represented atelectasis that may have been observed as reversible on scans obtained in the prone position had they been obtained. Other limitations include the nonuniform scanning intervals among all patients caused by the retrospective nature of this study. However, because SARS is highly infectious, it would have been inappropriate and against institutional infection-control policy to systematically evaluate all SARS patients. Thin-

section CT should be reserved for patients in whom a diagnosis is uncertain or for patients with clinical deterioration in whom further evaluation of lung abnormalities is required.

We conclude that there is a temporal pattern of lung abnormalities in SARS, and the abnormalities increased considerably at the 2nd week of illness and were observed at thin-section CT; these abnormalities resulted in substantial residual disease in 50% (12 of 24) of patients at 4 weeks or longer after disease onset. Of these 24 patients, 21% (five) had normal scans and 29% (seven) had minimal residual abnormalities. The residual abnormalities most commonly consisted of a reticular pattern with or without associated ground-glass opacities and bronchial or bronchiolar dilatation. Long-term follow-up with thin-section CT and concomitant functional studies are required to determine the long-term pulmonary sequelae of SARS.

Abstract

Manaus, the capital of the Brazilian State of Amazonas, is the current epicenter of the COVID-19 epidemic in Amazonia. The sharp increase in deaths is a huge concern for health system administrators and society. The study aimed to analyze excess overall mortality according to Epidemiological Week (EW) in order to identify changes potentially associated with the epidemic in Manaus. Overall and cause-specific mortality data were obtained from the Central Database of the National Civil Registry and the Mortality Information System for 2018, 2019, and 2020. The study analyzed age bracket, sex, place of death, EW, calendar year, and causes of death. Ratios were calculated between deaths in 2019/2018 and 2020/2019 to estimate excess deaths, with 5% confidence intervals. No significant excess overall mortality was seen in the ratios for 2019/2018, independently of EW. Meanwhile, the ratios for 2020/2019 increased from 1.0 (95%CI: 0.9-1.3) in EW 12 to 4.6 (95%CI: 3.9-5.3) in EW 17. Excess overall mortality was observed with increasing age, especially in individuals 60 years or older, who accounted for 69.1% (95%CI: 66.8-71.4) of the deaths. The ratios for 2020/2019 for deaths at home or on public byways were 1.1 (95%CI: 0.7-1.8) in EW 12 and 7.8 (95%CI: 5.4-11.2) in EW 17. The explosion in overall mortality in Manaus and the high proportion of deaths at home or on public byways reveals the epidemic's severity in contexts of heavy social inequality and weak effectiveness of government policies, especially policies meant to deal with social inequalities and strengthen the Unified Health System.

Introduction

As of May 20, 2020, two months after the World Health Organization (WHO) declared COVID-19 a pandemic, some five million cases and approximately 320,000 deaths had been reported in 216 countries/areas/territories. Even with strong evidence of underestimation of its official statistics ¹, Brazil is now the third most heavily affected country, with 280,000 cases and 18,000 deaths (World Health Organization. WHO coronavirus disease (COVID-19) dashboard. <https://covid19.who.int/>, accessed on 20/May/2020).

Distribution of COVID-19 mortality reflects Brazil's social and geographic heterogeneity, with five states accounting for 81% of the deaths: São Paulo, Rio de Janeiro, Ceará, Pernambuco, and Amazonas, the latter having the highest proportion of infected individuals, with 10.6% (95%CI: 8.8-12.1) ².

The State of Amazonas is located in the Brazilian Amazonia, a region occupying approximately 60% of Brazil's territory and whose population has been exposed historically to poverty and social inequality ³. A study on the Greater Metropolitan Area of Manaus identified extensive inequality in access to health services ⁴. This is a common reality for populations living in remote areas and on indigenous lands ⁵, whose social and economic vulnerability limits their mobility in the territory, making them more susceptible to the dramatic spread of COVID-19, especially in the more serious forms of the disease.

For more than four weeks, Manaus has shown signs of exhaustion of the public hospital network due to the rapid increase in COVID-19 cases. In the first two weeks of May alone, there were nearly 7,000 new cases, double the number identified until then. In addition, from April 19 to 28, the average daily number of burials in Manaus was 123, four times more than the daily average in the same period in 2019 ⁶. The average daily number of COVID-19 deaths confirmed by health services during the same period was only 14, suggesting extensive underreporting, a problem seen elsewhere in the world, especially in places with precarious testing and deficient health services ^{7,8}.

Despite uncertainties on COVID-19-specific mortality ⁹, indicators of excess deaths are one of the most objective and comparable parameters to assess the epidemic's impact on mortality ¹⁰. This study thus aimed to analyze excess overall mortality according to Epidemiological Week (EW) in order to identify changes in the risk of death potentially associated with the epidemic.

Methods

Study design and data sources

This was a cross-sectional study with mortality data from the Central Database of the National Civil Registry (National CRC. <https://sistema.registrocivil.org.br>) and the Mortality Information System (SIM. <http://www2.datasus.gov.br>).

Due to the pandemic scenario, the National CRC assembled a COVID-19 Registration Panel (Portal da Transparência. <https://transparencia.registrocivil.org.br/registrar-COVID>, accessed on 10/May/2020), aimed at furnishing data on causes of death from Death Certificates recorded at notary public offices, which represents the totality of natural deaths, treated here as a proxy for general mortality. The data are updated daily and comply with legal guidelines and deadlines. The time between recording of the death and its transfer to the COVID-19 Registration Panel is 14 days or less, after which the data become public.

Working definitions

According to the National CRC criteria, a suspected or confirmed death from COVID-19 is one in which the death certificate mentions the terms COVID-19, coronavirus, or novel coronavirus in sections I (lines a, b, c, d) or II (other preexisting disease conditions not directly related to the death and not recorded in the causal sequence listed in part I). Besides COVID-19, other possible causes were considered based on the National CRC: severe acute respiratory syndrome (SARS); pneumonia; septicemia; and respiratory failure. Deaths not classified in any of the above-mentioned conditions

were included in the category “other causes”. Finally, “indeterminate” deaths (causes of deaths related to respiratory causes, but inconclusive) accounted for fewer than 1% of the sample and were not presented separately.

The National CRC data were updated on May 19, 2020, 66 days after the start of EW 12 and 24 days after the last day of EW 17. The start of EW 12 corresponds to the two days after confirmation of the first case of COVID-19 and to the 15 days prior to the first death from COVID-19 in Manaus.

For purposes of comparison, we also used data on overall mortality from the SIM, furnished for the EW in question in 2018 in the city of Manaus.

Study variables

The study variables were age bracket, sex, death at home or on public byways, EW, calendar year, and causes of death. Deaths from SARS, pneumonia (PNM), and respiratory failure (RF) were aggregated in a variable called “SARS+PNM+RF”, which excludes the group of deaths suspected or confirmed by COVID-19 and according to the criteria of the National CRC.

Data analysis

We calculated the ratios between deaths in 2019 and 2018 (2019/2018) and in 2020 and 2019 (2020/2019), in EW 12 to 17 in Manaus. We also calculated the ratios between deaths in 2020/2019 in EW 14 to 17, stratified by sex, age bracket, and cause of death. For the mortality ratios, we calculated confidence intervals with 5% significance. The analyses were performed in the R program, version 3.6.1 (<http://www.r-project.org>).

Results

In 2018, according to the SIM, the mean weekly number of deaths in Manaus was 230, close to the weekly number observed in the first 70 days of 2019 and 2020 according to data from the National CRC, or 225 and 218 deaths, respectively.

As shown in Figure 1, the overall mortality ratio for 2019/2018 is very close to one, independently of EW, while the ratio 2020/2019 only showed a similar pattern (close to one) from EW 12 to 14, with a major increase in the subsequent weeks. In other words, the ratio increased from 1.0 (95%CI: 0.9-1.3) in EW 12 to 4.6 (95%CI: 3.9-5.3) in EW 17.

The overall mortality ratios for 2020/2019 according to age bracket were not statistically significant in males under 40 years of age or females under 30 years of age, revealing the excess mortality from those age brackets upwards in 2020, especially in males (Table 1).

When comparing the 2020/2019 mortality ratio according to groups of causes of death, the data showed a gradual increase over the weeks, especially starting in EW 15, for deaths from “SARS+PNM+RF” (Figure 2). In the group of “other causes”, the mortality ratio remained close to one until EW 14, when it increased, reaching a ratio of 3 by EW 17.

As for the distribution of deaths across age brackets, 69.1% of the deaths occurred in individuals 60 years or older (95%CI: 66.8-71.4). The ratio of deaths occurring at home or on public byways (43/38) in EW 12 was 1.1 (95%CI: 0.7-1.8). This same ratio (268/33) reached 8.1 (95%CI: 5.7-11.7) in EW 17 (data not shown).

Discussion

According to the results, total deaths reported in 2019 were similar to 2018, comparing EW 12 through 17 in those two years. However, the comparison between total deaths in 2020 and 2019 revealed excess mortality starting in the 15th EW of 2020, with the ratio exploding in EW 17, when the number of deaths was 200% higher than in 2019.

The increase in deaths started in EW 15, approximately 15 days after confirmation of the first 30 cases of COVID-19 in Manaus. In EW 17, the anomalous number of deaths coincided with the collapse in the public hospital system. During this period, the mean number of burials per day tripled. Deaths at home or on public byways also increased, as did COVID-19 cases in neighboring municipalities. This set of events probably resulted from a major acceleration in the epidemic in Manaus ¹¹ in the previous weeks.

The fragility of the healthcare network in Manaus and in neighboring municipalities ⁴, combined with extensive social inequality ³, help explain the critical situation with the COVID-19 epidemic. Excess mortality in the pandemic is not limited to low- and middle-income countries, but has also appeared in New York City, United States, and in the provinces of Bergamo and Brescia in northern Italy ^{9,12,13}.

In relation to age, nearly 70% of the deaths occurred in persons 60 years or older, consistent with studies in other countries ^{9,12,13,14}. In this age bracket, comorbidities are more prevalent and have been associated with worse prognosis in cases of hospitalization for COVID-19 ¹⁵.

Another key aspect involves gender differences, with a higher risk of mortality among men, corroborating findings from other studies ^{16,17}. Lower case-fatality may be associated with women's heightened perception of the symptoms and search for health services, whereas men would only tend to turn to health services in the more serious stages of COVID-19, when therapeutic possibilities are more limited. However, Zeng et al. ¹⁸ argued that higher IgG antibody levels in women could partially explain the relatively higher case-fatality in men.

There was an explosive increase in mortality from respiratory problems (SARS+PNM+RF), common complications of COVID-19 ¹⁴, during the COVID-19 pandemic. There was also a significant increase in mortality from other causes, possibly resulting from factors such as: the patient's postponement of treatment in order to avoid exposure to the virus in hospitals, health services' prioritization of care for COVID-19 patients ¹⁹.

One strength of this study was the use of the overall mortality indicator to estimate excess deaths, which appears to be a useful resource for rapid and low-cost evaluations, besides serving as a more robust and comparable indicator in a pandemic scenario ¹⁰. Unlike COVID-19-specific mortality, overall mortality does not depend on testing strategies, health systems' organization and financing, demographic structure, or the choice of denominator, which can make the case-fatality estimates vary widely ⁹. However, the interpretation of this study's results should take some limitations into account, such as the lack of standardization or review of the causes of death on the death certificates and a possible under-recording of deaths on the digital platform of the National CRC, especially in 2019, which could overestimate the ratios between total deaths in 2020 and 2019, for example. However, judging by the comparisons between total deaths in 2019 and 2018, where the ratios were always close to one, this distortion may possibly be small.

The analytical strategy adopted in this study unequivocally reveals the high excess mortality in Manaus and the epidemic's severity in contexts of great social inequality, weak effectiveness of public policies, and fragility in health services. Efforts must be stepped up by administrators at the municipal, state, and federal levels to contain or mitigate the harmful effects of COVID-19, especially in more vulnerable areas where the pandemic tends to have a heavier impact on mortality.

Resumo

Manaus, capital do estado brasileiro do Amazonas, é o atual epicentro da epidemia na Amazônia com um aumento repentino de mortes que preocupa gestores e sociedade. O objetivo do estudo foi analisar o excesso na mortalidade geral, segundo Semanas Epidemiológicas (SE), visando a identificar mudanças potencialmente associadas à epidemia em Manaus. Dados de mortalidade geral e grupos de causas foram obtidos na Central de Informações do Registro Civil Nacional e no Sistema de Informações sobre Mortalidade, para 2018, 2019 e 2020. Analisou-se faixa etária, sexo, local de ocorrência do óbito, SE, ano-calendário e causas de morte. Calcularam-se razões entre as mortes ocorridas em 2019/2018 e 2020/2019 para avaliar o excesso de mortes, com intervalos de confiança no nível de 5%. Não observou-se excesso de mortalidade geral significativo nas razões 2019/2018, independentemente da SE. Já as razões de 2020/2019 passaram de 1,0 (IC95%: 0,9-1,3) na SE 12 para 4,6 (IC95%: 3,9-5,3) na SE 17. Observou-se excesso de mortalidade geral com a progressão da idade, especialmente em indivíduos com 60 anos e mais, os quais concentraram 69,1% (IC95%: 66,8-71,4) das mortes. A razão 2020/2019 para óbitos em domicílio/via pública foi de 1,1 (IC95%: 0,7-1,8) na SE 12 e de 7,8 (IC95%: 5,4-11,2) na SE 17. A explosão da mortalidade geral em Manaus e a elevada proporção de óbitos em domicílio/via pública expõe a gravidade da epidemia em contextos de grande desigualdade social e fraca efetividade de ações governamentais, em especial aquelas voltadas ao enfrentamento das desigualdades sociais e para a garantia e fortalecimento do Sistema Único de Saúde.

Manaus, capital del estado brasileño del Amazonas, es el actual epicentro de la epidemia en Amazonia y el aumento repentino de muertes preocupa a gestores y a la sociedad. El objetivo del estudio fue analizar el exceso en la mortalidad general, según Semanas Epidemiológicas (SE), con el objetivo de identificar cambios potencialmente asociados a la epidemia en Manaus. Los datos de mortalidad general y grupos de causas se obtuvieron en la Central de Información del Registro Civil Nacional y en el Sistema de Información sobre Mortalidad, referentes a 2018, 2019 y 2020. Se analizó franja de edad, sexo, lugar donde se produjo el fallecimiento, SE, año-calendario y causas de muerte. Se calcularon las causas entre las muertes acaecidas en 2019/2018 y 2020/2019 para evaluar el exceso de muertes, con intervalos de confianza en el nivel de 5%. No se observó un exceso de mortalidad general significativo en las causas 2019/2018, independientemente de la SE. Ya las causas de 2020/2019 pasaron de 1,0 (IC95%: 0,9-1,3) en la SE 12 a 4,6 (IC95%: 3,9-5,3) en la SE 17. Se observó un exceso de mortalidad general con la progresión de la edad, especialmente en individuos con 60 años y más, quienes concentraron un 69,1% (IC95%: 66,8-71,4) de las muertes. La razón 2020/2019 para óbitos en domicilio/vía pública fue de 1,1 (IC95%: 0,7-1,8) en la SE 12 y de 7,8 (IC95%: 5,4-11,2) en la SE 17. La explosión de la mortalidad general en Manaus y la elevada proporción de óbitos en domicilio/vía pública expone la gravedad de la epidemia en contextos de gran desigualdad social y débil efectividad de las acciones gubernamentales, en especial aquellas dirigidas al combate de las desigualdades sociales y para la garantía y fortalecimiento del Sistema Único de Salud.

Contact Tracing during Coronavirus Disease Outbreak, South Korea, 2020

Young Joon Park,¹ Young June Choe,¹ Ok Park, Shin Young Park, Young-Man Kim, Jieun Kim, Sanghui Kweon, Yeonhee Woo, Jin Gwack, Seong Sun Kim, Jin Lee, Junghee Hyun, Boyeong Ryu, Yoon Suk Jang, Hwami Kim, Seung Hwan Shin, Seonju Yi, Sangeun Lee, Hee Kyoung Kim, Hyeyoung Lee, Yeowon Jin, Eunmi Park, Seung Woo Choi, Miyoung Kim, Jeongsuk Song, Si Won Choi, Dongwook Kim, Byoung-Hak Jeon, Hyosoon Yoo, Eun Kyeong Jeong, on behalf of the COVID-19 National Emergency Response Center, Epidemiology and Case Management Team

We analyzed reports for 59,073 contacts of 5,706 coronavirus disease (COVID-19) index patients reported in South Korea during January 20–March 27, 2020. Of 10,592 household contacts, 11.8% had COVID-19. Of 48,481 nonhousehold contacts, 1.9% had COVID-19. Use of personal protective measures and social distancing reduces the likelihood of transmission.

Effective contact tracing is critical to controlling the spread of coronavirus disease (COVID-19) (1). South Korea adopted a rigorous contact-tracing program comprising traditional shoe-leather epidemiology and new methods to track contacts by linking large databases (global positioning system, credit card transactions, and closed-circuit television). We describe a nationwide COVID-19 contact tracing program in South Korea to guide evidence-based policy to mitigate the pandemic (2).

The Study

South Korea's public health system comprises a national-level governance (Korea Centers for Disease Control and Prevention), 17 regional governments, and 254 local public health centers. The first case of COVID-19 was identified on January 20, 2020; by May 13, a total of 10,962 cases had been reported.

Author affiliations: Korea Centers for Disease Control and Prevention, Cheongju, South Korea (Y.J. Park, O. Park, S.Y. Park, Y.-M. Kim, J. Kim, S. Kweon, Y. Woo, J. Gwack, S.S. Kim, J. Lee, J. Hyun, B. Ryu, Y.S. Jang, H. Kim, S.H. Shin, S. Yi, S. Lee, H.K. Kim, H. Lee, Y. Jin, E. Park, S.W. Choi, M. Kim, J. Song, S.W. Choi, D. Kim, B.-H. Jeon, H. Yoo, E.K. Jeong); Hallym University College of Medicine, Chuncheon, South Korea (Y.J. Choe)

All reported COVID-19 patients were tested using reverse transcription PCR, and case information was sent to Korea Centers for Disease Control and Prevention.

We defined an index case as the first identified laboratory-confirmed case or the first documented case in an epidemiologic investigation within a cluster. Contacts in high-risk groups (household contacts of COVID-19 patients, healthcare personnel) were routinely tested; in non-high-risk groups, only symptomatic persons were tested. Non-high-risk asymptomatic contacts had to self-quarantine for 14 days and were placed under twice-daily active surveillance by public health workers. We defined a household contact as a person who lived in the household of a COVID-19 patient and a nonhousehold contact as a person who did not reside in the same household as a confirmed COVID-19 patient. All index patients were eligible for inclusion in this analysis if we identified ≥ 1 contact. We defined a detected case as a contact with symptom onset after that of a confirmed COVID-19 index patient.

We grouped index patients by age: 0–9, 10–19, 20–29, 30–39, 40–49, 50–59, 60–69, 70–79, and ≥ 80 years. Because we could not determine direction of transmission, we calculated the proportion of detected cases by the equation [number of detected cases/number of contacts traced] $\times 100$, excluding the index patient; we also calculated 95% CIs. We compared the difference in detected cases between household and nonhousehold contacts across the stratified age groups.

We conducted statistical analyses using RStudio (<https://rstudio.com>). We conducted this study as a

legally mandated public health investigation under the authority of the Korean Infectious Diseases Control and Prevention Act (nos. 12444 and 13392).

We monitored 59,073 contacts of 5,706 COVID-19 index patients for an average of 9.9 (range 8.2–12.5) days after severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection was detected (Table 1). Of 10,592 household contacts, index patients of 3,417 (32.3%) were 20–29 years of age, followed by those 50–59 (19.3%) and 40–49 (16.5%) years of age (Table 2). A total of 11.8% (95% CI 11.2%–12.4%) of household contacts of index patients had COVID-19; in households with an index patient 10–19 years of age, 18.6% (95% CI 14.0%–24.0%) of contacts had COVID-19. For 48,481 nonhousehold contacts, the detection rate was 1.9% (95% CI 1.8%–2.0%) (Table 2). With index patients 30–39 years of age as reference, detection of COVID-19 contacts was significantly higher for index patients >40 years of age in nonhousehold settings. For most age groups, COVID-19 was detected in significantly more household than nonhousehold contacts (Table 2).

Conclusions

We detected COVID-19 in 11.8% of household contacts; rates were higher for contacts of children than adults. These risks largely reflected transmission in the middle of mitigation and therefore might characterize transmission dynamics during school closure (3). Higher household than nonhousehold detection might partly reflect transmission during social distancing, when family members largely stayed home except to perform essential tasks, possibly creating spread within the household. Clarifying the dynamics of SARS-CoV-2 transmission will help in determining control strategies at the individual and population levels. Studies have increasingly examined transmission within households. Earlier studies on the infection rate for symptomatic household contacts in the United States reported 10.5% (95% CI 2.9%–31.4%), significantly higher than for nonhousehold contacts (4). Recent reports on COVID-19 transmission have

estimated higher secondary attack rates among household than nonhousehold contacts. Compiled reports from China, France, and Hong Kong estimated the secondary attack rates for close contacts to be 35% (95% CI 27%–44%) (5). The difference in attack rates for household contacts in different parts of the world may reflect variation in households and country-specific strategies on COVID-19 containment and mitigation. Given the high infection rate within families, personal protective measures should be used at home to reduce the risk for transmission (6). If feasible, cohort isolation outside of hospitals, such as in a Community Treatment Center, might be a viable option for managing household transmission (7).

We also found the highest COVID-19 rate (18.6% [95% CI 14.0%–24.0%]) for household contacts of school-aged children and the lowest (5.3% [95% CI 1.3%–13.7%]) for household contacts of children 0–9 years in the middle of school closure. Despite closure of their schools, these children might have interacted with each other, although we do not have data to support that hypothesis. A contact survey in Wuhan and Shanghai, China, showed that school closure and social distancing significantly reduced the rate of COVID-19 among contacts of school-aged children (8). In the case of seasonal influenza epidemics, the highest secondary attack rate occurs among young children (9). Children who attend day care or school also are at high risk for transmitting respiratory viruses to household members (10). The low detection rate for household contacts of preschool-aged children in South Korea might be attributable to social distancing during these periods. Yet, a recent report from Shenzhen, China, showed that the proportion of infected children increased during the outbreak from 2% to 13%, suggesting the importance of school closure (11). Further evidence, including serologic studies, is needed to evaluate the public health benefit of school closure as part of mitigation strategies.

Our observation has several limitations. First, the number of cases might have been underestimated because all asymptomatic patients might

Table 1. Contacts traced by age group of index coronavirus disease patients, South Korea, January 20–March 27, 2020

Index patient age, y	No. (%) index patients	No. (%) contacts traced	No. contacts traced/index patient	Average time contacts monitored, d
0–9	29 (0.5)	237 (0.4)	8.2	12.5
10–19	124 (2.2)	457 (0.8)	3.7	9.0

Table 2. Rates of coronavirus disease among household and nonhousehold contacts, South Korea, January 20–March 27, 2020

Index patient age, y	Household		Nonhousehold	
	No. contacts positive/ no. contacts traced	% Positive (95% CI)	No. contact positive/ no. contacts traced	% Positive (95% CI)
0–9	3/57	5.3 (1.3–13.7)	2/180	1.1 (0.2–3.6)
10–19	43/231	18.6 (14.0–24.0)	2/226	0.9 (0.1–2.9)
20–29	240/3,417	7.0 (6.2–7.9)	138/12,393	1.1 (0.9–1.3)
30–39	143/1,229	11.6 (9.9–13.5)	70/7,407	0.9 (0.7–1.2)
40–49	206/1,749	11.8 (10.3–13.4)	161/7,960	2.0 (1.7–2.3)
50–59	300/2,045	14.7 (13.2–16.3)	166/9,308	1.8 (1.5–2.1)
60–69	177/1,039	17.0 (14.8–19.4)	215/7,451	2.9 (2.5–3.3)
70–79	86/477	18.0 (14.8–21.7)	92/1,912	4.8 (3.9–5.8)
≥80	50/348	14.4 (11.0–18.4)	75/1,644	4.6 (3.6–5.7)
Total	1,248/10,592	11.8 (11.2–12.4)	921/48,481	1.9 (1.8–2.0)

not have been identified. In addition, detected cases could have resulted from exposure outside the household. Second, given the different thresholds for testing policy between households and nonhousehold contacts, we cannot assess the true difference in transmissibility between households and nonhouseholds. Comparing symptomatic COVID-19 patients of both groups would be more accurate. Despite these limitations, the sample size was large and representative of most COVID-19 patients early during the outbreak in South Korea. Our large-scale investigation showed that pattern of transmission was similar to those of other respiratory viruses (12). Although the detection rate for contacts of preschool-aged children was lower, young children may show higher attack rates when the school closure ends, contributing to community transmission of COVID-19.

The role of household transmission of SARS-CoV-2 amid reopening of schools and loosening of social distancing underscores the need for a time-sensitive epidemiologic study to guide public health policy. Contact tracing is especially important in light of upcoming future SARS-CoV-2 waves, for which social distancing and personal hygiene will remain the most viable options for prevention. Understanding the role of hygiene and infection control measures is critical to reducing household spread, and the role of masking within the home, especially if any family members are at high risk, needs to be studied.

We showed that household transmission of SARS-CoV-2 was high if the index patient was 10–19 years of age. In the current mitigation strategy that includes physical distancing, optimizing the likelihood of reducing individual, family, and community disease is important. Implementation of public health recommendations, including hand and respiratory hygiene, should be encouraged to reduce transmission of SARS-CoV-2 within affected households.

Acknowledgments

We thank the Ministry of Interior and Safety, Si/Do and Si/Gun/Gu, medical staff in health centers, and medical facilities for their efforts in responding to COVID-19 outbreak.

About the Author

Dr. Young Joon Park is the preventive medicine physician leading the Epidemiology and Case Management Team for the COVID-19 National Emergency Response Center, Korea Centers for Disease Control and Prevention. His primary research interests include epidemiologic investigation of infectious disease outbreaks. Dr. Choe is an assistant professor at Hallym University College of Medicine. Her research focuses on infectious diseases epidemiology.

Coronavirus Disease Outbreak in Call Center, South Korea

Shin Young Park, Young-Man Kim, Seonju Yi, Sangeun Lee, Baeg-Ju Na, Chang Bo Kim, Jung-il Kim, Hea Sook Kim, Young Bok Kim, Yoojin Park, In Sil Huh, Hye Kyung Kim, Hyung Jun Yoon, Hanaram Jang, Kyungham Kim, Yeonhwa Chang, Inhye Kim, Hyeyoung Lee, Jin Gwack, Seong Sun Kim, Miyong Kim, Sanghui Kweon, Young June Choe, Ok Park, Young Joon Park, Eun Kyeong Jeong

We describe the epidemiology of a coronavirus disease (COVID-19) outbreak in a call center in South Korea. We obtained information on demographic characteristics by using standardized epidemiologic investigation forms. We performed descriptive analyses and reported the results as frequencies and proportions for categorical variables. Of 1,143 persons who were tested for COVID-19, a total of 97 (8.5%, 95% CI 7.0%–10.3%) had confirmed cases. Of these, 94 were working in an 11th-floor call center with 216 employees, translating to an attack rate of 43.5% (95% CI 36.9%–50.4%). The household secondary attack rate among symptomatic case-patients was 16.2% (95% CI 11.6%–22.0%). Of the 97 persons with confirmed COVID-19, only 4 (1.9%) remained asymptomatic within 14 days of quarantine, and none of their household contacts acquired secondary infections. Extensive contact tracing, testing all contacts, and early quarantine blocked further transmission and might be effective for containing rapid outbreaks in crowded work settings.

Since the first imported case of coronavirus disease (COVID-19) was confirmed in South Korea on January 20, 2020, a sharp increase in the number of COVID-19 cases has been observed, with most infections being reported from specific clusters (1). Outbreaks of COVID-19 related to mass gathering,

religious activities, workplaces, and hospitals have accounted for the largest portion cases in the national outbreak (1).

In March 2020, the Korea Centers for Disease Control and Prevention (KCDC), South Korea's national-level public health authority, was informed about a cluster of cases of COVID-19 in a call center located in a commercial-residential mixed-use building (building X) in the capital city of Seoul. We describe the epidemiology of this COVID-19 outbreak and detail the containment efforts to limit the spread of the disease.

Materials and Methods

Setting

On March 8, the Seoul Metropolitan Government was notified of a confirmed case of COVID-19 in a person who worked in building X; the case reportedly was associated with a possible cluster of cases. On March 9, KCDC and local governments (in Seoul, the city of Incheon, and Gyeonggi Province) formed a joint response team and launched an epidemiologic investigation with contact tracing. Building X is a 19-story floor in one of the busiest urban area of Seoul. Commercial offices are located on the 1st through 11th floors, and residential apartments are located on the 13th through 19th floors. We identified and investigated 922 employees who worked in the commercial offices, 203 residents who lived in the residential apartments, and 20 visitors. The call center is located on the 7th through 9th floors and the 11th floor; it has a total of 811 employees. Employees do not generally go between floors, and they do not have an in-house restaurant for meals.

Case Definition

We defined a patient under investigation (PUI) as one who worked at, lived at, or visited building X during February 21–March 8, 2020. We defined a confirmed

Author affiliations: Korea Centers for Disease Control and Prevention, Cheongju, South Korea (S.Y. Park, Y.-M. Kim, S. Yi, S. Lee, H. Lee, J. Gwack, S.S. Kim, M. Kim, S. Kweon, O. Park, Y.J. Park, E.K. Jeong); Seoul Metropolitan Government, Seoul, South Korea (B.-J. Na, J.-i. Kim, H.S. Kim, Y.B. Kim); Seoul Health Foundation, Seoul (C.B. Kim); Seoul Center for Infectious Disease Control and Prevention, Seoul (Y. Park, I.S. Huh); Incheon Metropolitan City, Incheon, South Korea (H.K. Kim, H.J. Yoon, H. Jang); Gyeonggi Provincial Office, Suwon, South Korea (K. Kim, Y. Chang, I. Kim); Hallym University College of Medicine, Chuncheon, South Korea (Y.J. Choe)

DOI: <https://doi.org/10.3201/eid2608.201274>

Figure 1. Epidemic curve of a coronavirus disease outbreak in a call center, by date of symptom onset, Seoul, Korea, 2020. Asymptomatic cases are excluded.

case-patient as a PUI with a positive COVID-19 laboratory test. We confirmed the diagnosis of COVID-19 by using real-time reverse transcription PCR assays. We defined a symptomatic case-patient as a confirmed case-patient with symptoms at the time of positive testing, a presymptomatic case-patient as a confirmed case-patient who was asymptomatic at the time of positive testing but later had symptoms during the 14 days of monitoring, and an asymptomatic case-patient as confirmed a case-patient with a positive COVID-19 test result who remained asymptomatic during the entire 14-day period.

Response Measures

Building X was closed on March 9, 2020, immediately after the outbreak was reported. We offered testing to all occupants (office workers and apartment residents) during March 9–12. We collected nasopharyngeal and oropharyngeal swab specimens from PUIs for immediate real-time reverse transcription

PCR testing; the average turnaround time was 12–24 hours. Confirmed case-patients were isolated, and negative case-patients were mandated to stay quarantined for 14 days. We followed and retested all test-negative case-patients until the end of quarantine. We also investigated, tested, and monitored household contacts of all confirmed case-patients for 14 days after discovery, regardless of symptoms. During March 13–16, we sent a total of 16,628 text messages to persons who stayed >5 minutes near the building X; we tracked these persons by using cell phone location data. The messages instructed the recipients to avoid contact with others and go to the nearest COVID-19 screening center to get tested.

Data Collection and Analysis

We obtained information on demographic characteristics and presence of symptoms through face-to-face interviews with case-patients, using standardized epidemiologic investigation forms. We performed

Table 1. Attack rate by location during a coronavirus disease outbreak in a call center, Seoul, South Korea, 2020

Location type and floor	Potentially exposed, no. (%)	Confirmed cases, no. (%)	Attack rate, % (95% CI)
Commercial			
1st–6th	84 (7.3)	0	0
7th (call center)	182 (15.9)	0	0
8th (call center)	207 (18.1)	0	0
9th (call center)	206 (18.0)	1 (1.0)	0.5 (0.0–3.1)
10th	27 (2.4)	2 (2.1)	7.4 (1.3–25.8)

Total	1,143	97	8.5 (7.0–10.3)

SYNOPSIS

descriptive analyses reported the results as frequencies and proportions for categorical variables. The investigation was a part of public health response and was not considered research subject to institutional review board approval; therefore, written informed consent by participants was not required.

Results

Of 1,145 PUIs, we tested 1,143 (99.8%) for COVID-19 (922 employees, 201 residents, and 20 visitors) and

identified 97 (8.5%, 95% CI 7.0–10.3) confirmed case-patients (Figure 1). Of 857 patients for whom demographic information was available, 620 (72.3%) were women; mean age was 38 years (range 20–80 years). Most (94 [96.9%]) of the confirmed case-patients were working on the 11th-floor call center, which had a total of 216 employees, resulting in an attack rate of 43.5% (95% CI 36.9%–50.4%) (Table 1; Figure 2). Most of the case-patients on the 11th floor were on the same side of the building. Among the 97

Figure 2. Floor plan of the 11th floor of building X, site of a coronavirus disease outbreak, Seoul, South Korea, 2020. Blue indicates the seating places of persons with confirmed cases.

confirmed case-patients, 89 (91.7%) were symptomatic at the time of investigation and 4 (4.1%) were presymptomatic during the time of investigation but later had onset of symptoms within 14 days of monitoring; 4 (4.1%) case-patients remained asymptomatic after 14 days of isolation.

The first case-patient with symptom onset, who worked in an office on the 10th floor (and reportedly never went to 11th floor), had onset of symptoms on February 22. The second case-patient with symptom onset, who worked at the call center on the 11th floor, had onset of symptoms on February 25. Residents and employees in building X had frequent contact in the lobby or elevators. We were not able to trace back the index case-patient to another cluster or an imported case.

We followed up on a total of 225 household contacts of confirmed COVID-19 case-patients (average 2.3 household members per confirmed case-patient). COVID-19 had occurred in 34 household members who had contact with symptomatic case-patients, translating to a secondary attack rate of 16.2% (Table 2). Among 11 household members of presymptomatic case-patients and 4 household members of asymptomatic case-patients, none had COVID-19 symptoms nor tested positive after 14 days of quarantine.

Discussion

We described the epidemiologic characteristics of a COVID-19 outbreak centered in a call center in South Korea. We identified 97 confirmed COVID-19 case-patients in building X, indicating an attack rate of 8.5%. However, if we restrict our results to the 11th floor, the attack rate was as high as 43.5%. This outbreak shows alarmingly that severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) can be exceptionally contagious in crowded office settings such as a call center. The magnitude of the outbreak illustrates how a high-density work environment can become a high-risk site for the spread of COVID-19 and potentially a source of further transmission. Nearly all the case-patients were on one side of the building on 11th floor. Severe acute respiratory syndrome coronavirus, the predecessor of SARS-CoV-2, exhibited multiple superspreading events in 2002 and 2003, in which a few persons infected others, resulting in

many secondary cases. Despite considerable interaction between workers on different floors of building X in the elevators and lobby, spread of COVID-19 was limited almost exclusively to the 11th floor, which indicates that the duration of interaction (or contact) was likely the main facilitator for further spreading of SARS-CoV-2.

Unique features of this outbreak investigation include a complete 14-day follow-up of close contacts of case-patients after containment measures were implemented. Close contact with an infected person is a well-recognized risk factor for acquiring SARS-CoV-2 (2). In a recent US study, the symptomatic secondary attack rate among 445 close contacts of COVID-19 case-patients was 10.5% among household members (3). In this outbreak in South Korea, we found that the secondary attack rate within the household was 16.5% among symptomatic index case-patients, which is consistent with other reports.

The role of asymptomatic COVID-19 case-patients in spreading the disease is of great concern. Among 97 confirmed COVID-19 case-patients in this study, 4 (4.1%) remained asymptomatic during the 14-days of monitoring. This rate is lower than the 30.8% rate estimated in previous modeling (4). A case-patient series from Beijing, China, indicated that asymptomatic case-patients accounted for 5% (13/262) of patients transferred to a designated COVID-19 hospital (5). Our data might represent the likely proportion of asymptomatic COVID-19 infections in the community setting. We also found that, among 17 household contacts of asymptomatic case-patients, none had secondary infections. Previous reports have postulated that SARS-CoV-2 in asymptomatic (or presymptomatic) case-patients might become transmissible to others (6); however, given the high degree of self-quarantine and isolation measures that were instituted after March 8 among this cohort, our analyses might have not detected the actual transmissibility in asymptomatic COVID-19 case-patients. Robust mass testing of all suspected case-patients might have prevented asymptomatic transmission because asymptomatic persons were given information about their possible infection and therefore might have self-isolated from their household members.

Table 2. Household secondary attack rate, by presence of symptoms, during a coronavirus disease outbreak in a call center, Seoul, South Korea, 2020

Symptom status of index patients	Exposed, no. (%)	Confirmed cases, no. (%)	Secondary attack rate, % (95% CI)
Symptomatic	210 (93.3)	34 (100.0)	16.2 (11.6–22.0)
Presymptomatic	11 (4.8)	0	0
Asymptomatic	4 (1.9)	0	0
Total	225	34	15.1 (10.8–20.6)

SYNOPSIS

This outbreak investigation has several limitations. First, we could not track these cases to another cluster, making it difficult to identify the actual index case-patient. Second, not all clinical information was available for all confirmed cases, prohibiting detailed description of clinical syndromes. Date of symptom onset by office seat would be informative in understanding SARS-CoV-2 transmission in close contact area. However, our findings demonstrate the power of screening all potentially exposed persons and show that early containment can be implemented and used in the middle of national COVID-19 outbreak. By testing all potentially exposed persons and their contacts to facilitate the isolation of symptomatic and asymptomatic COVID-19 case-patients, we might have helped interrupt transmission chains. In light of the shift to a global pandemic, we recommend that public health authorities conduct active surveillance and epidemiologic investigation in this rapidly evolving landscape of COVID-19.

In summary, this outbreak exemplifies the threat posed by SARS-CoV-2 with its propensity to cause large outbreaks among persons in office workplaces. Targeted preventive strategies might help mitigate the risk for SARS-CoV-2 infection in these vulnerable group.

Acknowledgments

We thank the relevant ministries (including the Ministry of Interior and Safety, Si/Do, and Si/Gun/Gu), medical staffs in health centers, and medical facilities for their efforts in responding to the COVID-19 outbreak.

The SARS-CoV-2 B.1.617 lineage was identified in October 2020 in India^{1–5}. It has since then become dominant in some Indian regions and UK and further spread to many countries⁶. The lineage includes three main subtypes (B.1.617.1, B.1.617.2 and B.1.617.3), harbouring diverse Spike mutations in the N-terminal domain (NTD) and the receptor binding domain (RBD) which may increase their immune evasion potential. B.1.617.2, also termed variant Delta, is believed to spread faster than other variants. Here, we isolated an infectious Delta strain from a traveller returning from India. We examined its sensitivity to monoclonal antibodies (mAbs) and to antibodies present in sera from COVID-19 convalescent individuals or vaccine recipients, in comparison to other viral strains. Variant Delta was resistant to neutralization by some anti-NTD and anti-RBD mAbs including Bamlanivimab, which were impaired in binding to the Spike. Sera from convalescent patients collected up to 12 months post symptoms were 4 fold less potent against variant Delta, relative to variant Alpha (B.1.1.7). Sera from individuals having received one dose of Pfizer or AstraZeneca vaccines barely inhibited variant Delta. Administration of two doses generated a neutralizing response in 95% of individuals, with titers 3 to 5 fold lower against Delta than Alpha. Thus, variant Delta spread is associated with an escape to antibodies targeting non-RBD and RBD Spike epitopes.

The variant Delta has been detected in many countries. It has become predominant in the state of Maharashtra and probably other Indian regions⁴ and represented 77% of sequenced viruses circulating in UK between June 2 and 9, 2021⁶. It has been classified as a Variant of Concern (VOC) and is believed to be 60% more transmissible than variant Alpha. Little is known about its sensitivity to the humoral immune response. Recent reports indicated a reduced sensitivity of members of the B.1.617 lineage to certain monoclonal and polyclonal antibodies^{1–5,7–9}.

Isolation and characterization of the variant Delta

We isolated the variant Delta from a nasopharyngeal swab of a symptomatic individual, a few days upon his return to France from India. The virus was amplified by two passages on Vero E6 cells. Sequences of the swab and the outgrown virus were identical and identified the

variant Delta (GISAID accession ID: EPI_ISL_2029113) (Extended Data Fig. 1). In particular, the Spike protein contained 9 mutations, when compared to the D614G strain (belonging to the basal B.1 lineage) used here as a reference, including five mutations in the NTD (T19R, G142D, Δ156, Δ157, R158G), two in the RBD (L452R, T478K), one mutation close to the furin cleavage site (P681R) and one in the S2 region (D950N) (Extended Data Fig. 1). This set of mutation was different from those observed in other members of the B.1.617 lineage and other VOCs (Extended Data Fig. 1). Viral stocks were titrated using S-Fuse reporter cells and Vero cells^{10,11}. Viral titers were similar in the two target cells and reached 10⁵–10⁶ infectious units/ml. Large syncytia expressing the Spike were observed in Delta-infected cells (Extended Data Fig. 2). Future work will help determining whether Delta is more fusogenic than other variants, as suggested here by the large size of Delta-induced syncytia.

Phylogenetic analysis of the B.1.617 lineage

To contextualize the Delta isolate reported here, we inferred a global phylogeny subsampling the diversity of SARS-CoV-2 sequences available on the GISAID EpiCoV database (Extended Data Fig. 3). The B.1.617 lineage, subdivided into three sublineages according to the PANGO classification¹², derives from the B.1 lineage (D614G). The three sublineages present multiple changes in the Spike, including the L452R substitution in the RBD, already seen in other variants such as B.1.429 and P681R, located in the furin cleavage site and which may enhance Spike fusogenic activity¹³. The E484Q substitution, which may be functionally similar to the antibody-escape mutation E484K found in variants Beta and Gamma (B.1.351 and P.1), is present in B.1.617.1 and B.1.617.3, and has likely reverted in the Delta sublineage, as it was present in a sequence (B.1.617) ancestral to the three sublineages (Extended Data Fig. 1)¹⁴. Whether the absence of E484Q, the presence of T478K, other changes in the Spike or elsewhere may facilitate viral replication and transmissibility remains unknown. Interestingly, the B.1.617 lineage is not homogeneous, with multiple mutations fixed in a sublineage (e.g. Spike:T19R, G142D or D950N) also detected at lower frequencies in other sublineages. This may reflect founder effects or similar selective pressures acting on these emerging variants.

Mutational changes in variant Delta

The locations of the Spike mutations in the variant Delta showed a similar overall distribution to those that appeared in other VOCs. In particular, in addition to D614G, the D950N mutation mapped to the trimer interface (Extended Data Fig. 4a), suggesting a potential contribution in regulating Spike dynamics, as shown with D614G¹³. As with other VOCs, some mutations in Delta cluster in the NTD (Extended Data Fig. 4b). The 156-157 deletion and G158R mutation map to the same surface as the 144 and 241-243 deletions in variants Alpha and Beta (B.1.351), respectively. The T19R maps to the surface patch that has several mutations in Alpha. These altered residues lie in the NTD “supersite” targeted by most anti-NTD neutralizing antibodies¹⁵. In the RBD, mutations appearing in VOCs map to the periphery of the ACE2 binding surface (Extended Data Fig. 4c), suggesting that the virus accumulates mutations there to reduce or avoid antibody recognition while maintaining binding to ACE2. For instance, the L452R mutation found in Delta impairs neutralization by antibodies¹⁶ and is located at this periphery. The only mutation within the ACE2 patch is at location 501, which increases affinity of the RBD for ACE2 and is also involved in antibody escape¹³. The T478K mutation in the RBD is unique to Delta and falls within the epitope region of potent neutralizing mAbs categorized as “Class 1” (Extended Data Fig. 4c)¹⁷. This mutation is close to the E484K mutation that facilitates antibody escape¹³. These observations prompted us to analyze the neutralization potential of mAbs and sera from convalescents and vaccinees against variant Delta.

Neutralization of variant Delta by monoclonal antibodies

We assessed the sensitivity of Delta to a panel of human mAbs using the S-Fuse assay. We tested four clinically approved mAbs, Bamlanivimab (LY-CoV555), Etesivimab (LY-CoV016), Casirivimab (REGN10933) and Imdevimab (REGN10987) targeting the RBD^{18,19} as well as eight anti-RBD (RBD-48, RBD-85, RBD-98 and RBD-109) and anti-NTD (NTD-18, NTD-20, NTD-69 and NTD-71) mAbs derived from convalescent individuals (Planchais et al, in preparation). Neutralizing anti-RBD mAbs can be classified into 4 main categories^{17,20}. RBD-48 and RBD-85 belong to the first category (“Class 1”) and act by blocking binding of the “up” conformation of RBD to ACE2¹⁷. The precise epitopes of RBD-98 and RBD-109 are not yet defined but overlap with those of RBD-48 and RBD-85. The anti-NTD antibodies bind uncharacterized epitopes.

We measured the potency of the four therapeutic antibodies against variant Delta and included as a comparison D614G (B.1), Alpha and Beta variants. The antibodies neutralized D614G, with IC50 (Inhibitory Concentration 50%) varying from 1.2×10^{-3} to 6.5×10^{-2} $\mu\text{g/mL}$ (Fig. 1). Etesivimab displayed a 200-fold increase of IC50 against Alpha. As previously reported, Bamlanivimab and Etesivimab did not neutralize Beta²¹. Bamlanivimab lost antiviral activity against Delta, in line with previous results demonstrating that L452R is an escape mutation for this mAb¹⁶. Etesivimab, Casirivimab and Imdevimab remained active against Delta (Fig. 1).

The four other anti-RBD mAbs neutralized D614G. The IC50 of RBD-48 and RBD-98 were about 15-100-fold higher with Alpha than with D614G, whereas RBD-85 displayed increased activity against Alpha. Three mAbs inhibited Delta whereas RBD-85 was inactive (Extended Data Fig. 5).

The four anti-NTD mAbs were globally less efficient than anti-RBD mAbs. They inhibited D614G with high IC50 (1-60 $\mu\text{g/mL}$) (Extended Data Fig. 5). Three anti-NTD antibodies lost activity against Alpha and Delta, whereas the fourth (NTD-18) inhibited to some extent the two variants. Thus, Delta escapes neutralization by some antibodies targeting the RBD or NTD.

We examined by flow cytometry the binding of each mAb to Vero cells infected with the different variants. Radar plots show the binding of all antibodies tested (Extended Data Fig. 6). D614G was recognized by the 12 mAbs tested. Alpha and Delta were recognized by 9 and 7 mAb, respectively. Bamlanivimab no longer bound Delta. We also analyzed the binding of the 12 mAbs to variant Beta, which is more resistant to neutralization. Bamlanivimab and Etesivimab lost their binding to Beta and only 5 of the antibodies bound this variant (Extended Data Fig. 6). Thus, escape of Delta and other variants to neutralization is due to a reduction or loss of binding of the antibodies.

Sensitivity of variant Delta to sera from convalescent individuals

We examined the neutralization ability of sera from convalescent subjects. We first selected samples from 56 donors in a cohort of infected individuals from the French city of Orléans. All individuals were diagnosed with SARS-CoV-2 infection by RT-qPCR or serology and included critical, severe, mild-to-moderate and asymptomatic cases (Extended Data Table 1). They were not vaccinated at the sampling time. We recently characterized the potency of these sera against D614G, Alpha and Beta isolates¹¹. We analyzed individuals sampled at a median of 188 days post onset of symptoms (POS), referred to as Month 6 (M6) samples. We calculated ED50 (Effective Dose 50%) for each combination of serum and virus (Extended Data Fig. 7a). With the Alpha variant, we obtained similar ED50 values in this series of experiments than in our previous analysis¹¹ (Extended Data Fig. 7b). We thus included our published data for D614G and Beta in the comparison. With Delta, neutralization titers were significantly decreased by 4 to 6-fold when compared to Alpha and D614G strains, respectively (Extended Data Fig. 7a). This reduction in neutralizing titers was similar against Delta and Beta (Extended Data Fig. 7a).

We asked whether this neutralization profile was maintained for longer periods of time. We analyzed sera from 47 individuals from another cohort of RT-qPCR-confirmed health care workers from Strasbourg University Hospitals who experienced mild disease^{22,23}. Twenty six individuals were unvaccinated, whereas 21 received a single dose of vaccine 7-81 days before sampling. The samples were collected at a later time point (M12), with a median of 330 and 359 days for unvaccinated and vaccinated individuals, respectively (Extended Data Table 1)²³. As observed²³, the neutralization activity was globally low at M12 in unvaccinated individuals (Fig. 2a). There was a 4 fold decrease of ED50 against Beta and Delta, relative to Alpha (Fig. 2a). The 21 single-dose vaccine recipients of the M12 cohort included 9 vaccinated with AstraZeneca, 9 with Pfizer and 3 with Moderna vaccines. Sera from these vaccinated participants showed a dramatic increase in neutralizing antibody titers

against Alpha, Beta and Delta variants, as compared to unvaccinated convalescents (Fig. 2a). Therefore, as shown with other variants^{23,24}, a single dose of vaccine boosts cross-neutralizing antibody responses to Delta.

We then classified the cases as neutralizers (defined as harboring neutralizing antibodies detectable at the first serum dilution of 1/30) and non-neutralizers, for the viral variants and the two cohorts (Extended Data Fig. 7c). Between 76% and 92% of the individuals neutralized the four strains at M6. The fraction of neutralizers was lower in the second cohort at M12, a phenomenon which was particularly marked for Beta and Delta. 88% of individuals neutralized Alpha and only 47% neutralized Delta. After vaccination, 100% of convalescent individuals neutralized the four strains (Extended Data Fig. 7c).

Thus, variant Delta displays enhanced resistance to neutralization by sera from unvaccinated convalescent individuals, particularly one year after infection.

Sensitivity of variant Delta to sera from vaccine recipients

We next asked whether vaccine-elicited antibodies neutralized variant Delta in individuals that were not previously infected with SARS-CoV-2. We randomly selected 59 individuals from a cohort of vaccinated subjects established in Orléans. The characteristics of vaccinees are depicted in Extended Data Table 2. 16 individuals received the Pfizer vaccine. They were sampled at week 3 (W3) after the first dose and W8 (corresponding to week 5 after the second dose). 13 individuals were also sampled at W16. 43 individuals received the AstraZeneca vaccine. Sera from 23 individuals were sampled after one dose (W10) and from 20 other individuals after two doses (W16, corresponding to week 4 after the second dose). We measured the potency of the sera against D614G, Alpha, Beta and Delta strains (Fig. 2b,c).

With the Pfizer vaccine, after a single dose (W3), the levels of neutralizing antibodies were low against D614G, and almost undetectable against Alpha, Beta and Delta variants (Fig. 2b). Titers significantly increased after the second dose. We observed a 3-fold and 16-fold reduction in the neutralization titers against Delta and Beta, respectively, when compared to Alpha (Fig. 2b). Similar differences between strains were observed at a later time point (W16), although titers were globally slightly lower (Extended Data Fig. 7b).

A similar pattern was observed with the AstraZeneca vaccine. It induced low levels of antibodies neutralizing Delta and Beta, when compared to D614G and Alpha, after a single dose (W10) (Fig. 2c). Four weeks after the second dose (W16), neutralizing titers were strongly increased. There was however a 5-fold and 9-fold reduction in neutralization titers against Delta and Beta, respectively, relative to Alpha (Fig. 2c).

We classified the vaccine recipients as neutralizers and non-neutralizers, for the four viral strains (Extended Data Fig. 7d,e). With Pfizer, 13% of individuals neutralized the variant Delta after a single dose. 81 to 100% of individuals neutralized any of the four strains after the second dose, at W8. This fraction remained stable at W16, with the exception of variant Beta, which was neutralized by only 46% of the individuals. 74% and 61% of individuals that received a single dose of AstraZeneca vaccine neutralized D614G and Alpha strains, respectively. This fraction sharply dropped with Beta and Delta variants, which were inhibited by only 4 and 9% of the sera. Four weeks after the second dose of AstraZeneca, 95-100% of individuals neutralized the four strains.

Therefore, a single dose of Pfizer or AstraZeneca was either poorly or not at all efficient against Beta and Delta variants. Both vaccines generated a neutralizing response that efficiently targeted variant Delta only after the second dose.

Discussion

We studied the cross-reactivity of mAbs to pre-existing SARS-CoV-2 strains, sera from long-term convalescent individuals and recent

vaccine recipients against an infectious Delta isolate. Some mAbs, including Bamlanivimab, lost binding to the Spike and no longer neutralized variant Delta. We further show that Delta is less sensitive to sera from naturally immunized individuals. Vaccination of convalescent individuals boosted the humoral immune response well above the threshold of neutralization. These results strongly suggest that vaccination of previously infected individuals will be most likely protective against a large array of circulating viral strains, including variant Delta.

In individuals that were not previously infected with SARS-CoV-2, a single dose of either Pfizer or AstraZeneca vaccines barely induced neutralizing antibodies against variant Delta. About 10% of the sera neutralized this variant. However, a two-dose regimen generated high sero-neutralization levels against variants Alpha, Beta and Delta, in subjects sampled at W8 to W16 post vaccination. Neutralizing antibody levels are highly predictive of immune protection from symptomatic SARS-CoV-2 infection²⁵. A recent report analyzing all sequenced symptomatic cases of COVID-19 in England was used to estimate the impact of vaccination on infection²⁶. Effectiveness was notably lower with Delta than with Alpha after one dose of AstraZeneca or Pfizer vaccines. The two-dose effectiveness against Delta was estimated to be 60% and 88% for AstraZeneca and Pfizer vaccines, respectively²⁶. Our neutralization experiments indicate that Pfizer and AstraZeneca vaccine-elicited antibodies are efficacious against variant Delta, but about 3-5 fold less potent than against variant Alpha. There was no major difference in the levels of antibodies elicited by Pfizer or AstraZeneca vaccines.

Potential limitations of our work include a low number of vaccine recipients analyzed and the lack of characterization of cellular immunity, which may be more cross-reactive than the humoral response. Future work with more individuals and longer survey periods will help characterize the role of humoral responses in vaccine efficacy against circulating variants.

Our results demonstrate that the emerging variant Delta partially but significantly escapes neutralizing mAbs, and polyclonal antibodies elicited by previous SARS-CoV-2 infection or vaccination.

Fig. 1 | Neutralization of SARS-CoV-2 variants D614G, Alpha, Beta and Delta by therapeutic mAbs. Neutralization curves of mAbs. Dose response analysis of the neutralization by four therapeutic mAbs (Bamlanivimab, Etesivimab,

Casirivimab and Imdevimab) on D614G strain and variants Alpha, Beta and Delta. Data are mean \pm SD of four independent experiments.

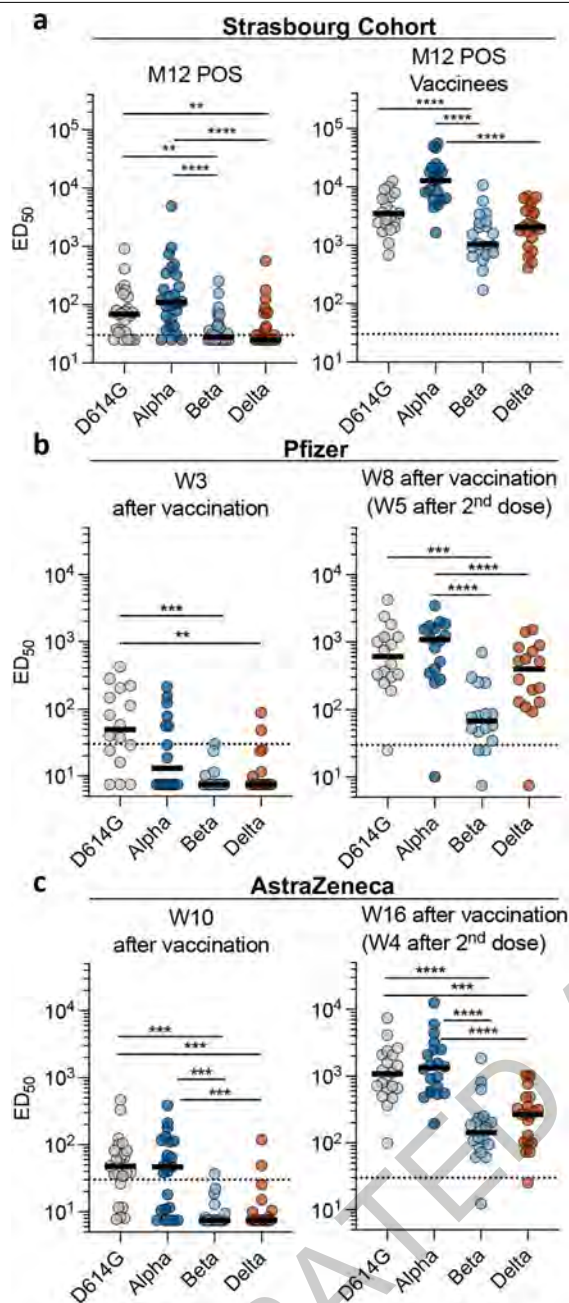

Fig. 2 | Sensitivity of SARS-CoV-2 variants D614G, Alpha, Beta and Delta to sera from convalescent individuals and vaccine recipients. Neutralization titers of the sera against the indicated viral isolates are expressed as ED₅₀.

a. Neutralizing activity of sera from the Strasbourg cohort of convalescent (n=26, left panel) and convalescent and vaccinated individuals (n=21, right panel) were sampled at Month 12 (M12) post onset of symptoms (POS).

b. Neutralizing activity of sera from Pfizer vaccinated recipients sampled at W3 (n=16) (left panel) and W8 post-vaccination (W5 after second dose) (n=16) (right panel).

c. Neutralizing activity of sera from AstraZeneca vaccinated recipients sampled at W10 (n=23) (left panel) and W16 post-vaccination (W4 post second dose) (n=20) (right panel). The dotted line indicates the limit of detection (ED₅₀=30). Data are mean from two independent experiments. Two-sided Friedman test with Dunn's multiple comparison was performed between each viral strain. **P* < 0.05, ***P* < 0.01, ****P* < 0.001, *****P* < 0.0001. M12 POS: D614G versus Beta, *P* = 0.0052; D614G versus Delta, *P* = 0.0052; Alpha versus Beta, *P* < 0.0001; Alpha versus Delta, *P* < 0.0001. M12 POS Vaccinees: D614G versus Beta, *P* < 0.0001; Alpha versus Beta, *P* < 0.0001; Alpha versus Delta, *P* < 0.0001.

Pfizer (W3): D614G versus Beta, *P* = 0.0001; D614G versus Delta, *P* = 0.0013. Pfizer (W8): D614G versus Beta, *P* = 0.0002; Alpha versus Beta, *P* < 0.0001; Alpha versus Delta, *P* = 0.0098. AstraZeneca (W10): D614G versus Beta, *P* < 0.0001; D614G versus Delta, *P* < 0.0001; Alpha versus Beta, *P* = 0.0006; Alpha versus Delta, *P* = 0.0056. AstraZeneca (W16): D614G versus Beta, *P* < 0.0001; D614G versus Delta, *P* = 0.0375; Alpha versus Beta, *P* < 0.0001; Alpha versus Delta, *P* = 0.0375.

Methods

No statistical methods were used to predetermine sample size. The experiments were not randomized and the investigators were not blinded to allocation during experiments and outcome assessment. Our research complies with all relevant ethical regulation.

Orléans Cohort of convalescent and vaccinated individuals

Since August 27, 2020, a prospective, monocentric, longitudinal, interventional cohort clinical study enrolling 170 SARS-CoV-2-infected individuals with different disease severities, and 59 non-infected healthy controls is on-going, aiming to describe the persistence of specific and neutralizing antibodies over a 24-months period. This study was approved by the ILE DE FRANCE IV ethical committee. At enrolment, written informed consent was collected and participants completed a questionnaire which covered sociodemographic characteristics, virological findings (SARS-CoV-2 RT-PCR results, including date of testing), clinical data (date of symptom onset, type of symptoms, hospitalization), and data related to anti-SARS-CoV-2 vaccination if ever (brand product, date of first and second doses). Serological status of participants was assessed every 3 months. Those who underwent anti-SARS-CoV-2 vaccination had regular blood sampling after first dose of vaccine (ClinicalTrials.gov Identifier: NCT04750720). The primary outcome was the presence of antibodies to SARS-CoV-2 Spike protein as measured with the S-Flow assay. The secondary outcome was the presence of neutralizing antibodies as measured with the S-Fuse assay. For the present study, we selected 56 convalescent and 59 vaccinated participants (16 with Pfizer and 43 with AstraZeneca). Study participants did not receive any compensation.

Strasbourg Cohort of convalescent individuals

Since April 2020, a prospective, interventional, monocentric, longitudinal, cohort clinical study enrolling 308 RT-PCR-diagnosed SARS-CoV-2 infected hospital staff from the Strasbourg University Hospitals is on-going (ClinicalTrials.gov Identifier: NCT04441684). At enrolment (from April 17, 2020), written informed consent was collected and participants completed a questionnaire which covered sociodemographic characteristics, virological findings (SARS-CoV-2 RT-PCR results including date of testing) and clinical data (date of symptom onset, type of symptoms, hospitalization). This study was approved by Institutional Review Board of Strasbourg University Hospital. The serological status of the participants has been described at Months 3 (M3) and Months 6 (M6) POS^{22,23}. Laboratory identification of SARS-CoV-2 was performed at least 10 days before inclusion by RT-PCR testing on nasopharyngeal swab specimens according to current guidelines (Institut Pasteur, Paris, France; WHO technical guidance). The assay targets two regions of the viral RNA-dependent RNA polymerase (RdRp) gene with a threshold of detection of 10 copies per reaction. The primary outcome was the presence of antibodies to SARS-CoV-2 Spike protein as measured with the S-Flow assay. The secondary outcome was the presence of neutralizing antibodies as measured with the S-Fuse assay. For the present study, we randomly selected 47 patients collected at M12 (26 unvaccinated and 21 vaccinated). Study participants did not receive any compensation.

Phylogenetic analysis

All SARS-CoV-2 sequences available on the GISAID EpiCov™ database as of May 21, 2021 were retrieved. A subset of complete and high coverage sequences, as indicated in GISAID, assigned to lineages B.1.617.1, B.1.617.2, B.1.617.3 were randomly subsampled to contain up to 5 sequences per country and epidemiological week in R with packages tidyverse and lubridate. Together with a single B.1.617 sequence this subset was included in the global SARS-CoV-2 phylogeny reconstructed with augur and visualized with auspice as implemented in the Nextstrain pipeline (<https://github.com/nextstrain/ncov>, version from 21 May 2021)²⁸. Within Nextstrain, a random subsampling approach capping

a maximum number of sequences per global region was used for the contextual non-B.1.617 sequences. The acknowledgment of contributing and originating laboratories for all sequences used in the analysis is provided in Supplementary Table 1.

3D representation of mutations on B.1.617.2 and other variants to the Spike surface

Panels in Fig. 1 were prepared with The PyMOL Molecular Graphics System, Version 2.1 Schrödinger, LLC. The atomic model used (PDB:6XR8) has been previously described²⁹.

S-Fuse neutralization assay

U2OS-ACE2 GFP1-10 or GFP 11 cells, also termed S-Fuse cells, become GFP+ when they are productively infected by SARS-CoV-2^{10,11}. Cells were tested negative for mycoplasma. Cells were mixed (ratio 1:1) and plated at 8×10^3 per well in a µClear 96-well plate (Greiner Bio-One). The indicated SARS-CoV-2 strains were incubated with serially diluted mAb or sera for 15 minutes at room temperature and added to S-Fuse cells. The sera were heat-inactivated 30 min at 56 °C before use. 18 hours later, cells were fixed with 2% PFA, washed and stained with Hoechst (dilution 1:1,000, Invitrogen). Images were acquired with an Opera Phenix high content confocal microscope (PerkinElmer). The GFP area and the number of nuclei were quantified using the Harmony software (PerkinElmer). The percentage of neutralization was calculated using the number of syncytia as value with the following formula: $100 \times (1 - (\text{value with serum} - \text{value in "non-infected"}) / (\text{value in "no serum"} - \text{value in "non-infected"}))$. Neutralizing activity of each serum was expressed as the half maximal effective dilution (ED50). ED50 values (in µg/ml for mAbs and in dilution values for sera) were calculated with a reconstructed curve using the percentage of the neutralization at the different concentrations.

Clinical history of the patient infected with B.1.617.2

A 54-year-old man was admitted April, 27, 2021 in the Emergency department of the Hôpital Européen Georges Pompidou hospital in Paris, France, for an acute respiratory distress syndrome with fever. He had no medical background and came back from India (West Bengali and few days spent in Delhi) 10 days before (April 17, 2021), where he stayed 15 days for his work. Onset of symptoms (abdominal pain and fever) was approximately April 18, 2021. The nasopharyngeal swab was tested positive for SARS-CoV-2 at his date of admission. Lung tomo-densitometry showed a mild (10-25%) COVID-19 pneumonia without pulmonary embolism. He initially received oxygen therapy 2 L/min, dexamethasone 6mg/day and enoxaparin 0,4 ml twice a day. His respiratory state worsened on day 3 (April 30, 2021). He was transferred in an intensive care unit, where he received high flow oxygen therapy (maximum 12 L/min). His respiratory condition improved, and he was transferred back in a conventional unit on day 8 (May 5, 2021). He was discharged from hospital on day 15 (May 10, 2021).

Virus strains

The reference D614G strain (hCoV-19/France/GE1973/2020) was supplied by the National Reference Centre for Respiratory Viruses hosted by Institut Pasteur (Paris, France) and headed by Pr. S. van der Werf. This viral strain was supplied through the European Virus Archive goes Global (Evag) platform, a project that has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement n° 653316. The variant strains were isolated from nasal swabs using Vero E6 cells and amplified by one or two passages. B.1.1.7 originated from a patient in Tours (France) returning from United Kingdom. B.1.351 (hCoV-19/France/IDF-IPP00078/2021) originated from a patient in Creteil (France). B.1.617.2 was isolated from a nasopharyngeal swab of a hospitalized patient returning from India. The swab was provided and sequenced by the laboratory of Virology of Hôpital Européen Georges Pompidou (Assistance Publique – Hôpitaux

Article

de Paris). Both patients provided informed consent for the use of the biological materials. Titration of viral stocks was performed on Vero E6, with a limiting dilution technique allowing a calculation of TCID₅₀, or on S-Fuse cells. Viruses were sequenced directly on nasal swabs, and after one or two passages on Vero cells. Sequences were deposited on GISAID immediately after their generation, with the following IDs: D614G: EPI_ISL_414631; B.1.1.7: EPI_ISL_735391; B.1.1.351: EPI_ISL_964916; B.1.617.2: ID: EPI_ISL_2029113.

Flow Cytometry

Vero cells were infected with the indicated viral strains at a multiplicity of infection (MOI) of 0.1. Two days after, cells were detached using PBS-EDTA and transferred into U-bottom 96-well plates (50,000 cell/well). Cells were fixed in 4% PFA for 15-30 min at RT. Cells were then incubated for 15-30 min at RT with the indicated mAbs (1 µg/mL) in PBS, 1% BSA, 0.05% sodium azide, and 0.05% Saponin. Cells were washed with PBS and stained using anti-IgG AF647 (1:600 dilution) (ThermoFisher). Stainings were also performed on control uninfected cells. Data were acquired on an Attune Nxt instrument using Attune Nxt Software v3.2.1 (Life Technologies) and analysed with FlowJo 10.7.1 (Becton Dickinson).

Antibodies

The four therapeutic antibodies were kindly provided by CHR Orleans. Human anti-SARS-CoV2 mAbs were cloned from S-specific blood memory B cells of COVID-19 convalescents (Planchais et al, manuscript in preparation). Recombinant human IgG1 mAbs were produced by co-transfection of Freestyle 293-F suspension cells (Thermo Fisher Scientific) as previously described³⁰, purified by affinity chromatography using protein G sepharose 4 fast flow beads (GE Healthcare) and validated using ELISA against the trimeric S, RBD, S2 and NTD proteins (Planchais et al, in preparation).

Statistical analysis

Flow cytometry data were analyzed with FlowJo v10 software (TriStar). Calculations were performed using Excel 365 (Microsoft). Figures were drawn on Prism 9 (GraphPad Software). Statistical analysis was conducted using GraphPad Prism 9. Statistical significance between different groups was calculated using the tests indicated in each figure legend.

Reporting summary

Further information on research design is available in the Nature Research Reporting Summary linked to this paper.

Data availability

All data supporting the findings of this study are available within the article or from the corresponding authors upon request. Source data are

provided with this paper. Viral sequences are available upon request and were deposited at GISAID (<https://www.gisaid.org/>) under the following numbers: hCoV-19/France/GE1973/2020 (D614G): EPI_ISL_414631; Alpha (B.1.1.7): EPI_ISL_735391; Beta (B.1.351): EPI_ISL_964916 and Delta (B.1.617.2): EPI_ISL_2029113. Extended Data Fig. 1 | Schematic overview of the B.1.617 sublineage and variants of concern. Schematic overview of B.1.617 sublineage (a) and variants of concern B.1.1.7 (Alpha), P.1 (Gamma) and B.1.351 (Beta) (b). Consensus

sequences with a focus on the Spike were built with the Sierra tool²⁷. Amino acid modifications in comparison to the ancestral Wuhan-Hu-1 sequence (NC_045512) are indicated.

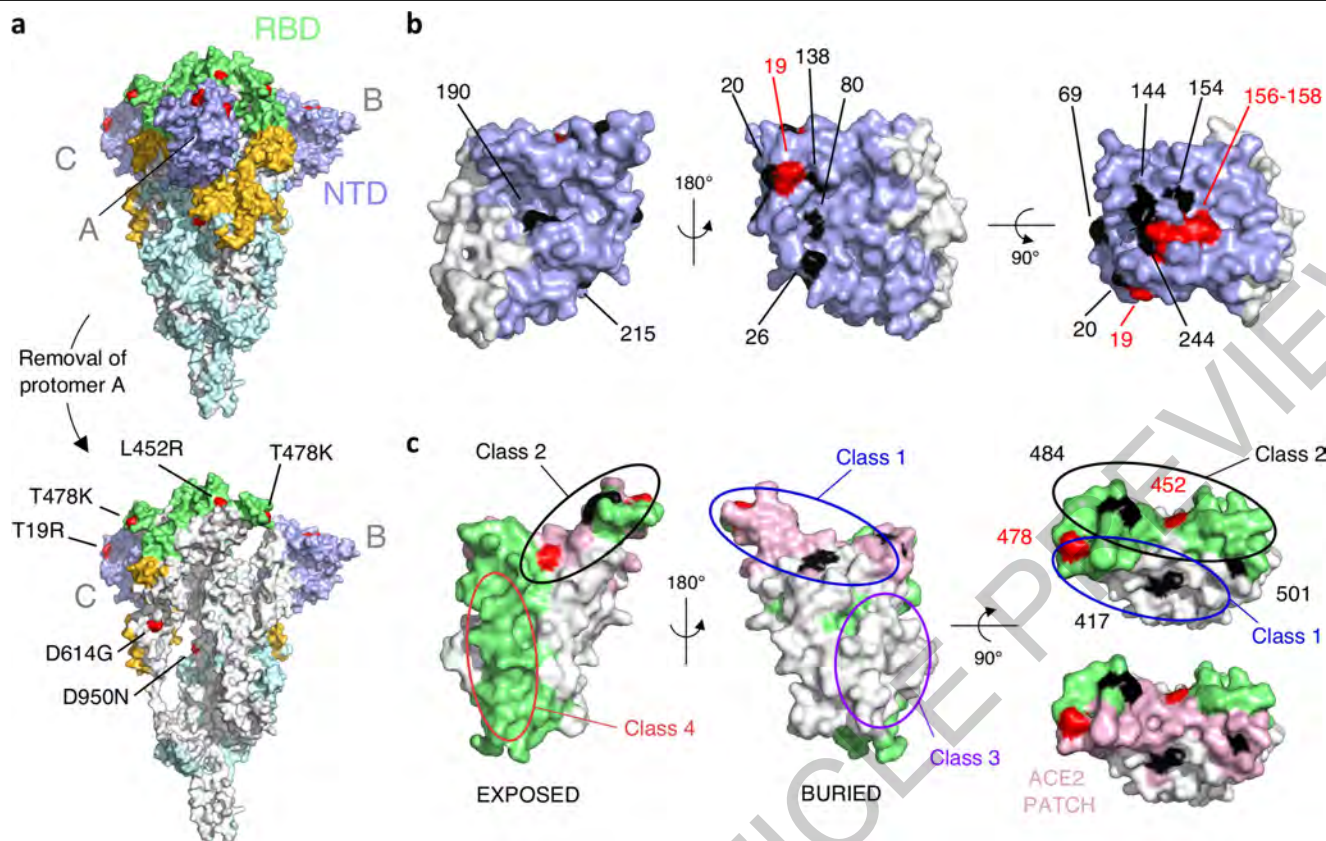

Extended Data Fig. 2 | SARS-CoV-2 variants induce syncytia in S-Fuse cells. S-Fuse cells were exposed to the indicated SARS-CoV-2 strain (MOI10³). The cells become GFP+ when they fuse together. After 20 h, infected cells were

stained with anti-Spike antibodies and Hoechst to visualize nuclei. Syncytia (green), Spike (red) and nuclei (blue) are shown. Representative images from three independent experiments are shown. Scale bar: 50 μ m.

Extended Data Fig. 3 | Global phylogeny of SARS-CoV-2 highlighting the B.1.617 lineage. The maximum likelihood tree was inferred using IQ-Tree, as implemented in the Nextstrain pipeline on a subsampled dataset of 3794 complete genomes. Branch lengths are scaled according to the number of

nucleotide substitutions from the root of the tree. The branches corresponding to key lineages are colored: B.1.1.7, dark blue; B.1.351, light blue; P.1, beige; B.1.617, pink; B.1.617.1, green; B.1.617.2, red; B.1.617.3, orange. A black circle indicates the position of the viruses studied here.

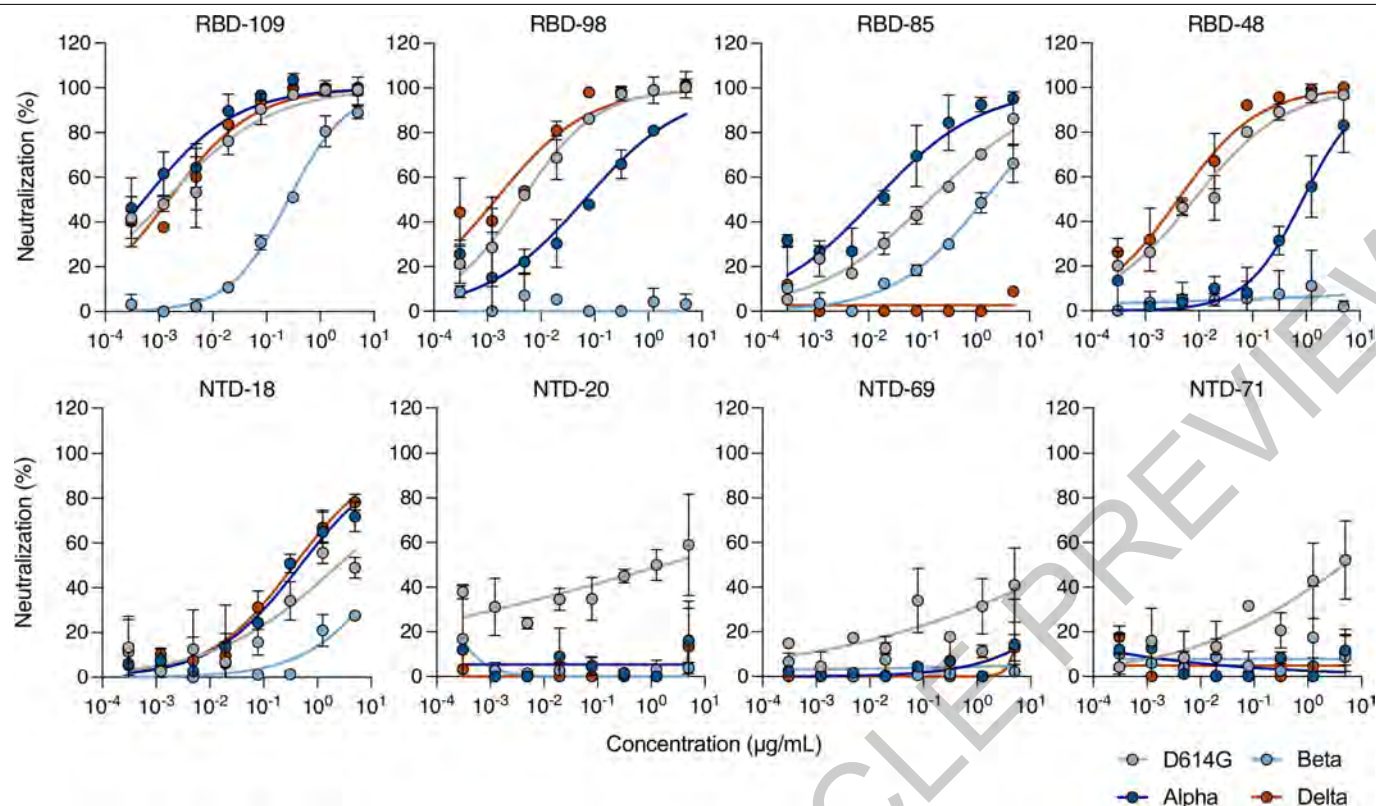

Extended Data Fig. 4 | Mapping mutations of variant Delta and other variants of concern to the Spike surface.

a. The Spike protein trimer (PDB:6XR8, corresponding to a closed spike trimer with all three RBDs in the “down” conformation) is shown with its surface colored according to domains: NTD in dark blue, RBD in green, the remainder of S1 in yellow and S2 in light blue. Interfaces between protomers were left white to help visualize the protomers’ boundaries. The three polypeptide chains in the trimer were arbitrarily defined as A, B and C. Surface patches corresponding to residues mutated in the variant Delta are colored in red. The bottom panel has the front protomer (chain A) removed to show the trimer interface (buried regions in the trimer are in white). The mutations in Delta are labelled in the bottom panel.

b. NTD shown in three orthogonal views. The left panel corresponds roughly to the orientation seen in chain B in a, and the middle panel shows a view from the

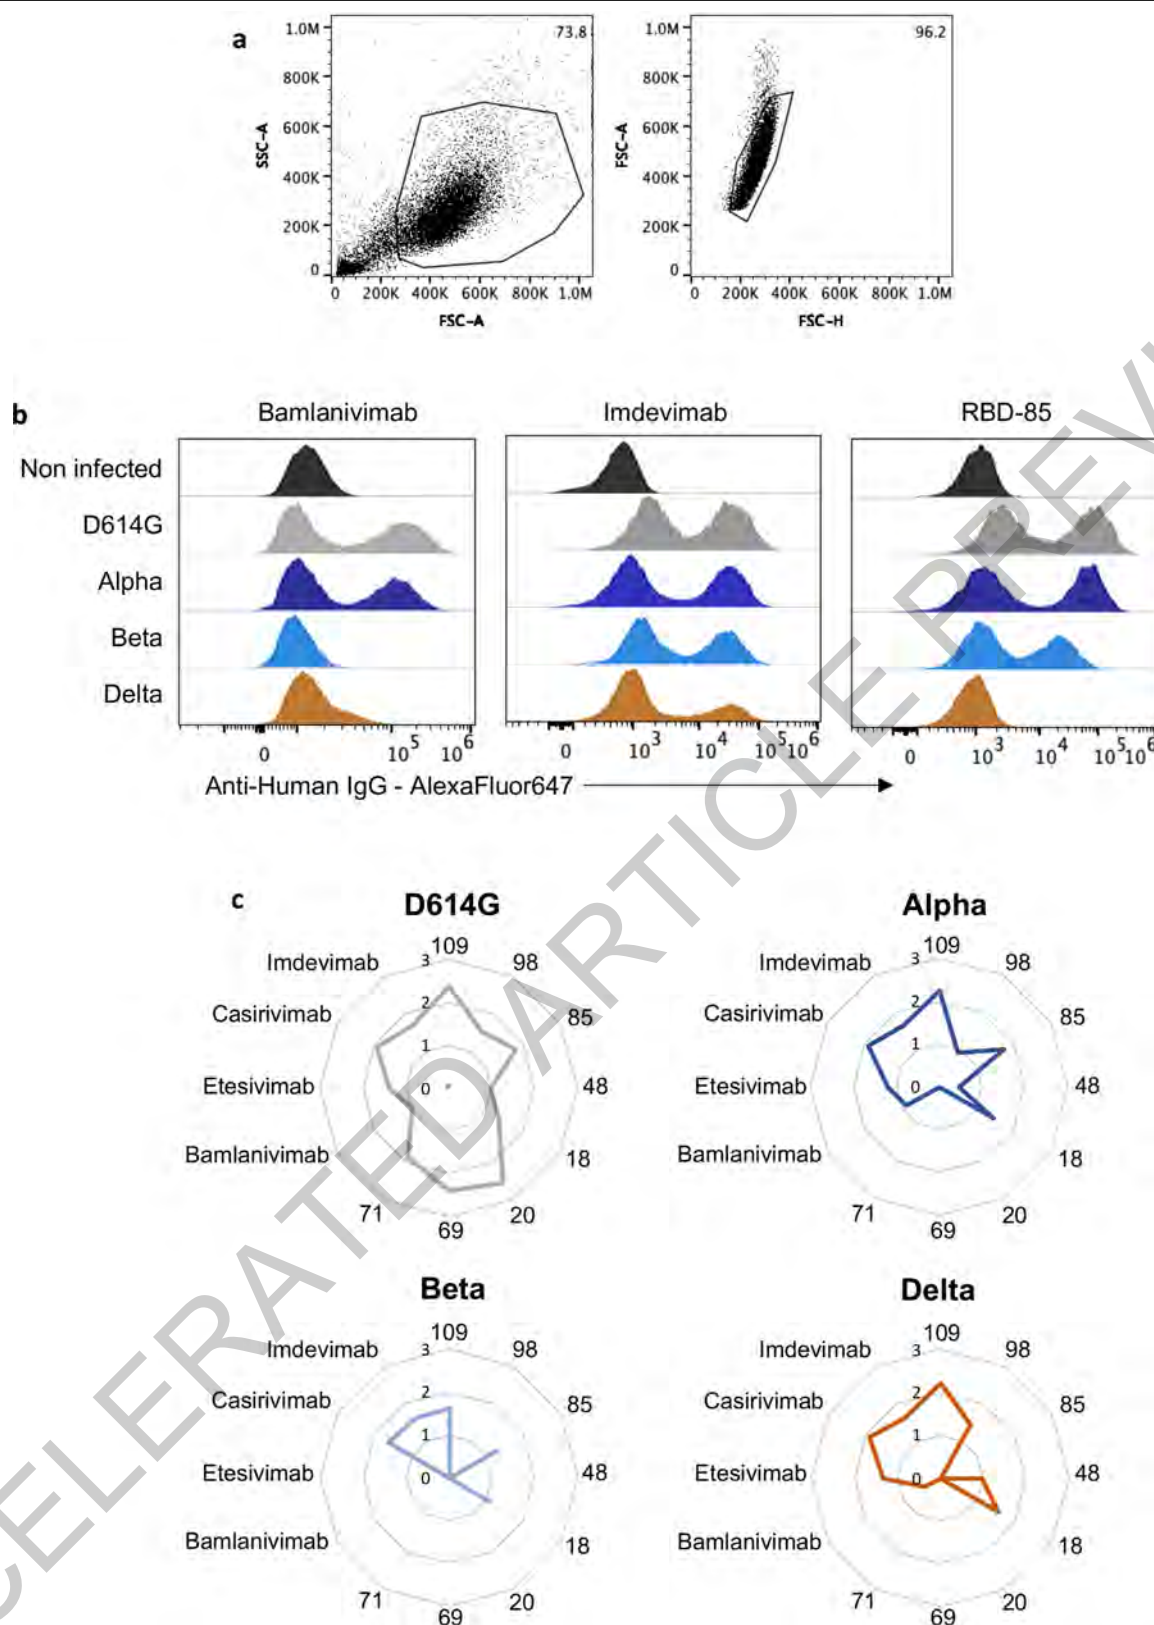

back. The right panel shows a view from the top of the trimer. Mutations found in the main variants of concern are indicated. The mutations found in variant Delta are in red. **c.** RBD shown in three orthogonal views, colored according to solvent exposure in the context of the closed spike: green and white indicate exposed and buried surfaces, as in a. The ACE2-binding surface is colored in pink. The left panel shows a view from the top of the trimer, and the middle panel a view from below. The right panels show a view down the ACE2 binding surface, highlighted in pink in the bottom panel. Mutations found in the main variants of concern are indicated. The mutations found in variant Delta are in red. The ovals indicate the epitope regions of the four main classes of anti-RBD neutralizing antibodies. Note that the mutations on the RBD cluster all around the ACE2 patch. Panels were prepared with The PyMOL Molecular Graphics System, Version 2.1 Schrödinger, LLC.

Extended Data Fig. 5 | Neutralization of SARS-CoV-2 variants D614G, Alpha, Beta and Delta by mAbs targeting the RBD and the NTD domains.

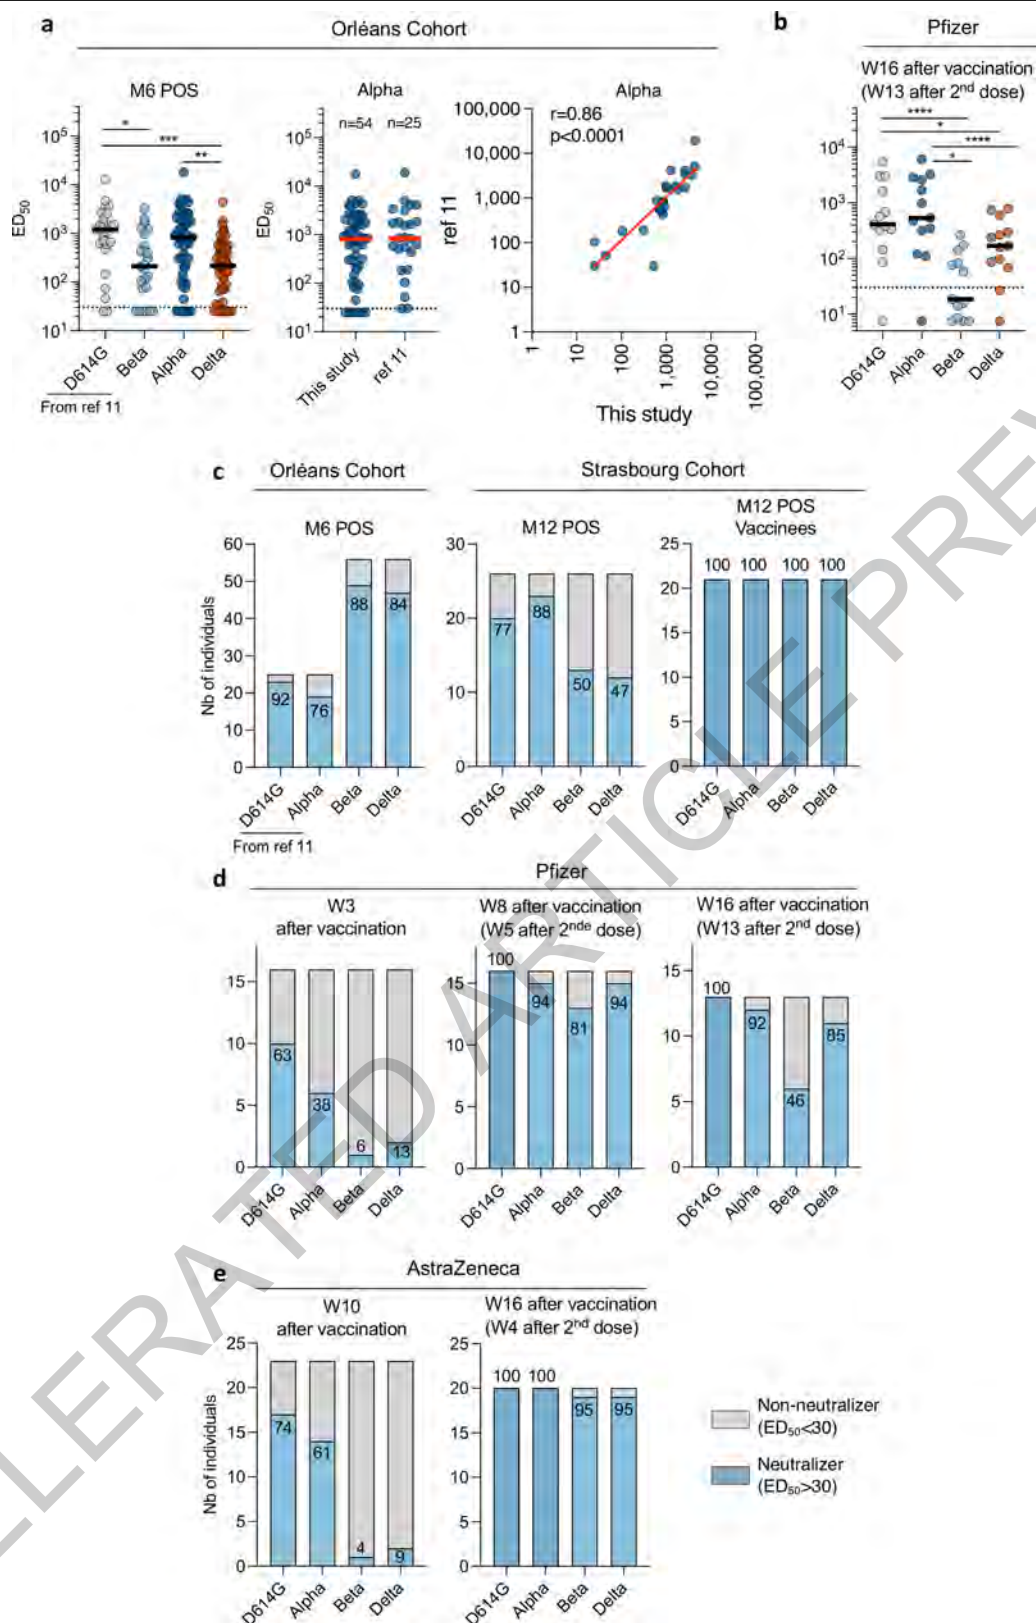

Neutralization curves of mAbs. Dose response analysis of the neutralization by

four anti-RBD and four anti-NTD on D614G strain (grey), and variants Alpha (dark blue), Beta (light blue) and Delta (orange). Data are mean \pm SD of three independent experiments.

Extended Data Fig. 6 | Binding of anti-SARS-CoV-2 mAbs to Vero cells infected with variants D614G, Alpha, Beta and Delta. Vero cells were infected with the indicated variants at a MOI of 0.1. After 48h, cells were stained with anti-SARS-CoV-2 mAbs (1 μ g/ml) and analyzed by flow-cytometry. **a.** Gating strategy. **b.** Histograms show the binding of Bamlanivimab,

Imdevimab and RBD-85 to Vero cells infected with the indicated variants. **c.** Radar charts represent for each antibody the logarithm of the mean of fluorescent intensity of the staining, relative to the non-infected condition. Data are representative of three independent experiments.

Extended Data Fig. 7 | See next page for caption.

Article

Extended Data Fig. 7 | Sensitivity of SARS-CoV-2 variants D614G, Alpha, Beta and Delta to sera from convalescent individuals and vaccine recipients. **a.** ED50 of neutralization of convalescent individuals from the Orléans cohort against the four viral variants are depicted. Samples were collected 6 months post onset of symptoms (M6 POS). Sensitivity of variants D614G and Alpha was assessed on 25 individuals previously published in ref.¹¹. Fifty six sera (including the 25 previous sera) were tested against variants Beta and Delta. Neutralization data obtained in this study and in ref.¹¹ were compared (middle panel) and correlated (right panel). Similar results were obtained, allowing to bridge the datasets. Data are mean from two independent experiments. The dotted line indicates the limit of detection (ED50=30). Two-sided Kruskal-Wallis test with Dunn's multiple comparison was performed between each viral strain. * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$, **** $P < 0.0001$. D614G versus Beta, $P = 0.0153$; D614G versus Delta, $P = 0.0008$; Alpha versus Delta, $P = 0.0014$. **b.** ED50 of neutralization of Pfizer-vaccinated individuals sampled at W16 (corresponding to W13 after the second dose). Data are mean from two independent experiments. The dotted line indicates the

limit of detection (ED50=30). Two-sided Kruskal-Wallis test with Dunn's multiple comparison was performed between each viral strain. * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$, **** $P < 0.0001$. D614G versus Beta, $P < 0.0001$; D614G versus Delta, $P = 0.0375$; Alpha versus Beta, $P < 0.0001$; Alpha versus Delta, $P = 0.0375$. **c,d,e.** Fraction of neutralizers in the cohorts of convalescent or vaccinated individuals. Individuals with an ED50 of neutralization above 30 were categorized as neutralizers and are indicated in blue. Non-neutralizers are in grey. **c.** Analysis of convalescent individuals from the Orléans cohort collected at M6 (left panel, related to Extended Data Fig. 7a.), from the Strasbourg cohort collected at M12 and unvaccinated (middle panel, related to Fig. 2a) or vaccinated (right panel, related to Fig. 2a). **c.** Sera from Pfizer vaccinated recipients were sampled at W3, W8 (left and middle panels, related to Fig. 2c), and W16 post-vaccination (related to Extended Data Fig. 7b). **e.** Sera from AstraZeneca vaccinated recipients sampled at W10 and W16 post-vaccination (related to Fig. 2c). The numbers indicate the % of neutralizers.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see our [Editorial Policies](#) and the [Editorial Policy Checklist](#).

Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.

n/a Confirmed

- ☐ ☒ The exact sample size (n) for each experimental group/condition, given as a discrete number and unit of measurement
- ☐ ☒ A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
- ☐ ☒ The statistical test(s) used AND whether they are one- or two-sided
Only common tests should be described solely by name; describe more complex techniques in the Methods section.
- ☐ ☒ A description of all covariates tested
- ☐ ☒ A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
- ☐ ☒ A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
- ☐ ☒ For null hypothesis testing, the test statistic (e.g. F , t , r) with confidence intervals, effect sizes, degrees of freedom and P value noted
Give P values as exact values whenever suitable.
- ☒ ☐ For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
- ☒ ☐ For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
- ☒ ☐ Estimates of effect sizes (e.g. Cohen's d , Pearson's r), indicating how they were calculated

Our web collection on [statistics for biologists](#) contains articles on many of the points above.

Software and code

Policy information about [availability of computer code](#)

Data collection Harmony Software v4.9 (Perkin-Elmer), Attune NXT Software v3.2.1 (ThermoFischer), Flowjo Software v10.7.1, R v4.1.0, tidyverse v1.3.1, Lubridate v1.7.10

Data analysis Excel 365 v16.46 (Microsoft), Prism v9.0.2 (GraphPad Software)

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors and reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research [guidelines for submitting code & software](#) for further information.

Data

Policy information about [availability of data](#)

All manuscripts must include a [data availability statement](#). This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

All data are provided as supplementary tables

Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

☒ Life sciences ☐ Behavioural & social sciences ☐ Ecological, evolutionary & environmental sciences

For a reference copy of the document with all sections, see [nature.com/documents/nr-reporting-summary-flat.pdf](https://www.nature.com/documents/nr-reporting-summary-flat.pdf)

Life sciences study design

All studies must disclose on these points even when the disclosure is negative.

Sample size	162 sera from convalescent, vaccinated and vaccinated convalescent individuals were analyzed in the study. Given the explanatory nature of the study aiming at describing a phenomenon whose frequency has not yet been established we did not use statistical methods to predetermine sample size. Thus, we included between 20 and 50 patients per group to allow statistical analysis
Data exclusions	None.
Replication	All experiments were performed and verified in multiple replicates as indicated in their methods/figure legends.
Randomization	The experiments were not randomized as this is not relevant for an observational study.
Blinding	The investigators were not blinded to allocation as this is not relevant for an observational study. However, the clinical sampling and biological measurement were performed by different teams. Only the final assembly of the data revealed the global view of the results.

Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.

Antibodies

Antibodies used	The anti-S RBD-48, RBD-85, RBD-98, RBD-109, NTD-18, NTD-20, NTD-69 and NTD-71 are human anti-S monoclonal antibodies isolated and produced by Hugo Mouquet (Institut Pasteur). Bamlanivimab, Etesivimab, Casirivimab and Imdevimab are kind gifts of Thierry Prazuck and Laurent Hocqueloux. The Goat anti-Human IgG (H+L) Cross-Adsorbed Secondary Antibody, Alexa Fluor 647 (A21445) was obtained from thermoFisher Scientific.
Validation	The human anti-S RBD-48, RBD-85, RBD-98, RBD-109, NTD-18, NTD-20, NTD-69 and NTD-71 were validated using ELISAs (against the trimeric S, RBD, S2 and NTD proteins) by the team of H.Mouquet. Bamlanivimab, Etesivimab, Casirivimab and Imdevimab were validated by measuring their binding and neutralizing activity against SARS-CoV-2. Validation of the goat anti-human IgG is available from the ThermoFisher website.

Eukaryotic cell lines

Policy information about [cell lines](#)

Cell line source(s)	Vero E6 (ATCC® CRL-1586™), Freestyle 293-F (ThermoFisher) and U2OS cells (ATCC® HTB-96™), all obtained from the ATCC.

Population characteristics

Orleans' Cohort of convalescent and/or vaccinated individuals: since April 2020, a prospective, monocentric, longitudinal, cohort clinical study enrolling 170 SARS-CoV-2-infected individuals and 59 non-infected healthy controls is on-going, aiming to describe the persistence of specific and neutralizing antibodies over a 24-months period. Relevant co-variables are available in extended table 1a and 2.

Strasbourg Cohort of convalescent individuals: Since April 2020, a prospective, interventional, monocentric, longitudinal, cohort clinical study enrolling 308 RT-PCR-diagnosed SARS-CoV-2 infected hospital staff from the Strasbourg University Hospitals is on-going. Given the exploratory design of the two studies, the characteristics of participants were not pre-established when entering the cohorts. Relevant co-variables are available in extended table 1b.

Recruitment

Orléans cohort : Individuals admitted to the hospital for COVID-19 or with known COVID-19 consulting for a chronic disease were invited to participate.

Strasbourg Cohort : Hospital staff with PCR-confirmed COVID-19 were invited to participate.

Individuals were included without any selection other than those imposed by the entry criteria (known COVID-19 or vaccination). Under these conditions, no particular bias is envisaged.

Ethics oversight

Orléans was approved by national external committee (CPP Ile de France IV, IRB No. 00003835). Strasbourg cohort was approved by the institutional review board of Strasbourg University Hospitals. At enrolment a written informed consent was collected for all participants.

Note that full information on the approval of the study protocol must also be provided in the manuscript.

Clinical data

Policy information about [clinical studies](#)

All manuscripts should comply with the ICMJE [guidelines for publication of clinical research](#) and a completed [CONSORT checklist](#) must be included with all submissions.

Clinical trial registration

NCT04750720 and NCT04441684

Study protocol

All protocols can be accessed on [clinicaltrial.gov](#)

Data collection

Orléans and strasbourg cohorts started on April 2020 in Strasbourg Hospital (Hopitaux universitaires de Strasbourg) and Orléans Hospital (Centre hospitalier Régional Orléans) respectively, and are on-going.

Outcomes

The primary outcome of both studies was the presence of antibodies to SARS-CoV-2 Spike protein as measured with the S-Flow assay. The secondary outcome was the presence of neutralizing antibodies as measured with the S-Fuse assay.

Flow Cytometry

Plots

Confirm that:

- ☒ The axis labels state the marker and fluorochrome used (e.g. CD4-FITC).
- ☒ The axis scales are clearly visible. Include numbers along axes only for bottom left plot of group (a 'group' is an analysis of identical markers).
- ☒ All plots are contour plots with outliers or pseudocolor plots.
- ☒ A numerical value for number of cells or percentage (with statistics) is provided.

Methodology

Sample preparation

SARS-CoV-2 infected Vero cells were stained as indicated in the method section. All samples were acquired within 24h.

Instrument

Attune NxT Acoustic Focusing Cytometer, blue/red/violet/yellow (catalog number : 15360667)

Software

AttuneNxT Software v3.2.1

Cell population abundance

At least 10,000 cells were acquired for each condition.

Gating strategy

All gates were set on uninfected Vero cells.

- ☒ Tick this box to confirm that a figure exemplifying the gating strategy is provided in the Supplementary Information.

Use of Stay-at-Home Orders and Mask Mandates to Control COVID-19 Transmission — Blackfeet Tribal Reservation, Montana, June–December 2020

Caroline Q. Pratt, MSN, MPH^{1,2}; Anna N. Chard, PhD^{1,2}; Rosaula LaPine, MSN³; K. Webb Galbreath³; Cinnamon Crawford, MPH³; Albert Plant⁴; Garland Stiffarm, MPH⁴; Neil Sun Rhodes, MD⁴; Lorissa Hannon⁴; Thu-Ha Dinh, MD²

COVID-19 has disproportionately affected persons who identify as non-Hispanic American Indian or Alaska Native (AI/AN) (1). The Blackfeet Tribal Reservation, the northern Montana home of the sovereign Blackfeet Nation, with an estimated population of 10,629 (2), detected the first COVID-19 case in the community on June 16, 2020. Following CDC guidance,* and with free testing widely available, the Indian Health Service and Blackfeet Tribal Health Department began investigating all confirmed cases and their contacts on June 25. The relationship between three community mitigation resolutions passed and enforced by the Blackfeet Tribal Business Council and changes in the daily COVID-19 incidence and in the distributions of new cases was assessed. After the September 28 issuance of a strictly enforced stay-at-home order and adoption of a mask use resolution, COVID-19 incidence in the Blackfeet Tribal Reservation decreased by a factor of 33 from its peak of 6.40 cases per 1,000 residents per day on October 5 to 0.19 on November 7. Other mitigation measures the Blackfeet Tribal Reservation used included closing the east gate of Glacier National Park for the summer tourism season, instituting remote learning for public school students throughout the fall semester, and providing a Thanksgiving meal to every household to reduce trips to grocery stores. CDC has recommended use of routine public health interventions for infectious diseases, including case investigation with prompt isolation, contact tracing, and immediate quarantine after exposure to prevent and control transmission of SARS-CoV-2, the virus that causes COVID-19 (3). Stay-at-home orders, physical distancing, and mask wearing indoors, outdoors when physical distancing is not possible, or when in close contact with infected or exposed persons are also recommended as nonpharmaceutical community mitigation measures (3,4). Implementation and strict enforcement of stay-at-home orders and a mask use mandate likely helped reduce the spread of COVID-19 in the Blackfeet Tribal Reservation.

The potential effects of community mitigation measures on changes in the number and incidence of new COVID-19 cases in the Blackfeet Tribal Reservation during June 16–December 10, 2020, were assessed using deidentified

laboratory and case investigation data. The tribal health clinic, the Indian Health Service, a dialysis clinic, and a long-term care facility performed testing for SARS-CoV-2 and used various data collection tools. Local public health nurses abstracted case investigation data, including patient age, sex, race, ethnicity, test date, and exposure information. A case was defined as receipt of a positive SARS-CoV-2 result from either a nucleic acid amplification test, such as a polymerase chain reaction test, or a rapid antigen detection test by a resident of the Blackfeet Tribal Reservation. Incidence was calculated as the daily number of new COVID-19 cases per 1,000 residents. Analyses were conducted using SAS (version 9.4; SAS Institute). Population estimates for the Blackfeet Tribal Reservation and for Montana were obtained from the U.S. Census Bureau (2,5). This activity was reviewed by CDC and was conducted consistent with applicable federal law and CDC policy.†

During 2020, the Blackfeet Nation implemented three stay-at-home orders; mask use in public was required by all three orders. The first was a mandatory stay-at-home order,§ which was in place during June 29–July 31; violations of isolation or quarantine orders could result in a fine up to \$500.¶,** The second was a recommended stay-at-home order,†† which began August 19. The third was an enforced stay-at-home order,§§ which began September 28. Under this third order, breaking quarantine or isolation orders could result in up to 3 years in jail and a fine up to \$5,000.¶¶ Patients unable to isolate at home were provided temporary housing in two local hotels. A COVID-19 dispatch team delivered medications and food to community members, as needed.

* <https://www.cdc.gov/coronavirus/2019-ncov/php/contact-tracing/contact-tracing-plan/overview.html>

During June 16–December 10, 2020, a total of 1,180 COVID-19 cases were reported in the Blackfeet Tribal Reservation (Table). The median age of patients was 36 years (range = 0–96 years); 50.5% of cases occurred in females, and 91.9% of patients self-identified as AI/AN. After the first COVID-19 case was reported in the community on June 16, the Blackfeet Tribal Business Council voted not to open the east gate of Glacier National Park, which borders the reservation, through the end of the 2020 tourist season (6). The Blackfeet Tribal Reservation recorded few cases during July, when mandatory stay-at-home orders and ongoing case investigation and contact tracing were in effect, with an average daily incidence of 0.10 cases per 1,000 residents (Figure 1). On July 31, the Blackfeet Tribal Reservation opened its campgrounds to residents when the mandatory stay-at-home orders expired. In August, a slight increase in incidence was observed, to 0.19 cases per 1,000.

The second, or recommended, stay-at-home order commenced on August 19. However, the number of cases increased after gatherings at the Northwest Montana Fair and Rodeo (August 19–23) in Kalispell, outside of the reservation, and during Labor Day weekend (September 5–7). Daily incidence peaked at 6.40 cases per 1,000 residents on October 5, which was 63 times the incidence in July.

On September 28, a third stay-at-home order was issued, with strict enforcement and substantial fines for violation. Afterward, incidence decreased to 0.19 cases per 1,000 by November 7. A gradual increase in newly identified cases among persons aged 5–17 years and 30–39 years began the week of August 9, after the campgrounds opened on July 31, and peaked the week of August 16 (Figure 2). During August, the numbers of cases in these age groups were higher than those in other age groups. Incident cases among persons aged 18–39 years and 50–64 years increased after the Northwest Montana Fair and Rodeo (week of August 16) and Labor Day weekend (week of September 6), and peaked during the week of September 27, before the enforced stay-at-home order was issued.

Among 142 (12.0%) of 1,180 patients with available household exposure data, 121 (85.2%) reported at least one household contact with COVID-19. Workplace exposure data were available for 198 (16.8%) patients, 12 (6.1%) of whom reported a workplace exposure. Community exposure data were available for 133 (11.3%) patients; among these, 53 (39.8%) reported known community exposure. Twelve patients (1.0%) reported exposure in an adult congregate living facility.

† Blackfeet case investigation report.

‡ Unknown for 340 COVID-19 patients.

¶ Unknown for 441 COVID-19 patients.

Discussion

After implementation of mitigation measures, including case investigation, contact tracing, a mandatory stay-at-home order, and required mask use in public, the average reported daily COVID-19 incidence in the Blackfeet Tribal Reservation remained low (0.10 cases per 1,000 residents) during July. When the mandatory stay-at-home order expired on July 31, the Tribal Business Council issued a recommended stay-at-home order on August 19. After the opening of local campgrounds and Northwest Montana Fair and Rodeo and Labor Day weekend gatherings, daily COVID-19 incidence increased sharply, peaking October 5, and representing a sixty-three-fold increase over the daily average incidence in July. The continued increase in newly identified cases after September 28, when the enforced stay-at-home order commenced, reflects exposures that occurred in the preceding 2 weeks.*** The strictly enforced stay-at-home order, with increased penalties, likely contributed to the more than thirtyfold decrease in incidence by November 7.

*** <https://www.cdc.gov/coronavirus/2019-ncov/hcp/clinical-guidance-management-patients.html>

FIGURE 1. Number of COVID-19 cases, by test date and 7-day moving average incidence (N = 1,150) — Blackfeet Tribal Reservation, Montana, June 1–December 10, 2020*[†]

* Case data collected and recorded by Blackfeet and Indian Health Service public health nurses.

[†] Among 1,180 total cases, 30 were missing test date and are not included in the figure.

FIGURE 2. Number of weekly COVID-19 cases, by week of test and age group (N = 1,150) — Blackfeet Tribal Reservation, Montana, June 1–December 10, 2020*[†]

* Case data collected and recorded by Blackfeet and Indian Health Service public health nurses.

[†] Among 1,180 total cases, 30 were missing test date and are not included in the figure.

The steep declines in COVID-19 incidence in the Blackfeet Tribal Reservation might not have occurred without widespread and consistent enforcement of the mandate for mask use in public and stay-at-home orders. Wearing a mask reduces SARS-CoV-2 transmission from persons with symptomatic or asymptomatic infection and offers some protection for the wearer.^{†††} On July 15, Montana first implemented a limited mask use mandate, which only applied to counties with four or more active COVID-19 cases,^{§§§} but enforcement across the state was inconsistent (7). COVID-19 incidence in Montana increased throughout September and October, peaking November 14, at 1.54 cases per 1,000 residents (8). After the mask use mandate was applied to all Montana counties on November 17 (9), incidence in the state decreased (8).

The increases in COVID-19 cases among Blackfeet residents aged 5–17 years and 30–39 years followed relaxation of stay-at-home orders, the opening of campgrounds, and gatherings at the Northwest Montana Fair and Rodeo and during Labor Day weekend. The peaks in COVID-19 incidence in these groups were followed approximately 6 weeks later by a peak among persons aged 50–64 years. The average household size in the Blackfeet Tribal Reservation (3.4 persons) is higher than that in Montana (2.4 persons) (2,5). Using limited available household data (available for 12% of all cases), a household COVID-19 contact was reported for a larger proportion of cases among the Blackfeet (85%) than for cases among other Montana residents (22%) (10). Multigenerational households might contribute to COVID-19 transmission between age groups in the Blackfeet Tribal Reservation; however, information on multigenerational households for the Blackfeet was not available. Future planning for mitigation measures and data collection should take multigenerational households into account.

The findings in this report are subject to at least five limitations. First, the different performance characteristics of the two diagnostic tests (rapid antigen detection and molecular SARS-CoV-2 tests) created potential misclassification of cases. Second, complete standardized data were not available because the various entities conducting testing did not use the same data collection tools. Third, the lack of consistently collected data on contact tracing, exposures, order compliance, and relationships between COVID-19 cases prevented the assessment of secondary transmission. Fourth, data on household, workplace, and community exposure was limited; comparison with other populations should be made with caution. Finally, the relative contribution of each mitigation measure to the changes in COVID-19 rates could not be ascertained.

Summary

What is already known about this topic?

Community mitigation measures (e.g., stay-at-home orders and mask use), coupled with case investigation and contact tracing with immediate isolation or quarantine, are primary approaches to preventing and controlling community SARS-CoV-2 transmission.

What is added by this report?

In the Blackfeet Tribal Reservation, enforcement of stay-at-home orders and mandated use of face coverings in public, with potential fines and jail for noncompliance, were associated with a thirty-three-fold reduction in COVID-19 incidence from its peak of 6.40 cases per 1,000 residents per day on October 5 to 0.19 on November 7, 2020.

What are the implications for public health practice?

Enforcement of stay-at-home orders and mask use mandates, coupled with robust public health investigations, have been shown to reduce COVID-19 incidence.

The enforcement of stay-at-home orders, coupled with a mandate for mask use in public, likely contributed to a reduction in COVID-19 incidence, potentially helping to control the pandemic in the Blackfeet Tribal Reservation. A combination of mitigation measures, including case investigation, contact tracing, and enforced stay-at-home and mask use orders, will likely reduce COVID-19 transmission by limiting potential exposure to SARS-CoV-2. As of 2021, vaccination is available and recommended as another effective method of COVID-19 mitigation. In communities disproportionately affected by COVID-19, these mitigation strategies are likely to help reduce some COVID-19–associated health disparities.

Abstract

It is essential to understand where and how severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is transmitted. Case reports were extracted from the local Municipal Health Commissions of 320 prefectural municipalities in China (not including Hubei Province). We identified all outbreaks involving three or more cases and reviewed the major characteristics of the enclosed spaces in which the outbreaks were reported and their associated indoor environmental aspects. Three hundred and eighteen outbreaks with three or more cases were identified, comprising a total of 1245 confirmed cases in 120 prefectural cities. Among the identified outbreaks, 53.8% involved three cases, 26.4% involved four cases, and only 1.6% involved ten or more cases. Home-based outbreaks were the dominant category (254 of 318 outbreaks; 79.9%), followed by transport-based outbreaks (108; 34.0%), and many outbreaks occurred in more than one category of venue. All identified outbreaks of three or more cases occurred in indoor environments, which confirm that sharing indoor spaces with one or more infected persons is a major SARS-CoV-2 infection risk.

KEYWORDS

COVID-19, crowding, indoor environments, indoor hygiene, outbreak, SARS-CoV-2

1 | INTRODUCTION

In less than 4 months, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) spreads rapidly to all countries worldwide. By the end of June 2020, it had infected more than 10 million people and, by developing into coronavirus disease 2019 (COVID-19), had caused or contributed to the deaths of half a million people.¹ Understanding where and how person-to-person SARS-CoV-2 transmission occurs is essential for effective intervention.

The once-in-a-century COVID-19 pandemic has occurred in the age of artificial intelligence and big data. Many clusters/outbreaks were identified via contact tracing by local health authorities in China and elsewhere using both traditional and new technologies. The identification of these clusters allowed health authorities to quarantine close contacts for effective intervention and provided

an opportunity to study the characteristics of where and how these clusters occurred. The first COVID-19 patient was identified in Wuhan in December 2019, and the largest number of confirmed Chinese cases occurred in Hubei Province, of which Wuhan is the provincial capital.² Since January 20, 2020, the local health authorities of cities outside Hubei have reported online the details of most identified cases of infection. These were nearly only cases of SARS-CoV-2 infection that had progressed to actual disease (ie, COVID-19) and necessitated hospitalization, as by February 11, 2020, our knowledge of asymptomatic infection was non-existent.

In this study, we identified the outbreaks from these case reports from the local Municipal Health Commissions of 320 prefectural cities (municipalities) in China, not including Hubei Province, between January 4 and February 11, 2020. We also reviewed the major characteristics of the enclosed areas in which these outbreaks

Hua Qian, Te Miao and Yuguo Li contributed equally.

were determined to have occurred and their associated indoor environmental aspects.

2 | METHODS

We collected descriptions of each confirmed case from the local Municipal Health Commission website of 320 prefectural cities in mainland China, not including Hubei province. Each local Municipal Health Commission gave daily descriptions of the confirmed cases. The case descriptions generally included age, sex, venue of infection, symptoms, date of symptom onset, hospitalization, and confirmation and history of exposure. Many described cases also included patient's trajectory and relationship with other confirmed cases, and clusters had often already been identified. We consulted nationwide websites, except for those of cities in Hubei Province, and collected all available data up to February 11, 2020. Data from a few major cities—Beijing, Shanghai, and Guangzhou—were not included in our analysis due to insufficient case descriptions. Case descriptions from Hong Kong, Macao, and Taiwan were collected from their respective health authorities. We input the data into a database and conducted cross-validation to insure data reliability.

A total of 7324 cases with the minimum required descriptions (ie, the information listed above) were found; these accounted for 66.7% of the 10 980 confirmed non-Hubei cases in China by February 11, 2020.³ In this study, we defined a *cluster* as an aggregation of *three* or more cases that appeared to be linked to the same infection venue (eg, an apartment, an office, a school or a train) during a period in which people were insufficiently close proximity. We defined an *outbreak* as a cluster in which a common index patient was suspected, and we excluded tertiary and higher-generation infections in counting the number of cases involved. We also excluded outbreaks that involved only two cases, to exclude possible spouse-to-spouse transmission and to reduce the workload due to the large number of clusters or outbreaks with two cases. We also identified the index patient(s) of the identified outbreaks and their date of symptom onset.

We divided the identified outbreaks into categories for further analysis. First, the following six categories of infection venues were considered: homes (apartments and villas), transport (eg, normal and high-speed trains, private cars, buses, passenger planes, taxis, and cruise ships), restaurants and other food venues, entertainment venues (gyms, mah-jong halls, card houses, tea houses, and barbershops), and shopping venues (shopping malls and supermarkets), and an additional miscellaneous category (eg, hospitals, hotel rooms, unspecified communities, and thermal power plants). Second, the following four categories of infected individuals were considered based on their relationship: family members, family relatives, socially connected individuals, and socially non-connected individuals. A socially connected relationship was defined as one that existed between individuals who had possibly been in close contact due to friendships, acquaintances, or jobs, but did not

Practical Implication

- The indoor environments in which we live and work are the most common venues in which SARS-CoV-2 is transmitted.
- There is a need to improve the hygienic and ventilation conditions of these indoor environments to decrease the transmission of airborne infectious diseases.
- Given that there is an association between crowding and infection, in the post-pandemic future, we need to reflect deeply on the need for a healthy indoor environment.

include family connections (family members or relatives). A socially non-connected relationship was defined as one with no social connection or family connection.

3 | RESULTS

We identified 318 outbreaks involving 1,245 infected individuals in 120 cities. The top three cities (Table S2) were Shenzhen, Guangdong (24 outbreaks, 7.5%; 84 cases, 6.7%), Chongqing (16 outbreaks, 5.0%; 61 cases, 4.9%) and Bozhou, Anhui (nine outbreaks, 2.8%; 35, 2.8%). The average number (\pm standard deviation) of cases per outbreak was 3.92 ± 1.65 . More than half (171; 53.8%) of the 318 identified outbreaks involved three cases, more than a quarter (84; 26.4%) involved four cases, and only five (1.6%) outbreaks involved ten or more cases. Table S1 briefly describes four outbreaks, including the largest outbreak, which occurred in a shopping mall in Tianjin (21 cases).

Among the 318 outbreaks, 129 involved only family members, 133 involved family relatives, 29 involved socially connected individuals, 24 involved socially non-connected individuals, and only three involved multiple relationships. In addition to family members, family relatives and socially connected individuals constituted a large proportion of the infected cases (Figure 1A).

Eighty-three of the 318 identified outbreaks had multiple possible venues, which meant either that the exact venue of infection could not be identified or that more than one venue was involved in the infection. If we double- or triple-count these venues, we have a total of 416 infection venues for 318 outbreaks (Figure 1B). Among the 318 outbreaks, 254 (79.9%) occurred in a home (one in a villa; all others in apartments), 108 (34.0%) occurred on transport, 14 occurred at a restaurant or other food venue, seven occurred at an entertainment venue, and seven occurred at a shopping venue (shopping mall and supermarket), with an additional 26 occurring at a miscellaneous venue (eg, hospital, hotel room, unspecified community, and thermal power plant). Among the 235 outbreaks with an exact venue, 188 occurred in a home, 18 occurred on transport, 10 occurred at a restaurant,

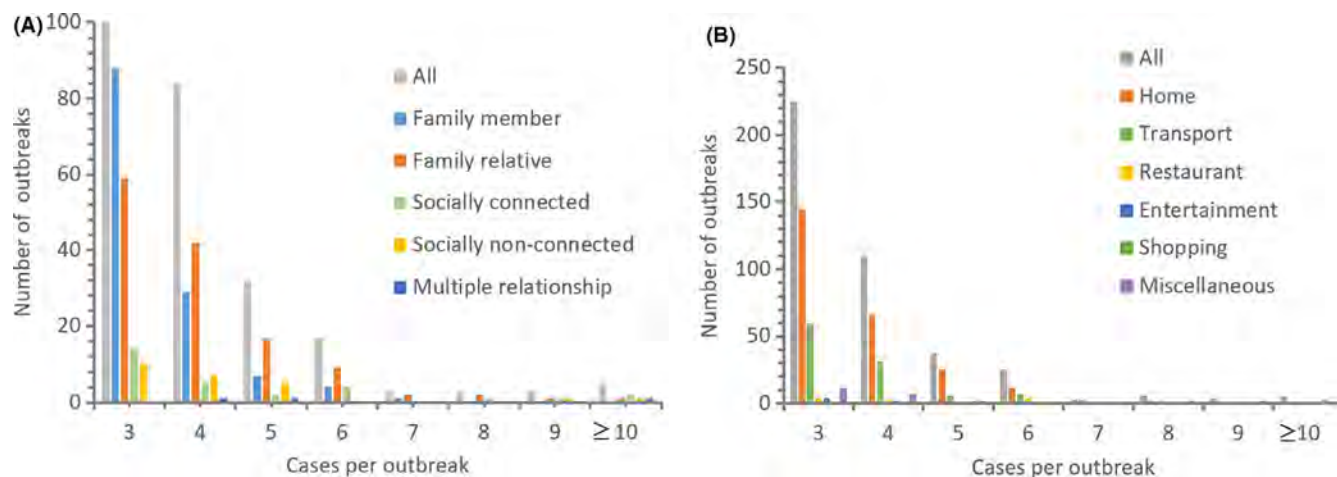

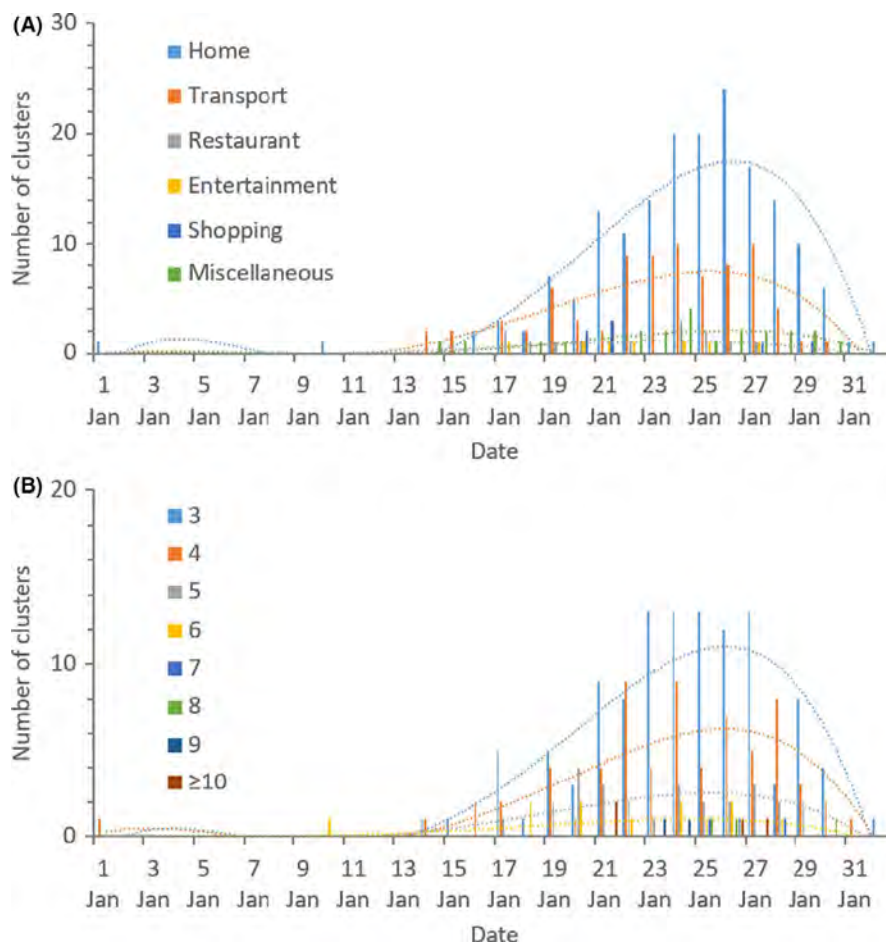

FIGURE 1 Distribution of all identified 318 outbreaks (A) involving confirmed cases of different relationships and (B) for each category of the 416 venues

FIGURE 2 Occurrence of outbreaks on median dates of infectious period for 231 actual outbreaks (A) in different categories for 300 venues and (B) with different numbers of cases in each outbreak on median dates of infectious period

six occurred at an entertainment venue, and seven occurred at a shopping venue, with an additional six occurring at a miscellaneous venue. For the 83 outbreaks with multiple possible venues, a total of 181 venues were identified (2.18 venues per outbreak). Among the 181 venues, 66 were homes, 90 were a form of transport, 4 were restaurants, 1 was an entertainment venue, and 20 were miscellaneous venues.

Most of the 254 home outbreaks comprised three to five cases (145 with three cases, 66 with four cases, and 25 with five cases). The average number of cases was 3.7 for outbreaks at homes, 3.8 for outbreaks on transport, 4.9 for outbreaks at food venues, 3.6 for outbreaks at entertainment venues, 8.7 for outbreaks at shopping venues, and 4.4 for outbreaks at miscellaneous venues. The proportion of large outbreaks was high for shops and food venues, possibly

because more susceptible individuals were present in these venues than in homes. Shopping and entertainment venues were each associated with only seven outbreaks. This suggests that it will be difficult to implement preventive measures in places that are frequented by large numbers of susceptible individuals if exact transmission routes are uncertain. In this context, it may be useful to provide further details of the seven outbreaks in shopping venues, as these had the highest average number of cases. There was one super-spreading event (outbreak) in a shopping center involving 21 cases, and there were also two outbreaks involving 10 cases (Table S1). In these three outbreaks, two of the index patients were shopping assistants in the shopping centers and one was a vegetable trimmer in the supermarket. These were all low-end shopping venues, where we suspect that the ventilation was poor or insufficient, at least for the 21-case outbreak; however, we have no direct evidence for this. In contrast, the index patient might have been a super-spreader, because the nature of the shopping assistants' job placed them in close contact with many people for a long duration. In the third case, the virus might have been present on the raw vegetables and thus been transferred to the vegetable trimmer.

Between December 29, 2019, and January 31, 2020, we also identified 231 outbreaks with known start and end dates of the suspected infectious period (Figure 2A). The identified outbreaks peaked between January 23 and 28 (Figure 2A), which coincides with the celebration period of the Chinese New Year (CNY). CNY 2020 lasted from New Year's Eve on January 24 to the Lantern Festival (ie, the 15th of Lunar January) on February 8. The official holiday in mainland China was from January 24 to 30, 2020. The peak date for the number of transport outbreaks was 1 to 2 days earlier than that for the home outbreaks as people traveled home for CNY.

Because home outbreaks dominated, the changes in the temporal profile of the number of cases (Figure 2A) closely followed that of the home outbreaks (Figure 2B). However, for outbreaks with more than six cases, no particular pattern was identified over time, which suggests a sporadic nature.

Among the 231 outbreaks with a known suspected infectious period, 126 included a known date of symptom onset for the index patient (Figure 3). We further divided those 126 outbreaks into two subgroups according to the index patient's symptom-onset date, as follows: on or before January 28 (96 outbreaks) and after January 28 (30 outbreaks). The average time from symptom onset to the end of the infectious period was 3.76 ± 4.42 days for those on and before January 28 and 0.87 ± 2.80 days for those afterward. The significant reduction in the average time from symptom onset to the end of the infectious period between these subgroups suggests the effectiveness of the early detection and isolation policy, which also explains the sharp decline in cases of infection after January 28.

Information is available on both the age and sex of the index patient for 139 outbreaks (Figure 4). Eighty-six outbreaks (62%) had a male index case, and 53 (38%) had a female index case. The average number of infected patients (excluding the index case) was approximately 3 for most age groups (3 for minors [ie, <18 years of age], with only one outbreak; 2.79 for young adults [ie, 18–35 years of age],

FIGURE 3 One hundred and twenty-six outbreaks with both possible starting and end infectious dates and date of symptom onset of index patient. Non-home outbreaks are shown in red

FIGURE 4 One hundred and thirty-nine outbreaks with information on the age of the index patient. Minors (<18 y old), young adults (18–35 y old), middle-aged adults (36–55 y old), senior adults (>55 y old)

in 33 outbreaks; and 3.11 for middle-aged adults [ie, 36–55 years of age], in 65 outbreaks). The average number of infected patients was 2.58 for senior adults [ie, >55 years of age], in 40 outbreaks. We were interested to note that among the outbreaks with a middle-aged index case, a female index case infected an average of 3.71 others, while a male index case infected 2.75 others. The dominant middle-aged group of reported index cases likely reflects the fact that returned migrant workers from Wuhan constituted the major pool of source patients in provinces outside Hubei.

4 | DISCUSSION

The first salient feature of the 318 identified outbreaks that involved three or more cases is that they all occurred in indoor environments. Although this finding was expected, its significance has not been

well recognized by the community or by policymakers. In a modern civilization, our lives and work are indoors. The transmission of SARS-CoV-2 from infected individuals to susceptible individuals is mainly an indoor phenomenon.

The emergence of homes as the most common COVID-19 outbreak venue in China is not surprising. During the COVID-19 epidemic in mainland China, homes became temporary quarantine places. Our estimated home dominance of 79.9% is close to the official estimate of 83% of the so-called household clusters among the nearly 1000 clusters (not outbreaks) defined by the China National Health Commission.⁴ After Wuhan announced its city lockdown on January 23, the warning message spread throughout the country. People in provinces outside Hubei also began to stay at home. Most Chinese families have one child, and some families may also include grandparents. The relatively low number of cases in these home outbreaks might be considered an advantage of the compulsory home quarantine because transmission was limited to a small number of family members. Similar stay-at-home policies have now been implemented elsewhere during the pandemic. Most urban homes are high-rise apartments, while rural homes may be single-family detached houses. Modern urban homes may be mechanically ventilated, while older homes are typically naturally ventilated. It is unfortunate that detailed characteristics of the homes in which the infections occurred are not available.

The rising trend shown before the peak period in Figure 2 was likely due to the introduction of imported cases due to the Spring Festival travel season (Chunyun in Chinese), a period around CNY during which many people leave the cities in which they work to visit their rural families. The 2020 Chunyun brought people from the epicenter Wuhan to their home cities before Wuhan's lockdown on January 23. Social and family gatherings continued after January 23 in most cities outside Hubei. Interventions such as contact tracing and confinement of estates, villages, and individual buildings were implemented gradually in most cities outside Hubei immediately after CNY, which explains the sharp declining curve after January 28. The significant reduction in the average time from symptom onset to the end of the infectious period between the before January 28 subgroup and after January 28 subgroup suggests the effectiveness of the early detection and isolation policy and explains the sharp decrease in infections after January 28.

Our study does not rule out outdoor transmission of the virus. However, among our 7324 identified cases in China with sufficient descriptions, only one outdoor outbreak involving two cases occurred in a village in Shangqiu, Henan. A 27-year-old man had a conversation outdoors with an individual who had returned from Wuhan on January 25 and had symptom onset on February 1. This outbreak involved only two cases.

The second salient feature of the 318 identified outbreaks is the relatively small number of outbreaks that involved 10 or more cases. The largest outbreak occurred in a Tianjin shopping mall and involved 21 cases, although Wu et al⁵ reported 25 cases (Table S1). This is distinct from the 2003 SARS-CoV epidemic, during which seven major super-spreading events in Hong Kong and Singapore

alone were identified to involve as many as 329 cases and super-spreading events dominated the epidemic.⁶ The occurrence of many small outbreaks (in terms of the number of cases) in the COVID-19 pandemic suggests a different transmission pattern from that of the 2003 SARS-CoV epidemic. Some viral, epidemiological, and environmental factors may have contributed to this difference between the 2003 SARS-CoV epidemic and the current COVID-19 pandemic. However, a number of large super-spreading events were later reported elsewhere in the world, including 94 people who were infected in an 11th-floor call center in Seoul with 216 employees,⁷ and 32 confirmed and 20 probable secondary cases after a 2.5-hour choir practice attended by 61 persons in Skagit County, Washington.⁸ We cannot pinpoint the exact transmission routes of these identified outbreaks. During the early phase of the pandemic, most health authorities advised that the SARS-CoV-2 was transmitted mainly by close contact and via the fomite route (eg, China NHC⁹ and US CDC¹⁰). The China NHC also suggested that long-range aerosol transmission may occur when certain conditions are met, such as in crowded enclosures or spaces with poor ventilation. By 5 November 2020, the US CDC¹¹ suggested that "It is possible that COVID-19 may spread through the droplets and airborne particles that are formed when a person who has COVID-19 coughs, sneezes, sings, talks, or breathes. There is growing evidence that droplets and airborne particles can remain suspended in the air and be breathed in by others, and travel distances beyond 6 feet (for example, during choir practice, in restaurants, or in fitness classes). In general, indoor environments without good ventilation increase this risk."

We do not have data on the hygiene conditions, such as ventilation rates and human densities, of the infection venues of the 318 outbreaks studied here. The exact location of the infection venues and the necessary parameters such as the floor area or the number of occupants were not provided in the case reports. Instead, we reviewed the current design standards of thermal and ventilation conditions, occupant density, and close-contact behavior in the various indoor environments discussed here (Table S3). The required ventilation rates vary significantly among homes, offices, trains, and buses. We note that the current ventilation rate guidelines in these environments do not consider infection control. For example, the required ventilation rate is only 3.9 L/s per person in shopping malls and 2.8 L/s per person in public buses, whereas a ventilation rate of at least 8–10 L/s is required for good indoor air quality.¹² The review showed that a rate as high as 25 L/s per person may be needed.¹² Some existing buildings are probably crowded, poorly ventilated, and unhygienic. A comprehensive review of ventilation conditions in Chinese indoor environments by Ye et al¹³ showed that the CO₂ concentration can reach 3500 pp min some buildings. The design and operation of buildings have also been under pressure to reduce energy use¹⁴ and increase human productivity. Balancing the need for energy efficiency, indoor environmental quality and health in both urban planning and building design have not been easy.¹⁵ The quality of indoor environments might be sacrificed by putting a greater focus on cost than on health.

Close-contact behavior and occupant density in the various indoor environments discussed are also reviewed in Table S3. Frequent close contact occurs indoors, and buildings have high-touch surfaces.¹⁶⁻¹⁹ Unfortunately, we do not have detailed data on surface-cleaning and hand-hygiene conditions in these indoor environments, but fomite transmission must nevertheless be considered in designing preventive approaches.

This study has limitations. We only studied outbreaks in China, where very strict intervention measures were implemented. We relied fully on the case reports of the local health authorities in each city, and variation exists in the details and the quality of their original epidemiological investigations. We also made no attempt to access any of the infection venues, and the details of each of these indoor spaces remains unknown.

This study shows that the individual indoor environments in which we live and work are the most common venues in which the virus of the once-in-a-century-pandemic is transmitted among us. An individual infected in one building may infect others in the building(s) that he or she later visits. People are in constant contact as they move from one indoor space or building to another, which creates an indoor contact network through which a virus can spread.²⁰ The buildings and transport cabins in various parts of the world are thus connected and facilitated the spread of the COVID-19 pandemic virus.

The association between crowding and infection has been known since Pringle.²¹ The most dramatic example in the current pandemic might be in the cruise ship outbreak on the crowded Diamond Princess, of which the peak basic production number was predicted to be 11²² or 14.8²³ before quarantine and much higher than elsewhere. The world's first statutory housing policy, the Artisans and Labourers Dwellings Act 1875²⁴ was developed following 19th-century empirical evidence that crowding led to a high incidence of infectious disease. A recent systematic review by the World Health Organization also found an association between crowding and infection.²⁵ A *Lancet* editorial in 2018 declared "[t]he right to a healthy home."²⁶ One WHO meeting also declared that "everyone has the right to breathe healthy indoor air"²⁷ and that "the provision of healthy indoor air should not compromise global or local ecological integrity, or the rights of future generations".²⁸ We hope that in the post-pandemic future, mankind will reflect deeply on the need for a healthy indoor environment.

coronavirus 2

Transmission

ABSTRACT

Background: Reports suggest that asymptomatic individuals (those with no symptoms at all throughout infection) with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) are infectious, but the extent of transmission based on symptom status requires further study.

Purpose: This living review aims to critically appraise available data about secondary attack rates from people with asymptomatic, pre-symptomatic and symptomatic SARS-CoV-2 infection.

Data sources: Medline, EMBASE, China Academic Journals full-text database (CNKI), and pre-print servers were searched from 30 December 2019 to 3 July 2020 using relevant MESH terms.

Study selection: Studies that report on contact tracing of index cases with SARS-CoV-2 infection in either English or Chinese were included.

Data extraction: Two authors independently extracted data and assessed study quality and risk of bias. We calculated the secondary attack rate as the number of contacts with SARS-CoV-2, divided by the number of contacts tested.

Data synthesis: Of 927 studies identified, 80 were included. Summary secondary attack rate estimates were 1% (95% CI 0%–2%) with a prediction interval of 0%–10% for asymptomatic index cases in ten studies, 7% (95% CI 3%–11%) with a prediction interval of 1%–40% for pre-symptomatic cases in 11 studies and 6% (95% CI 5%–8%) with a prediction interval of 5%–38% for symptomatic index cases in 40 studies. The highest secondary attack rates were found in contacts who lived in the same household as the index case. Other activities associated with transmission were group activities such as sharing meals or playing board games with the index case, regardless of the disease status of the index case.

Limitations: We excluded some studies because the index case or number of contacts were unclear.

Conclusion: Asymptomatic patients can transmit SARS-CoV-2 to others, but our findings indicate that such individuals are responsible for fewer secondary infections than people with symptoms.

Introduction

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) demonstrates efficient transmission in populations without effective public health interventions; basic reproduction numbers (R_0) range between 2 and 3 [1]. Although asymptomatic transmission has been described as the ‘Achilles’ heel’ of control efforts during

this pandemic, the extent to which transmission of SARS-CoV-2 by people without symptoms drives this pandemic remains uncertain [2]. SARS-CoV-2 infection that is asymptomatic at the time of laboratory testing is widely reported [3]; however, studies that follow infected people over time suggest that many infections are not asymptomatic throughout the entire disease course, and a large proportion of these individuals ultimately develop a diverse range of symptoms [4–7]. For instance, Sugano et al. reported a detailed cluster outbreak in music clubs in Japan, where the asymptomatic cases reported also included pre-symptomatic cases [8]. A living systematic review of studies published up to 10 June 2020 estimated that 20% (95% CI 17%–25%) of people who become infected with SARS-CoV-2 remain asymptomatic throughout infection [7].

One of the barriers to understanding the role of asymptomatic transmission is the lack of consistency in case definitions [9]. Although symptom severity exists on a spectrum, individuals infected with SARS-CoV-2 can be miscategorized as asymptomatic, when they have milder or atypical symptoms, leading to over-estimation of the proportion without symptoms [3,10]. For instance, in a detailed study of SARS-CoV-2 infections in Iceland where individuals deemed at high risk for coronavirus disease 2019 (COVID-19), including those with a consistent syndrome, were screened in a targeted manner, and other individuals were tested via a population screening mechanism, more than one-third of people in the second group reported symptoms potentially consistent with COVID-19 [3]. However, it is increasingly becoming clear that some individuals experience more diverse symptoms, including taste and smell disturbance or myalgia, either for the entire course of the illness or preceding respiratory symptoms. These symptoms can be so mild and insidious that they do not limit patients' daily activities [4,11]. The situation is further complicated by subjective patient perception and differences between studies in the elicitation and reporting of symptoms.

There are reports describing asymptomatic individuals with SARS-CoV-2 who are infectious [12] and who have infected one or more contacts [13], but the extent and significance of asymptomatic transmission requires further understanding. The aim of this review is to summarize the available evidence about secondary attack rates (defined as the probability that an infected individual will transmit the disease to a susceptible individual) among the contacts of individuals with SARS-CoV-2 with different symptom status to provide information about how contagious they are, and their role in driving the pandemic.

Materials and methods

This systematic review was registered in PROSPERO on 8 June 2020 (CRD42020188168) and will be updated in 4–6 months according to the availability of new evidence as a living systematic review [14]. The larger review aims to answer transmission dynamics of SARS-CoV-2. The analysis in this report addresses one of the review questions; to identify secondary attack rate based on symptom status.

Definitions

We defined 'asymptomatic' as an individual with laboratory-confirmed SARS-CoV-2 infection but without symptoms throughout their entire course of infection, or after 14 days of follow up; 'paucisymptomatic' as an individual with laboratory-confirmed SARS-CoV-2 infection with mild symptoms, and 'pre-symptomatic' as an individual who reports no symptoms at the time of the initial positive test result, but who subsequently develops symptoms attributable to COVID-19. We used these definitions to categorize the index cases. Secondary attack rate was

defined as the number of new SARS-CoV-2 infection cases among susceptible contacts of primary cases divided by the total number of susceptible contacts.

Search strategy

We retrieved articles about transmission of SARS-CoV-2 infection through systematic searches of eight databases: Medline, EMBASE, Europe PMC, Web of Science, SCOPUS, Chinese database (CNKI), and preprint servers (MedRxiv, BioRxiv) using relevant Medical Subject Headings (MeSH) terms (see Supplementary material, [Appendix S1](#)). The initial search was completed from 30 December 2019 to 21 May 2020, searches were repeated on 8 June 2020 and 3 July 2020, owing to the rapidly increasing number of studies.

Study selection

Studies were eligible if they met the inclusion criteria: (a) report on COVID-19 or SARS-CoV-2 infection and (b) report an outbreak investigation or contact tracing study. Exclusion criteria were: (a) review articles; (b) observational studies providing only the proportion of individuals infected; (c) studies that do not indicate the number of contacts or secondary infections; and (d) reports in media sources. We also manually screened the references of the included original studies and reviews to identify additional eligible studies.

Data extraction

Two authors (XQ and AIN) independently reviewed reports by title and abstract for relevance, with at least 20% of all reports being screened in duplicate to ensure consistency. Two authors then independently read the full-text report of all studies not excluded by title and abstract, to consider eligibility for inclusion. Any disagreements regarding study inclusion were resolved through discussion with a third author (MC). Data were extracted onto a standardized form. From each study, the following variables were extracted: the name of the first author, year of publication, country, sample size, details of index cases (categorized as asymptomatic, pre-symptomatic and symptomatic); event details such as environment, transmission details; number of contacts, number of secondary cases. If these data were not reported, we contacted authors to request them and checked with the authors about all symptoms that they sought.

Risk of bias in included studies

Two authors (XQ and AIN) independently assessed completeness of reporting and risks of bias, using an adapted version of the Joanna Briggs Institute Critical Appraisal Checklist for Case Series (see Supplementary material). Any disagreements were resolved through discussion with a third author (MC).

Data synthesis and statistical analysis

The studies are summarized in text and table form, descriptive statistics were completed for key outcome measures. Secondary attack rates were computed from raw data in each study, dividing the number of infected contacts of primary cases by the total number of susceptible exposed contacts. A pooled analysis was carried out to generate summary estimates for the secondary attack rate in each subgroup analysed (asymptomatic, pre-symptomatic and symptomatic index cases), in the framework of a random effect model. The Freeman–Tukey double-arcsine variance-

stabilizing transformation was used to combine data, because of its advantage over log and logit transformations, which do not allow computation of the proportion in the presence of zero event counts [15]. Secondary attack rates are presented as a proportion along with 95% CIs in forest plots. Heterogeneity between study estimates was gauged by means of the Cochran's Q and I^2 statistic: an I^2 value above 75% indicates high heterogeneity [16]. Moreover, a 95% prediction interval is displayed in the forest plots, which is an index of dispersion, providing information on how widely the true effect size varies. It can also provide the range of values in which a future observation will fall [17]. Analyses were performed though the software METAXL version 5.3 (Ersatz, EpiGear International, Sunrise Beach, QLD, Australia) [18].

Results

The systematic search identified 927 potentially relevant articles and 789 records were screened after removal of duplicates. Of 187 articles retrieved for full-text review and assessed for eligibility, 80 studies were included in the systematic review, and among those we identified 69 studies that indicated the symptom status of index case(s). In this analysis, we excluded 11 studies that reported asymptomatic and symptomatic index cases together or in which no symptom status of the index case was available. We re-classified three studies from asymptomatic to pre-symptomatic as the index cases developed symptoms later during the disease course after reviewing the details and contacting the authors [19–21]. The number of selected papers at each step of the screening and eligibility are reported in the flow diagram (Fig. 1).

Summary of secondary attack rates of asymptomatic index cases

Ten studies were included in the quantitative analysis (Table 1) [6,13,22–29]. Summary secondary attack rate estimate was 1% (95% CI 0%–2%) with a prediction interval range of 0%–10% (Fig. 2). All except one tested all close contacts for SARS-CoV-2, regardless of symptoms [26]. Cheng et al. only tested symptomatic cases, but they also tested high-risk populations regardless of symptoms including the household and hospital contacts [26]. Six studies reported on household contacts, two studies included hospital contacts and two studies included non-household close contacts.

Three studies identified no secondary cases after following up 17, 91 and 455 close contacts of asymptomatic index cases (asymptomatic secondary attack rate of 0%) [24–26]. Of those, two studies demonstrated higher symptomatic secondary attack rates: Cheng et al. demonstrated that mild cases had a secondary attack rate of 3.8% (95% CI 1.1%–12.8%) and severe cases had a 4% (95% CI 1.0%–15.8%) secondary attack rate [26], while Park et al. reported a household symptomatic secondary attack rate of 16.2% (95% CI 11.6%–22.0%) [24]. In another study, 305 contacts of eight asymptomatic cases were followed up, identifying one secondary case (secondary attack rate 0.3%, 95% CI 0.0%–1.8%) [28]. In the same study, attack rates from index cases with mild, moderate and severe diseases were 3.3%, 5.6% and 6.2%, respectively. Zhang et al. followed up 119 close contacts of 12 asymptomatic index cases and identified one secondary case, an asymptomatic secondary attack rate of 0.8% (95% CI 0.0%–4.6%). In the same study, the secondary attack rate was 3.5% (95% CI 1.5%–8.0%) for those with mild, 5.7% (95% CI 2.5%–12.8%) for those with moderate and 4.5% (95% CI 0.8%–21.8%) for those with severe symptoms [6]. In this study, close contacts that lived with an index case had 12 times the risk of infection as those who did not live with the index case (relative risk 12.5, 95% CI 1.6–100.8) and those who had frequent contact with an index case patient, and those who had more than five contacts had 29 times the risk of infection as those with fewer

contacts (relative risk 29.0, 95% CI 3.6–232.3). Two studies indicated an asymptomatic secondary attack rate of 1% and 1.9% [22,23]. Chaw et al. reported asymptomatic and pre-symptomatic contacts together. The authors clarified that three asymptomatic index cases and their 106 close contacts were followed up, leading to three secondary cases, a secondary attack rate of 2.8% (95% CI 0.06%–8.0%). In this study, the overall secondary attack rate was 10.6% in the household setting, which was higher for symptomatic cases (14.4%, 95% CI 8.8%–19.9%) than that of asymptomatic cases and for non-household contacts 0.7 (95% CI 0.1%–1.3) [13]. Zeng et al. conducted the largest contact tracing study, following up 753 close contacts of asymptomatic index cases and identified one secondary case, an asymptomatic secondary attack rate of 0.13% (95% CI 0.0%–0.7%) [27].

Summary of pre-symptomatic secondary attack rates

Sixteen papers reported either outbreak investigations or contact tracing studies reporting transmission from an index case during the pre-symptomatic period [13,19,21,26,30–40] (Table 2). Of those, 11 studies were included in the quantitative analysis. The summary secondary attack rate estimate was 7% (95% CI 3%–11%) with a prediction interval of 1%–40% (Fig. 3). These studies followed up 22 to 585 close contacts whose initial exposure occurred before symptom onset of the index case. Even in studies that followed up large numbers of people, including community contacts, the majority of secondary cases identified were from the same household or among gatherings of friends. In these studies, having meals together, or playing cards with the index case were exposure activities associated with transmission. The remaining one study reported an outbreak in a restaurant [40] and four studies exclusively reported family cluster outbreaks [30,32,33,39]; these investigations did not test contacts outside the household, and it is challenging to truly differentiate transmission during the pre-symptomatic period from symptomatic transmission in the household setting (see Supplementary material, Fig. S1).

Summary of symptomatic secondary attack rates

Forty-six papers reported either outbreak investigations or contact tracing studies reporting transmission from symptomatic index case(s). Of those, 40 contact tracing studies reported secondary attack rates ranging from 0% to 38.89% [13,24,27,28,38,41–75] and six reported outbreak investigation [76–80] (see Supplementary material, Table S1). Forty contact tracing studies with 44 observations were included in the quantitative analysis (Fig. 4). The summary estimate of secondary attack rate from symptomatic index subjects was 6% (95% CI 5%–8%) with a prediction interval of 5%–38%. Of those, nine studies reported less than 1% secondary attack rates, two of these were in a health-care setting, two included outdoor interaction and four included non-household contacts. Higher frequency of contacts and household contacts were reported to be higher risk than non-household contacts.

Quality assessment

All papers included a clear definition of symptomatic and asymptomatic cases, number of secondary cases and number of contacts. The majority of studies identified index cases with a clear diagnosis, had an acceptable case definition and sufficiently followed up close contacts (for a minimum of 14 days). However, in some studies the definition of close contact and setting of transmission was not provided. In addition, it was unclear in four reports whether all potential close contacts were included; therefore, the

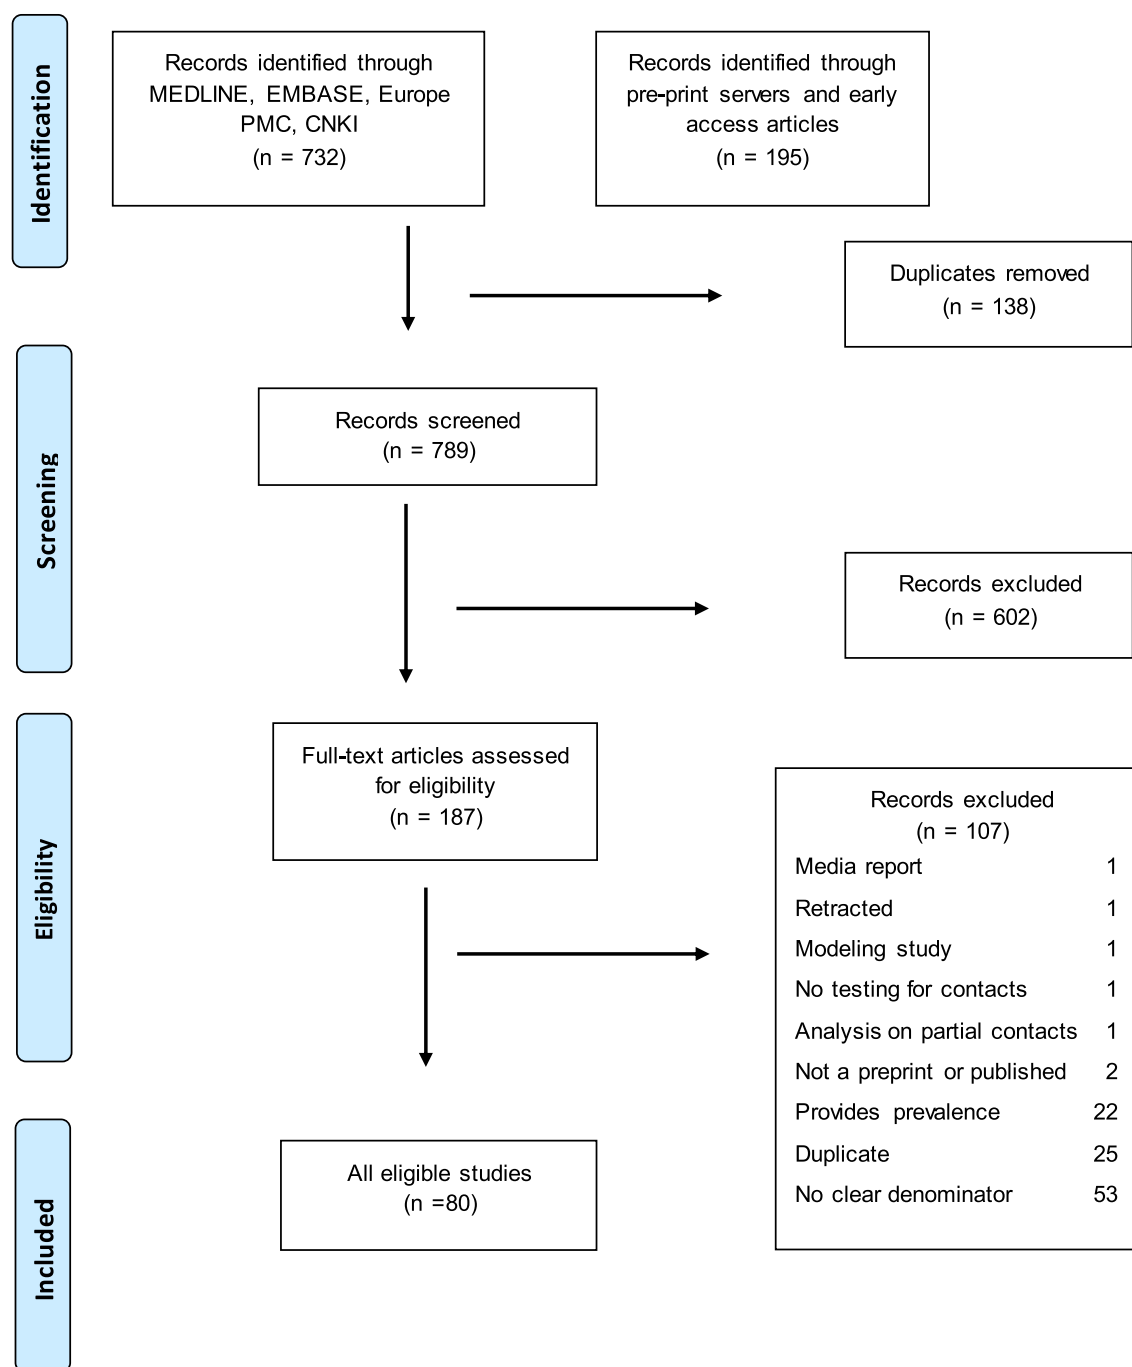

Fig. 1. Flowchart describing inclusion and exclusion of studies at each stage of the review.

direction of bias was uncertain. The quality assessment is summarized in the Supplementary material (Table S2).

Discussion

This systematic review provides comprehensive data on secondary attack rates based on symptom status of the index case(s). Although asymptomatic patients can transmit the virus to others [81], the findings from ten studies in this review found summary secondary attack rates of 1% with a prediction interval of 0%–10% for asymptomatic index cases compared with secondary attack rates of 6% with a prediction interval of 5%–38% in symptomatic

cases and 7% with a prediction interval of 1%–40% in pre-symptomatic cases. These findings suggest that individuals who are asymptomatic throughout the disease course are responsible for fewer secondary infections than symptomatic and pre-symptomatic cases. Most transmission events were associated with living with the index case or group activities such as sharing meals and playing board games.

Given the importance of transmission heterogeneity in propagating the pandemic, it is important that we learn about the various factors that contribute to transmission. According to modelling and contact tracing studies, around 80% of secondary infections can be linked to 20% of cases, which distinguishes SARS-CoV-2 from

Table 1
Transmission from truly asymptomatic index cases

	Index cases	Environment	Number of contacts	Number of secondary cases	Asymptomatic SAR (95% CI)	Symptomatic SAR (95% CI)

^a Authors contacted for more details.

seasonal influenza, although a similar pattern was also observed in SARS-CoV and Middle East respiratory syndrome-CoV [82–84]. There are multiple factors (environmental factors, contact patterns and socio-economic inequalities) that contribute to this heterogeneity, but some evidence is starting to emerge about the influence of individual's infectiousness on transmission dynamics. In this systematic review, we found that index cases with symptoms had a higher secondary attack rate compared with truly asymptomatic index cases. Although there is a need to better understand this difference, it may be due to shorter duration of infectiousness. In a living systematic review including studies published up to 6 June 2020, we found that asymptomatic people had a shorter duration of RNA shedding than symptomatic individuals [85]. Asymptomatic patients may therefore be contagious but for a shorter duration than symptomatic people; this might contribute to lower transmission to their contacts. However, we do not yet know the relative importance of behavioral factors by the host versus environmental

factors in determining transmission risk. It is not known whether the size of the cluster of secondary infections would be different according to index case symptom status in a high-risk environment with no mitigation measures in place.

Modelling studies suggest that it is not possible to have widespread infection without substantial pre-symptomatic transmission. Viral load dynamics of SARS-CoV-2 derived from confirmed cases suggest that peak viral loads are detected at the start of symptom onset up to day 5 of illness, indicating that the highest infectiousness occurs just before or within the first few days after symptom onset [85]. So far, several contact tracing studies emphasize that the highest risk of transmission occurs during the prodromal phase or early in the disease course [64,86]. For instance, in a prospective contact tracing study of 100 confirmed cases of COVID-19 and 2761 close contacts, no secondary cases were identified when the exposure occurred more than 5 days after symptom onset [26]. Our findings therefore have

Fig. 2. Secondary attack rates from asymptomatic index cases to their contacts. For each study the secondary attack rate is reported with its 95% CI. A prediction interval at the bottom of the forest plot is depicted.

Abbreviation: SAR, secondary attack rate.

^a Authors contacted for more details.

important implications from a public health perspective. In settings such as nursing homes, homeless shelters, prisons, cruise ships and meat-packing plants in which many people spend prolonged periods of time together in the same environment including sleeping, dining and sharing common facilities, and where several outbreaks have been documented, pre-symptomatic transmission may contribute substantially to transmission [87,88]. In these settings, when infection develops, most patients are already inside the facility with high viral loads that increase the risk of onward transmission. This highlights the importance of mitigation measures and surveillance in these settings to identify those patients early in the disease course to prevent onward transmission inside the facility.

This systematic review has several strengths. First, this is a living systematic review examining the transmission of SARS-CoV-2 through contact tracing and outbreak investigation studies. Second, we only included studies with clear case definitions, which indicated the number of contacts and secondary cases. We excluded studies in which the index case was unclear, or the numbers of contacts were not provided. The estimates from individual studies are also subject to limitations, such as imprecision

resulting from small study size, and multiple sources of bias in the estimation of the true secondary attack rate, which are detailed in this paper [89]. Moreover, while the number of index cases could influence the confidence interval estimation for secondary attack rate due to heterogeneity among index cases, we have constructed a prediction interval to yield conservative confidence interval estimates.

We identified two other systematic reviews that investigated asymptomatic transmission, with different research questions, which results in different search terms and studies retrieved. One living systematic review, which included studies published up to 10 June 2020, identified five studies that directly compared secondary attack rates between asymptomatic and symptomatic index cases; all were included in our review [7]. This study only included studies that provided data to allow relative risks to be estimated. The summary risk ratios for asymptomatic versus symptomatic (0.35, 95% CI 0.10–1.27) and pre-symptomatic versus symptomatic (0.63, 95% CI 0.18–2.26) are consistent with our findings. The second review estimated only household secondary attack rates and included studies published up to 29 July

Fig. 3. Secondary attack rates from pre-symptomatic index cases to their contacts. For each study the secondary attack rate is reported with its 95% CI. A prediction interval at the bottom of the forest plot is depicted.

Fig. 4. Secondary attack rates from symptomatic index cases to their contacts. For each study the secondary attack rate is reported with its 95% CI. A prediction interval at the bottom of the forest plot is depicted.

2020 [90]. Of three studies that included asymptomatic index cases, two were included in our review. We excluded one of the studies because the number of contacts of asymptomatic index cases was not specified; we have not yet received details of the study after contacting the authors. Advantages of our review over these two studies are inclusion of studies published in Chinese, search terms that aimed to capture studies specifically estimating secondary attack rates.

In summary, although asymptomatic transmission is a major concern for SARS-CoV-2 community spread, secondary attack rates from those who remain asymptomatic throughout their course of infection are low, suggesting limited infectiousness. Although it is difficult to estimate the proportion of pre-symptomatic transmission, these patients are likely to be highly infectious just before and around the time of symptom onset and appear to transmit efficiently, particularly within households. Given these results, in the context of limited resources, approaches should be targeted predominantly at identifying and immediately isolating patients with prodromal or mild symptoms and their contacts, which may avert a significant number of community transmission clusters [91]. Future clinical studies should incorporate clear definitions and assess a broad range of symptoms associated with COVID-19, include longitudinal follow up of patients, and calculate secondary attack rates for a wider range of settings and populations [9].

Abstract

On 31 December 2019 the Wuhan Health Commission reported a cluster of atypical pneumonia cases that was linked to a wet market in the city of Wuhan, China. The first patients began experiencing symptoms of illness in mid-December 2019. Clinical isolates were found to contain a novel coronavirus with similarity to bat coronaviruses. As of 28 January 2020, there are in excess of 4,500 laboratory-confirmed cases, with > 100 known deaths. As with the SARS-CoV, infections in children appear to be rare. Travel-related cases have been confirmed in multiple countries and regions outside mainland China including Germany, France, Thailand, Japan, South Korea, Vietnam, Canada, and the United States, as well as Hong Kong and Taiwan. Domestically in China, the virus has also been noted in several cities and provinces with cases in all but one province. While zoonotic transmission appears to be the original source of infections, the most alarming development is that human-to-human transmission is now prevalent. Of particular concern is that many healthcare workers have been infected in the current epidemic. There are several critical clinical questions that need to be resolved, including how efficient is human-to-human transmission? What is the animal reservoir? Is there an intermediate animal reservoir? Do the vaccines generated to the SARS-CoV or MERS-CoV or their proteins offer protection against 2019-nCoV? We offer a research perspective on the next steps for the generation of vaccines. We also present data on the use of *in silico* docking in gaining insight into 2019-nCoV Spike-receptor binding to aid in therapeutic development. Diagnostic PCR protocols can be found at <https://www.who.int/health-topics/coronavirus/laboratory-diagnostics-for-novel-coronavirus>.

Key words: 2019-nCoV; coronavirus; Wuhan; human-to-human transmission; vaccine readiness.

Current State of emergency – Novel coronavirus outbreak in Wuhan, China

Wuhan 2019-nCoV

A novel coronavirus (CoV) has emerged in Wuhan, China (Figure 1). This virus causes pneumonia of varying severity and has resulted in a high number of hospitalizations (> 4,500) and at least 105 deaths (case-fatality rate (CFR) estimated at 1.5-3%). This virus is

currently referred to as 2019-nCoV (also Wuhan virus) and is related to Severe Acute Respiratory Syndrome coronavirus (SARS-CoV), although with only approximately 80% similarity at the nucleotide level. With a seemingly comparable chain of events as the origin of SARS-CoV, the initial infections with 2019-nCoV appears to be linked to contact with animals in wet markets. Even though human-to-human

transmission was first thought to not be a mode of transmission, there are several documented cases that support that 2019-nCoV is capable of human-to-human transmission [1].

Atypical pneumonia of unexplained cause was first reported on 30 December 2019 in Wuhan city, the capital of Hubei province in central China. Initially, four cases were noted which presented with fever (greater than 38°C), malaise, dry cough, and shortness of breath. Imaging was consistent with pneumonia or acute respiratory distress syndrome (ARDS) and patients had either reduced or normal white blood cell counts. An early link to the Wuhan South China Seafood City (also known as the South China Seafood Wholesale Market or the Huanan Seafood Market) was identified as a common factor in four of the patients. Treatment with antibiotics did not improve their condition over the next 3-5 days and a viral etiology was suspected. The patients were placed in isolation conditions. On 31 December 2020, it was announced that 27 cases of pneumonia, with 7 severe cases, had

been identified [2]. Most of the patients were stall workers at Wuhan South China Seafood City. The market is reported to contain other animals such as birds (chickens, pheasants), bats, hedgehogs, marmots, tiger frogs, and snakes, as well as organs from rabbits and other animals. The market was closed on 1 January 2020 for environmental sanitation and disinfection and has not reopened [3].

By 3 January 2020, the cumulative number of cases rose to 44, with 11 in critical condition and 121 close contacts of infected patients being monitored. At this point influenza virus, avian influenza virus, and adenovirus had been ruled out [4]. As of 5 January 2020, the number of cumulative cases increased to 59 (with onset between 8 December 2019 and 2 January 2020), and 163 close contacts being followed. At this time, SARS-CoV and MERS-CoV were ruled out as the causative agent. The number of cumulative cases increased to 59 on 5 January 2020 [5].

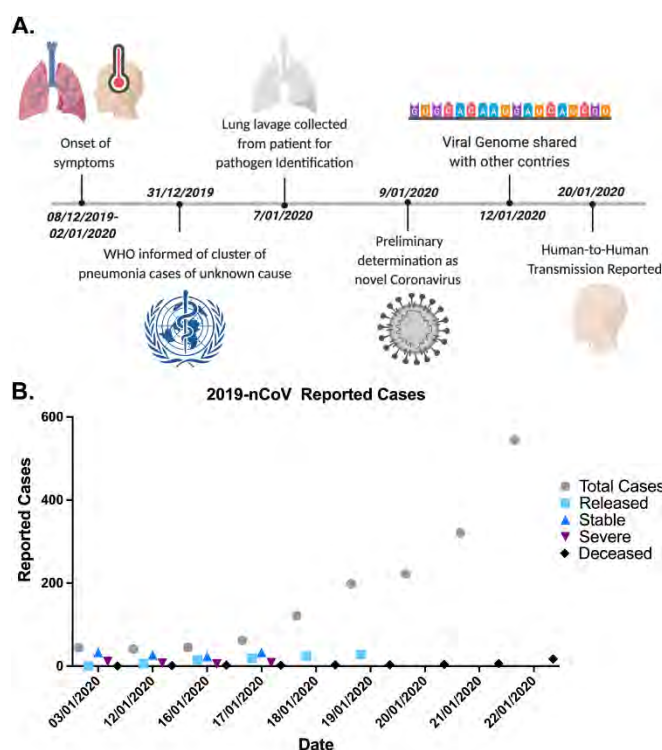

On 8 January 2020, it was reported that a novel coronavirus had been sequenced from one patient and subsequently identified in some of the other patients with pneumonia [6], later reported as 15 of the 59 patients [7]. The first report that some of the cases came from family clusters was the first suggestion that there may have been human-to-human transmission [8]. Virus isolation from one patient was reported [9]. The genome was made publicly available on 11 January 2020 on *virological.org* and later deposited into GenBank.

Additional updates should help clarify the incidence of human-to-human transmission. Given the rapid increase in case numbers, contact tracing will be vital to understanding the extent of human-to-human transmission and the possibility that 2019-nCoV mutations generate viruses with a greater potential for human-to-human transmission. It is important to note that in a Wuhan hospital cluster, 14 healthcare workers were infected by a 2019-nCoV patient [1]. This is reminiscent of several cases of healthcare workers infected by SARS-CoV and MERS-CoV patients. Hospital staff and Infectious Disease control should take necessary precautions in handling of 2019-nCoV patients (see WHO guidelines for handling of suspected and confirmed patients).

Travel-related cases

Another similarity to the SARS-CoV and the MERS-CoV epidemics is the occurrence of travel-related cases. On 13 January 2020, a single case of 2019-nCoV was reported in Thailand of a person who had travelled from Wuhan [10]. This person was not

Figure 1. Timeline of events and reported cases concerned with undiagnosed pneumonia and 2019-nCoV first identified in Wuhan, China.

The timeline of events concerning undiagnosed pneumonia, virus identification, and evidence of human-to-human transmission are shown (A). The number of reported cases plotted over time is shown (B). Case report numbers are acquired from ProMed and National Health Commission of the People's Republic of China.

reported to have been to the previously involved market, but had visited other markets [11]. The next day, a single case was reported in Japan, again following travel to Wuhan. This person reported no contact with the market, but possible contact with persons with pneumonia [12]. A second case, again originating from Wuhan, was identified in Thailand with no connection to other cases. One suspect case in Nepal with travel linked to Wuhan was also reported but not confirmed [8]. On 20 January 2020, a Chinese national, who had travelled from Wuhan, was identified as having 2019-nCoV upon arrival in South Korea and was quarantined [13]. Several airports in Asia and North America have now set up thermal screening at airports to detect possible 2019-nCoV infected individuals. On 21 January 2020, a 2019-nCoV-infected individual was identified in the state of Washington, USA [14]. This patient had also travelled to Wuhan but returned prior to the addition of thermal airport screening.

Current state of knowledge and knowledge gaps

The number of cases in Wuhan continued to increase due to retrospective testing, new cases, and changes in diagnostic evaluation for etiological agents [15]. By 28 January 2020, numerous cases had been identified in throughout China including Taiwan and Hong Kong. As of 28 January 2020, over 4,500 confirmed cases have been reported with > 100 deaths (National Health Commission of the PRC). Human-to-human transmission was suspected early in the outbreak and has now been confirmed and is the main source of infections [14] (National Health Commission of the PRC, update January 22, 2020). Many clinical questions remain unresolved at this time and await reporting and future publications. Some critical questions include: Do all infected individuals show symptoms? What is the frequency of asymptomatic infections? What is the time from exposure to onset of symptoms? Are asymptomatic individuals infectious? Is human-to-human transmission linked to specific mutations in the 2019-nCoV virus?

The extent of the outbreak geographically and epidemiologically currently remains unclear. To facilitate laboratory diagnosis of suspect cases of 2019-nCoV, the WHO has published guidelines for *Laboratory testing for 2019 novel coronavirus (2019-nCoV) in suspected human cases* (<https://www.who.int/health-topics/coronavirus/laboratory-diagnostics-for-novel-coronavirus>) [15]. At the same website PCR primer sets can be found for diagnostic testing. These primer sets

and protocols were developed by Hong Kong University and the CDC, China. An additional PCR protocol by V. Corman, T. Bleicker, S. Brünink, C. Drosten (Charité Virology, Berlin, Germany) O. Landt, (Tib-Molbiol, Berlin, Germany) M. Koopmans (Erasmus MC, Rotterdam, The Netherlands) and M. Zambon (Public Health England, London) can be found on the WHO website.

Clinical Disease and Pathogenesis of 2019-nCoV and other Coronaviruses

The clinical picture

Coronaviruses are endemic in the human population and are responsible for up to 30% of annual respiratory infections resulting in rhinitis, pharyngitis, sinusitis, bronchiolitis, and pneumonia [16,17]. While primarily associated with relatively mild, self-limiting respiratory infections, infection from these viruses can result in severe disease in neonates, the elderly, and those with underlying comorbidities [18]. However, coronaviruses are now considered potential threats to global public health following the emergence of SARS-CoV in 2002 (9% CFR), and MERS-CoV in 2012 (35% CFR).

Early clinical manifestations of MERS and SARS are largely similar. Influenza-like symptoms accompanied by fevers, chills, dry cough, headache, malaise, and dyspnea were common early in the disease course in SARS patients [19]. The mean incubation period was estimated as 4.6 days with a range of 2 to 8 days between symptom onset and hospitalization. The mean time from symptom onset to death in fatal cases was 23.7 days [20]. Fatal outcomes were most frequent in those > 60 years of age (43% CFR). No fatalities were reported in young children and adolescents and fatal disease was reported in 6.8% of patients < 60 years of age. Phase 1 of SARS was associated with increasing viral load and early disease symptoms (fever, malaise). Phase 2 was characterized by fever, hypoxemia, and decreasing viral loads, while radiographic progression of pneumonia was common. Twenty percent of patients progressed to acute respiratory distress syndrome (ARDS). Common laboratory features of SARS included lymphopenia, thrombocytopenia, disseminated intravascular coagulation, and elevated lactate dehydrogenase and creatine kinase levels [20-22]. Acute renal impairment and proteinuria were associated with 6.7% and 84% of patients, respectively [21].

Early symptoms of MERS include fever, chills, cough, shortness of breath, myalgia, and malaise following a mean incubation period of 5 days, with a range of 2 to 13 days [23]. The median times from

symptom onset to hospitalization, ICU admission, and death are 4, 5, and 11.5 days, respectively [24]. Symptomatic MERS patients present with a rapidly progressing pneumonia requiring mechanical ventilation and additional organ support within the first week of disease [20]. Severe and fatal disease is strongly linked to underlying comorbidities including diabetes mellitus, hypertension, obesity, and chronic cardiac, pulmonary, or renal disease [23]. Laboratory abnormalities include lymphopenia, leukopenia, thrombocytopenia, elevated serum creatinine levels consistent with acute kidney injury, and elevated liver enzymes [23,25-28]. High lactate levels and consumptive coagulopathy have also been reported [25,29]. Chest radiographic abnormalities are observed in most cases and the findings are consistent with viral pneumonitis, secondary bacterial pneumonia, or acute respiratory distress syndrome [23,25,28,30,31].

Therapeutics and supportive care

Currently, supportive care is the only treatment option for patients with severe SARS or MERS illness and there are no licensed therapeutics or vaccines. There are, however, several vaccine candidates as well as antiviral candidates for prophylactic and therapeutic treatment of SARS-CoV and MERS-CoV infections. Mechanical ventilation and pulmonary rescue therapy were utilized for SARS but have had limited benefit for MERS patients [32]. Extracorporeal membrane oxygenation has been employed for MERS though its use is limited due to numerous factors [26]. Renal replacement therapy has been used extensively in MERS treatment [25,33,34]. The efficacy of a variety of antiviral therapeutics has been investigated for MERS with limited success. Moderate improvements in clinical outcomes were noted in common marmosets treated with a combination of lopinavir (LPV) and ritonavir (RTV) [35]. Additional investigations of interferon (IFN) antiviral activity *in vitro* have demonstrated that IFN beta (IFN β) had superior activity as compared to other IFN types [36,37]. A randomized control trial investigating the efficacy of LPV/RTV-IFN β in MERS patients is currently ongoing [38].

Coronavirus biology and Coronavirus outbreak cycles

Molecular virology

Family *Coronaviridae* (order *Nidovirales*) is comprised of the *Coronavirinae* and *Torovirinae* subfamilies of viruses. Coronaviruses are enveloped RNA viruses with positive-sense RNA genomes ranging from 25.5 to ~32 kb in length. The spherical

virus particles range from 70-120 nm in diameter with four structural proteins. The viral envelope is covered by characteristic spike-shaped glycoproteins (S) as well as the envelope (E) and membrane (M) proteins. The S protein mediates host cell attachment and entry. The helical nucleocapsid, comprised of the viral genome encapsidated by the nucleocapsid protein (N), resides within the viral envelope. The 5' two-thirds of the coronavirus genome consists of the replicase complex (ORF1a and ORF1b) and codes for two large polyproteins, pp1a and pp1b. The viral replicase-transcriptase complex is made up of 16 non-structural proteins (nsp1-16) encoded for by the polyproteins pp1a and pp1b. Both polyproteins can be cleaved by the viral proteases PLpro (nsp3) and 3CLpro (nsp5). The non-structural proteins function in the formation of double-membrane vesicles derived from the rough endoplasmic reticulum, and are the sites of viral replication and transcription [20]. Coronaviruses also encode a unique proofreading exoribonuclease (ExoN) function of nsp14 that reduces the accumulation of mutations in the RNA genome. The remainder of the genome is transcribed into a nested set of subgenomic mRNAs. Five accessory proteins (ORF3, ORF4a, ORF4b, ORF5 and ORF8b) are also encoded; however, they are not required for replication but may play a role in pathogenesis. Remaining subgenomic RNAs encode for accessory proteins that have immunomodulatory properties or functions that remain unknown.

Coronavirus animal reservoirs and incidental hosts

Determining the animal reservoir and incidental hosts of a virus with evidence of zoonosis such as 2019-nCoV is important for controlling spillover events and limiting human infections. Although the ecological reservoir for both MERS-CoV and SARS-CoV remain undefined, evidence of viral presence in a variety of animal species has been found. Serologic evidence and the isolation of viral genomic material for SARS-CoV-related viruses have provided evidence for bats as the putative reservoir for SARS-CoV. While masked palm civets and raccoon dogs were involved in transmission to humans and initially considered potential reservoirs, they are now considered as incidental or spillover hosts [39-41]. In contrast, dromedary camels are considered to act a reservoir host for MERS-CoV, and over half of primary human infections report contact with camels, however, it is suspected that bats are likely the ancestral host for MERS-CoV or a MERS-CoV-like virus [42,43]. Zoonotic transmission of SARS-CoV likely results from direct contact with intermediate hosts [44], while human-to-human transmission of both viruses

occurs primarily through close contact and nosocomial transmission via respiratory secretions [45,46]. Considering the animals implicated as reservoir hosts for SARS-CoV and MERS-CoV, along with the conclusions from phylogenetic analyses from us and other groups, these potential reservoirs will be important starting points for investigation of the virus source.

Molecular Analysis of 2019-nCoV

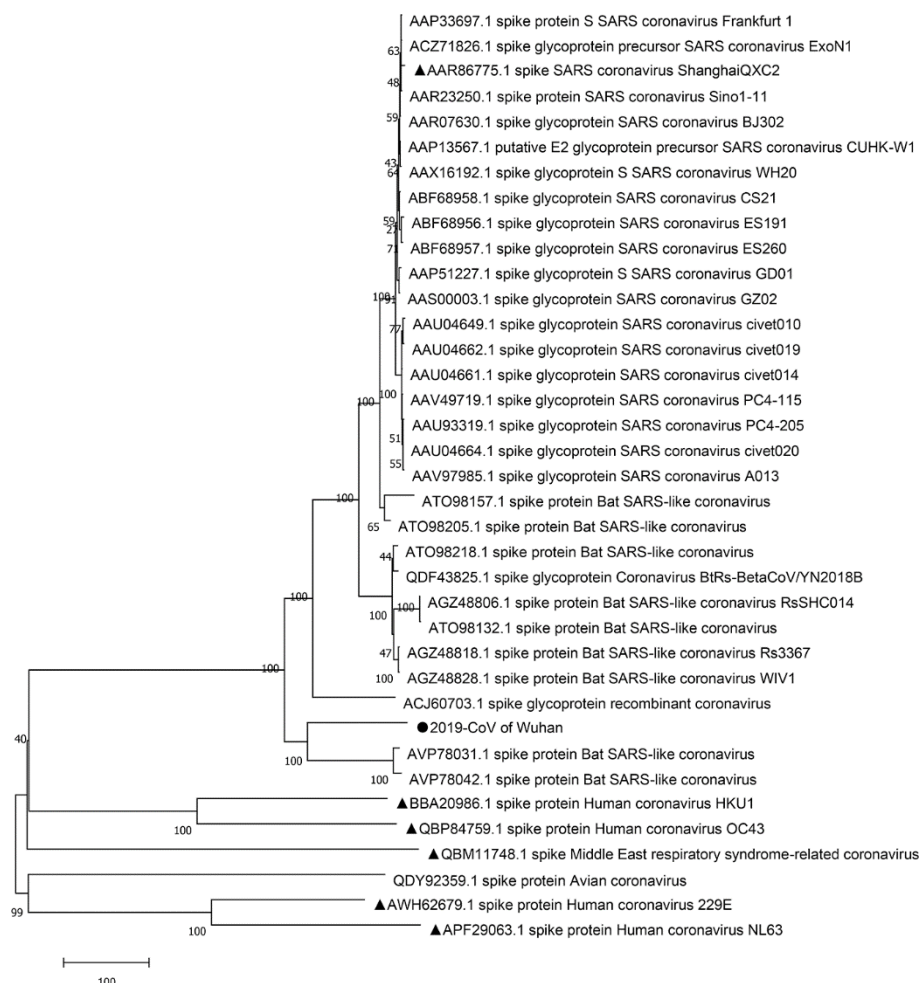

The CoV Spike protein and host receptors

The coronavirus spike protein mediates coronavirus entry into host cells. The S1 subunit of spike contains the receptor binding domain, which binds to receptors on host cells and dictates virus tropism. Viral entry is

mediated through viral and host membranes undergoing fusion via the S2 subunit of the spike protein [47]. Therefore, we analyzed and discuss the S1 domains, in particular the RBD, due to its role in determining host tropism and pathogenesis.

SARS-CoV utilizes the host ACE2 receptor for binding to host cells, including numerous respiratory epithelial cell types, alveolar macrophages, and monocytes [27,48]. Multiple cell types lacking ACE2 expression are also permissive for SARS-CoV, suggesting that additional receptors or co-receptors exist for SARS-CoV and may contribute to infection [49,50]. MERS-CoV targets DPP4 (also known as CD26), which is broadly expressed on numerous epithelial cell types and activated leukocytes.

Figure 2. Phylogenetic analysis of the Spike (S) protein of 2019-nCoV with known coronavirus S proteins.

Phylogenetic analysis of the spike protein sequences of the 2019-nCoV and some related coronaviruses. All the protein sequences used for the tree generation were downloaded from the National Center for Biotechnology Information (NCBI) and annotated by the accession number. Protein sequences were aligned using ClustalW. Then the tree was constructed with MEGA 7.0 by the neighbor-joining (NJ) method using 1,000 bootstraps. The Wuhan new coronavirus was marked by solid circle “●”. SARS coronavirus Shanghai, Human coronavirus HKU1, Human coronavirus OC43, Middle East respiratory syndrome, Human coronavirus 229E and Human coronavirus NL63 were marked by solid triangle “▲”. The NJ tree was well-constructed; the Wuhan new coronavirus showed high identity with Bat SARS-like coronavirus and separated from other coronavirus into different clusters.

Figure 3. Sequence comparison of the Spike (S) protein of 2019-nCoV to SARS-CoV and WIV-1 CoV.

Alignment of full-length S-protein from 2019-nCoV (QHD43416.1), SARS-CoV (P59594.1) and WIV1-CoV (AGZ48828.1). Red, yellow and white indicate completely conserved, functionally conserved and nonconserved residues respectively (A).

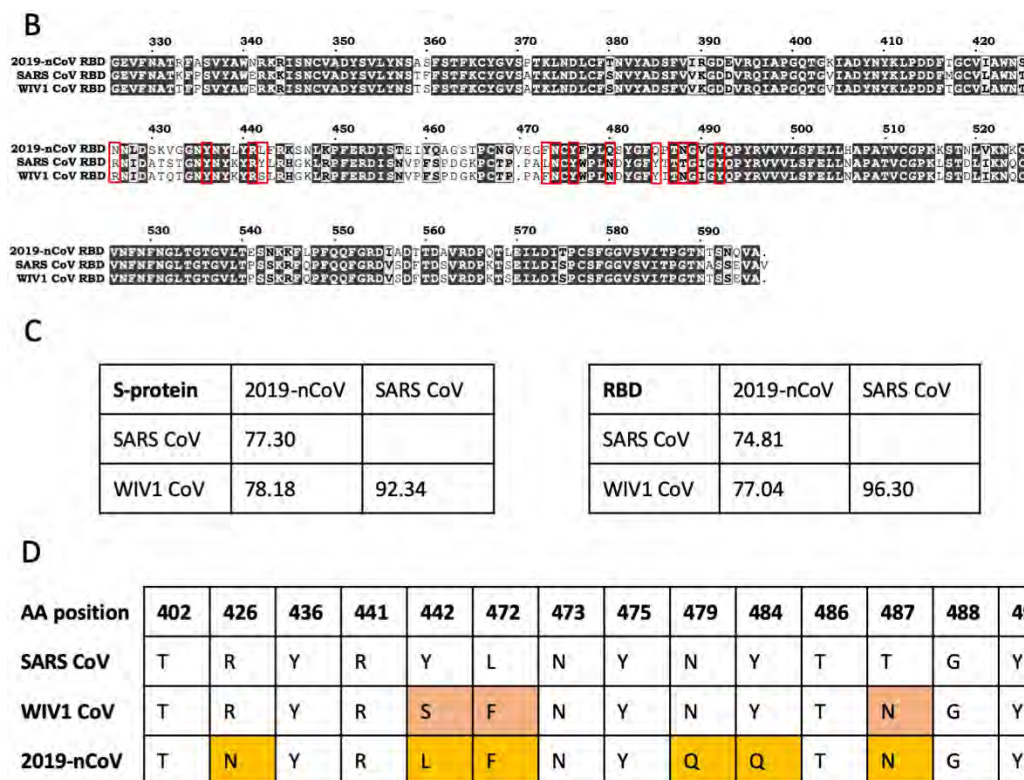

DPP4 is widely expressed in various kidney cells and likely contributes to MERS-CoV infiltration and subsequent renal dysfunction [51,52]. DCs and macrophages can also be productively infected by MERS-CoV *in vitro* [44]. The 2019-nCoV receptor(s) is currently unknown. To better understand the possible relationship of the 2019-nCoV S protein to other coronaviruses, we generated a phylogenetic tree of S protein sequences from various human and animal coronaviruses (Figure 2). Our phylogenetic data shows that 2019-nCoV S most closely resembles the S protein from a SARS-like bat CoV followed by SARS-CoV and distantly resembles other human coronaviruses including the MERS-CoV S protein.

A more in-depth analysis of S-proteins from 2019-nCoV, SARS-CoV, and WIV1-CoV, a SARS-like coronavirus that uses the ACE2 for cell entry, was conducted. An amino acid alignment of the S proteins (Figure 3A) shows high (92%) similarity between SARS-CoV and WIV1-CoV S-proteins. Lower similarity (77%) is observed between SARS-CoV and 2019-nCoV S-proteins. However, there may be

sufficient conservation in the RBD (75%) to expect that 2019-nCoV can still bind to ACE2. As a comparator, MERS-CoV S, which binds to a different receptor (dipeptidyl peptidase 4), has only 37% similarity to SARS-CoV S. Alignment of the RBD regions (Figure 3B) shows that 2019-nCoV has 6 amino acid substitutions in the 14 contact points between SARS-CoV S and ACE2 (Figure 3D). Three of these substitutions are also found in another group 2 coronavirus, WIV1-CoV, which has previously been shown to be capable of binding to human ACE2 in spite of these mutations [53].

To predict the binding affinity of 2019-nCoV to human ACE2, structural models of SARS-CoV RBD, WIV1-CoV RBD and 2019-nCoV RBD were generated to allow for comparison of amino acid side chain positions and putative binding energies (Figure 4A). Pairwise structural comparisons of the generated models to the crystalized structure of the SARS-CoV RBD complexed to ACE2 yielded RMSD values of 1.2, 0.9, and 0.9 for the SARS-CoV, WIV1-CoV, and 2019-nCoV RBDs, respectively. The low RMSD value for

Figure 3. Sequence comparison of the Spike (S) protein of 2019-nCoV to SARS-CoV and WIV-1 CoV.

Detailed alignment of the receptor binding domain (RBD) of nCoV-2019, SARS-CoV and WIV1-CoV (B). Black, grey and white indicate 100% conserved, functionally conserved, and nonconserved residues respectively. Red boxes indicate the S protein residues in the RBD that directly interact with the ACE2 receptor. Percent identity matrices for the full-length S-protein (left) and RBD (right) provided by ClustalW (C). Residues of the SARS-CoV RBD and the corresponding WIV1-CoV and 2019-nCoV amino acids that contact the human ACE2 receptor (D). Amino acid substitutions are shown in orange for WIV1 and in yellow for nCoV-2019

the modelled SARS-CoV RBD supports the accuracy of the WIV1-CoV and 2019-nCoV RBD homology models. To observe the effects of the three additional mutations within the RBD of 2019-nCoV compared to WIV1-CoV at the binding interface (Figure 4B), the RBD models were structurally aligned to the crystal structure of the SARS-CoV RBD complexed to ACE2 [54]. The three residues mutated in RBD of WIV1-CoV – Asp487, Ser442, and Phe472 – were previously shown to have no effect on receptor binding affinity [53]. The remaining three mutations identified within the RBD of 2019-nCoV that interact with ACE2 residues have not been studied. The substitution of Arg426 to Asn426 removes the positively charged R-group of Arg but maintains the side chain's polarity and presence of an amide. Arg426 in the SARS-CoV RBD interacts with ACE2 residues Gln325 and Glu329. The structural model of 2019-nCoV RBD (Figure 4C) shows that the side chain of Gln426 is still in close

proximity to ACE2 Gln325 and Glu329, suggesting that the substitution of Arg426 to Asn426 has little effect on receptor binding. Tyr484 to Gln484, introduces a polar amino acid within a region that includes several tyrosine residues. Within the SARS-CoV RBD, Tyr484 interacts with His34 of ACE2. The R-group of Gln should not inhibit receptor binding in this region, sterically or otherwise, when compared to the R-group of Tyr484. The third substitution unique to 2019-nCoV, Asn479 to Gln479, may induce a conformational change within the RBD due to its proximity to several tyrosines. However, a hydrogen bond is located in the area between RBD Gly488 and ACE2 Lys353 is conserved. This mutation is therefore unlikely to have any negative effect on ACE2 binding.

While the structure of the 2019-nCoV RBD appears to be well conserved, we wanted to determine whether the RBD/ACE2 interaction energies were comparable to the SARS-CoV RBD. Docking was carried out using

Figure 4. Receptor binding domain (RBD) structure predictions based on homology modelling by Phyre2.

The crystal structure of the SARS-CoV RBD bound to ACE2 (PDB 2AJF), shown in dark blue, was used as a reference template for pairwise comparison with the Phyre2 models (A). Structural models generated by homology modelling for SARS-CoV RBD (magenta), WIV1-CoV RBD (cyan), and nCoV-2019 RBD (green) are shown overlaid of 2AJF (blue). RMSD values for the structural comparison of the models to 2AJF were calculated by Dali-lite and are provided for each model. Binding interface of the SARS-CoV RBD (blue)/ACE2 (grey) crystal structure with the WIV1-CoV RBD model shown in cyan (B). ACE2 amino acids that interact with RBD residues are shown as grey sticks and the corresponding amino acids of the SARS-CoV RBD and the WIV1-CoV RBD homology model are shown in blue and cyan sticks, respectively, and have red labels detailing the WIV1 mutations. Binding interface of 2AJF SARS-CoV RBD (blue) and ACE2 (grey) overlaid with the 2019-nCoV homology model (green) (C). ACE2 interface residues are shown as grey sticks, and the SARS/2019-nCoV residues are shown in blue and green stick representation, respectively. The red labels for SARS/2019-nCoV residues detail the mutations present in the 2019-nCoV RBD homology model.

the modelled RBDs and the pre-determined crystal structure of ACE2 (PDB ID: 2AJF, chain B) using HADDOCK2.2 [55]. The top models from the top cluster was selected for calculation of binding energy. The crystal structure of ACE2 complexed with SARS-CoV RBD (PDB ID: 2AJF, chain B and E) was used as a positive binding control, while the crystal structure of SARS-CoV RBD (PDB ID: 2AJF, chain E) docked to rat ACE2 served as a negative binding control [56]. The binding energy of the crystallized ACE2/SARS-CoV complex was calculated as -8.0 kcal/mol, while the crystallized RBD structure docked to modeled rat ACE2 returned a binding energy of -6.0 kcal/mol (Figure 5A). The 2.0 kcal/mol difference in binding energy would likely be larger if a crystal structure of SARS-RBD and rat ACE2 was used for comparison. The *in silico* docking strategy used here favours flexibility in the binding interface as opposed to the rigid nature of crystal structures. This effect is demonstrated with the modelled SARS-RBD and crystal ACE2 structures returning a binding energy of -12.5 kcal/mol. Additionally, WIV1-CoV binds to

ACE2 for cell entry and the modelled WIV1-RBD/ACE2 returned a binding energy of -10.3 kcal/mol. A similar binding energy, -10.2 kcal/mol was observed for the modelled RBD of 2019-nCoV and ACE2 suggesting that 2019-nCoV is capable of binding to ACE2.

Three key residues within the RBD of SARS-CoV are associated with species-specific receptor recognition, Leu472, Asn479, and Thr487 [57]. All three of these residues are substituted in the 2019-nCoV RBD to Phe472, Gln479, and Asn487 respectively. The WIV1-CoV RBD contains Phe at position 472 and Asn at position 487, but Gln479 is unique to 2019-nCoV. As shown in Figure 5, the mutation in this region does not appear to have any effect on docking energies compared to WIV1 and is not predicted to have any negative effects on the ACE2 His34 residue it likely interacts with. Leu472 to Phe472 also should have little to no effect on binding and may increase binding affinity due to the interacting ACE2 residue, Met82, since the methionine-aromatic interaction is considered to be a multifunctional motif that is involved in the

Figure 5. Binding energies of RBD homology models and their electrostatic surface potential.

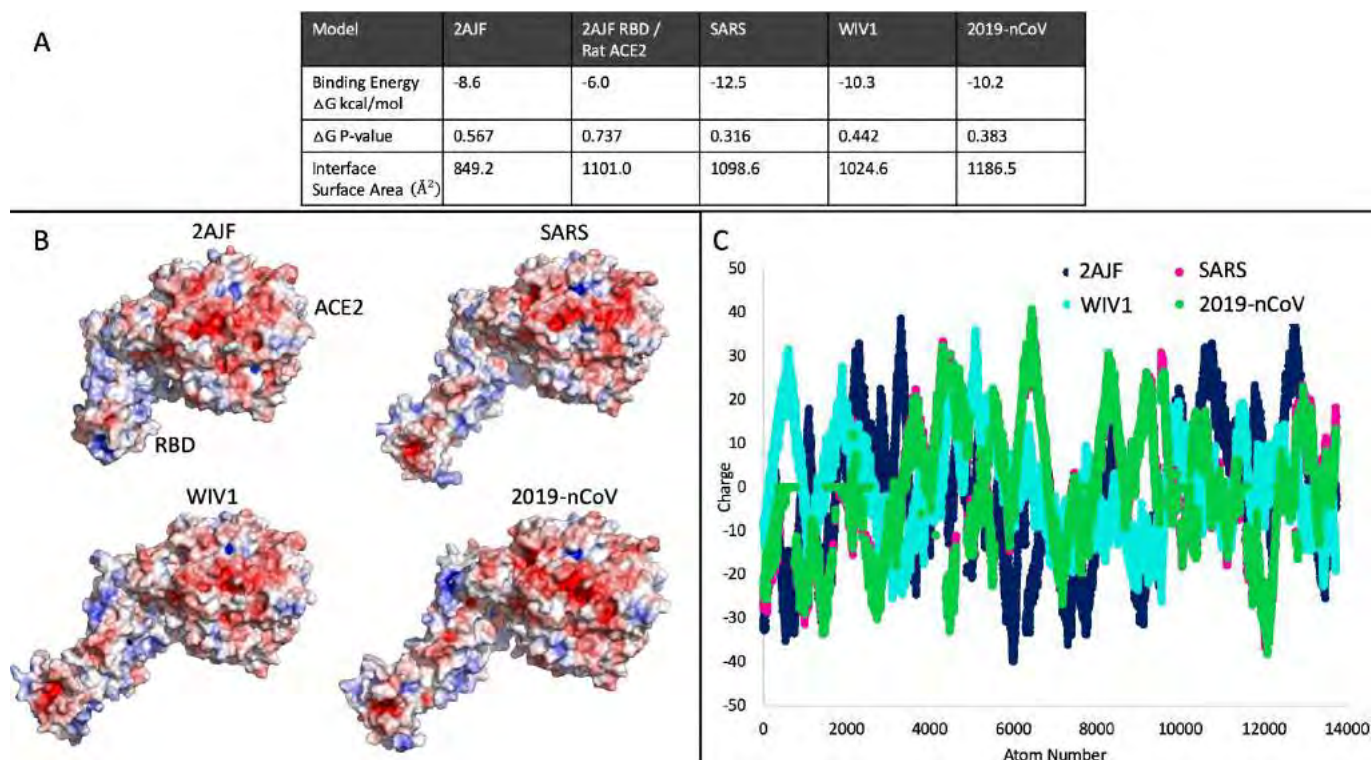

Table detailing the calculated binding energies for PDB ID 2AJF (chains B and E), the crystal structure of SARS-CoV RBD in complex with human ACE2, 2AJF chain E (SARS-CoV RBD) complexed with Rat ACE2, and the homology models complexed to ACE2 (2AJF, chain B) (A). The ΔG P-values and interface surface areas are also provided. Electrostatic potential of 2AJF and the complexed models calculated with APBS (B). The ACE2 and RBD labels on 2AJF are the same for all models. Red indicates regions of net negative charge while blue indicates a net positive charge, and white is neutral. Graphical comparison of individual atom charges for 2AJF and the models showing the individual charges of each atom (C).

stabilization of structures [58]. Thr487 to Gln487 does not inhibit binding as the substitution is also found in WIV1-CoV which can bind ACE2 for virus infection.

The electrostatic potentials of crystallized ACE2/SARS-CoV RBD and the RBD models were also determined (Figure 5C). Their atomic potential profiles are graphically represented and interestingly, 2019-nCoV traces best with the potential of the SARS-CoV RBD homology model bound to ACE2. This could indicate that the 2019-nCoV S-protein is more

functionally similar to the SARS-CoV S-protein than initially anticipated from sequence similarities.

Vaccines and Community Readiness

Vaccine development

Vaccines provide protection from viral pathogens prior to exposure by eliciting protective immune memory with an innocuous agent. The development of neutralizing antibodies from a vaccine remains one of the hallmarks of effective vaccines although vaccines

Figure 6. Phylogenetic analysis of the envelope (E) protein sequence in novel 2019-nCoV.

All protein sequences used for tree generation were obtained from the National Center for Biotechnology Information (NCBI) and annotated by accession number. Protein sequences were then aligned using the ClustalW algorithm, and the tree was constructed with MEGA X by the neighbor-joining (NJ) method using 1,000 bootstraps. The solid black circle indicates the novel Wuhan pneumonia virus, and the solid black triangle indicates SARS coronavirus Shanghai and human coronaviruses HKU1, NL63, 229E, and OC43. The novel Wuhan coronavirus envelope protein shows high identity with Bat SARS-like coronavirus.

that induce cell-mediated immunity have also shown potential and are in development for viral pathogens such as influenza viruses. Several vaccine platforms exist with the ability to induce protective responses: killed whole virus vaccines; split-virion vaccines; subunit vaccines; live-attenuated viral vaccines; virus-like particle vaccines; nanoparticle vaccines; and nucleic acid vaccines (DNA and RNA). In regard to choosing a vaccine target and platform, the vaccine candidate must be immunogenic and immune targeting must lead to virus neutralization or potent cytotoxic responses. To date, there is not a licensed vaccine for either SARS-CoV or MERS-CoV although clinical trials have been initiated for MERS-CoV vaccines. Much of the focus for the development of a SARS-CoV or MERS-CoV vaccine has been on the S protein since it is immunogenic and antibodies targeting it can neutralize the virus [59,60]. Our analysis of the S protein (Figure 2) suggests that it has potential for vaccine development which can be related to work previously done for SARS-CoV and MERS-CoV.

The envelope protein (E) is also an attractive vaccine target that has been proposed for leverage in the development of live-attenuated vaccines [60,61]. MERS-CoV mutants with the E protein deleted are replication-competent but propagation-defective [61]. Similar results were shown for the SARS-CoV when E was removed [62]. Together this suggests that deletion of E from coronaviruses may provide a safe-single replication live viral vaccine for use in inducing a mucosal immune response. We investigated the similarity of the E protein of 2019-nCoV by phylogenetic analysis against known coronavirus E protein sequences (Figure 6) and found clustering, although somewhat distant, with human SARS-CoV. Given that vaccines have been generated for MERS- and SARS-CoVs by mutating the E protein, an E-based vaccine may represent an alternate candidate for 2019-nCoV vaccines. As vaccine candidates are identified, the requirement of animal models for vaccine development and evaluation will be essential.

Animal model development

Establishing an animal model of infection and disease pathogenesis is imperative for understanding several essential elements of viral disease in the infected host, including host tropism, immune responses, and modes of transmission, as well as for the progression of therapeutic development. Having an animal model that can recapitulate human disease is essential for vaccine and therapeutic development as well as testing. For a potential animal model to be

susceptible to infection, the virus must be able to 1.) gain entry into host cells; 2.) overcome the host's antiviral responses; and 3.) disseminate virus following infection to allow infection of other neighbouring cells and tissues. It is also of importance for the model to be able to recapitulate human disease and viral transmission modes. When evaluating the ability of an animal to be infected by a virus and serve as a model, viral shedding, clinical disease, and seroconversion should be determined. The past animal models for SARS-CoV and MERS-CoV were not universal due to the expression of the virus-specific cellular receptors for entry [63]. As SARS-CoV and MERS-CoV do not share a cellular receptor, they do not share the same host range and susceptibility, which includes research animal models [64]. *Cynomolgus* macaques, ferrets, and cats were some of the first animals to be determined susceptible to SARS-CoV [65,66]. The advantage of ferrets is that they are a smaller animal compared to non-human primates and also are able to recapitulate some of the clinical symptoms and transmission kinetics of human respiratory viruses including coughing, sneezing, fever, and weight loss [67]. Although mice can be infected with SARS-CoV, as shown by recovery of vRNA and the elicitation of neutralizing antibodies, infection does not cause severe disease [68]. However, SARS-CoV could be passaged in mice (15 times) for the establishment of a model with clinical features [69]. After the identification of MERS-CoV, it was quickly determined that typical research animal models were not susceptible to the virus including mice, Syrian hamsters, and ferrets. Larger non-human primate models, such as Rhesus macaques and common marmoset were determined susceptible. To make use of small animal models, transgenic mice have been engineered for MERS-CoV susceptibility through expression of the human DPP4 receptor [70]. Other attempts at other mouse model developments were not successful, including an immunocompromised 129/SATA1-/-1 mouse [63]. Having an understanding of the animal models and model development previously utilized for the other coronaviruses of interest will aid in the development of a model for 2019-nCoV. As is necessary, elucidation of the receptor will help guide in development, and creating a clinical picture of the acute symptoms in humans will be essential for vaccine and antiviral evaluation.

Community Readiness

Community and healthcare preparedness in response to coronavirus outbreaks remain ongoing obstacles for global public health. For example, delays

between disease development and progression and diagnosis or quarantine can severely impact both patient management and containment [21,71]. Deficiencies in outbreak preparedness and healthcare network coordination efforts must ultimately be considered in response efforts. It is strongly recommended that universal reagents be maintained and available at global repositories for future outbreaks.

Future Directions

At the time of this writing, cases continue to be reported. Furthermore, there are also many unknowns regarding this outbreak, including the reservoir host, modes of transmission/transmission potential, and the effectiveness of potential vaccine candidates. Here we have attempted to address some of these issues using foundations from previous coronavirus outbreaks as well as our own analysis. What is certain is that the numbers of reported cases are increasing and will continue to increase before the knowledge gaps surrounding 2019-nCoV are filled. Cooperation among public health officials, healthcare workers, and scientists will be key to gaining a foothold and containing virus spread. Acknowledgement of coronaviruses as a constant spillover threat is important for pandemic preparedness. Two key take-away messages are important at this time: 1) As noted by the previous lopsided cases of healthcare, healthcare workers and care givers should exercise extreme caution and use personal protective equipment (PPE) in providing care to 2019-nCoV infected patients; and 2) The research community should endeavour to compile diverse CoV reagents that can quickly be mobilized for rapid vaccine development, antiviral discovery, differential diagnosis, and specific diagnosis.

Methods

Phylogenetic Tree Analysis

The nucleotide sequence of the novel coronavirus associated with the outbreak of pneumonia in Wuhan (2019-nCoV) was downloaded from the National Center for Biotechnology Information (NCBI) (<http://www.ncbi.nlm.nih.gov>) with the accession number MN908947.3 [72]. The encoded S proteins and E proteins from additional coronaviruses were selected for the construction of a neighbor-joining tree. All sequences were downloaded from NCBI, and the accession numbers were annotated in the NJ tree. Protein sequences were aligned using ClustalW [73] and then used to construct the tree with MEGA7.0 [74] using 1,000 bootstraps.

Receptor Binding Domain (RBD) Alignment, Predictions, and Modeling

Amino acid sequences for the S protein of SARS-CoV (P59594.1), WIV1-CoV (AGZ48828.1), and 2019-nCoV (QHD43416.1), were obtained from GenBank. Alignments were completed using ClustalW with default parameters and the output was formatted with Esript [75,76]. The S protein sequences were submitted to Phyre2 for homology modelling under 'Intensive' mode and the subsequent structures were further refined using 3D refined for energy minimization [77,78]. The refined model with the lowest RMSD value was selected for use in structural comparisons and docking. The RBD models were compared to the crystal structure of SARS-CoV RBD (PDB ID:2AJF, chain E) using DaliLite v.5 pairwise comparison tool for analysis [79]. The RBD models were submitted for docking analysis to human ACE2 (PDB ID: 2AJF, chain B) using HADDOCK 2.2 [55] with residues 24, 27, 31, 34, 37, 38, 41, 42, 45, 79, 82, 83, 90, 325, 329, 330, 353, and 354 of ACE2 specified as a binding domain as well as RBD residues 402, 426, 436, 441, 442, 472, 473, 475, 479, 484, 486, 487, 488, and 491 [55]. The complex with the lowest z-score was selected and the binding energy was calculated using the PDBePISA server [80]. Electrostatics of the complexes were also determined using adaptive Poisson-Boltzmann solver (APBS) calculations and PyMol to show surface electrostatics for the docked RBD models and 2AJF [81,82]. Individual atom charges of each model and 2AJF were used for comparison of electrostatic potential between 2AJF and the models.

Acknowledgements and Funding

Research into the novel coronavirus genome (2019-nCoV) was led by Dr. Yong-Zhen Zhang at the the Shanghai Public Health Clinical Center & School of Public Health, in collaboration with the Central Hospital of Wuhan, Huazhong University of Science and Technology, the Wuhan Center for Disease Control and Prevention, the National Institute for Communicable Disease Control and Prevention, the Chinese Center for Disease Control, and the University of Sydney, Sydney, Australia. We would like to thank and acknowledge the researchers who were working to identify this pathogen and make the data publically available. Specifically, we acknowledge the National Institute for Viral Disease Control and Prevention, China CDC; Wuhan Institute of Virology, Chinese Academy of Sciences; Institute of Pathogen Biology, Chinese Academy of Medical Sciences & Peking Union Medical College; and Wuhan Jinyintan Hospital. In addition, we acknowledge GISAID (<https://www.gisaid.org/>) for providing a platform that allows data to be freely shared. J.K.

is funded by a Tier 2 Canada Research Chair in the Molecular Pathogenesis of Emerging and Re-Emerging Viruses provided by the Canadian Institutes of Health Research (Grant no. 950-231498). A.A.K. is funded by the IWK Health Centre (Grant no. 602975) and Nova Scotia Health Research Foundation (Grant no. 602932). DJK is a Tier 1 Canada Research Chair in Translational Vaccinology and Inflammation. Support for DJK was provided by LKSF, Canada Foundation for Innovation (JELF), and DMRF (Dalhousie Medical Research Foundation). VIDO-InterVac receives operational funding from the Government of Canada through Canada Foundation for Innovation – Major Science Initiatives and the Government of Saskatchewan through Innovation Saskatchewan. D.F. receives support from Canadian Institutes for Health Research (PJT 388665).

Figure S1. Interaction of RBD residues involved in species specificity and ACE2. The RBD homology models docked to ACE2 are shown with emphasis placed on three residues associated with SARS-CoV species specificity: Leu472, Asn479, and Thr487.

ACE2 is shown in grey and ACE2 residues involved with each of the three RBD residues are shown in stick form. The SARS-CoV, WIV1-CoV, and 2019-nCoV RBD homology models are shown in magenta, cyan, and green, respectively. Amino acids involved in ACE2 binding are shown in stick representation in their respective colours. If a SARS-RBD amino acid is mutated in either WIV1-CoV RBD or 2019-nCoV, it is labelled in red. Hydrogen bonds are shown as dashed black lines.

Preliminary genomic characterisation of an emergent SARS-CoV-2 lineage in the UK defined by a novel set of spike mutations

Summary

Recently a distinct phylogenetic cluster (named lineage B.1.1.7) was detected within the COG-UK surveillance dataset. This cluster has been growing rapidly over the past 4 weeks and since been observed in other UK locations, indicating further spread.

Several aspects of this cluster are noteworthy for epidemiological and biological reasons and we report preliminary findings below. In summary:

The B.1.1.7 lineage accounts for an increasing proportion of cases in parts of England. The number of B.1.1.7 cases, and the number of regions reporting B.1.1.7 infections, are growing. B.1.1.7 has an unusually large number of genetic changes, particularly in the spike protein. Three of these mutations have potential biological effects that have been described previously to varying extents:

- Mutation N501Y is one of six key contact residues within the receptor-binding domain (RBD) and has been identified as increasing binding affinity to human and murine ACE2.
- The spike deletion 69-70del has been described in the context of evasion to the human immune response but has also occurred a number of times in association with other RBD changes.
- Mutation P681H is immediately adjacent to the furin cleavage site, a known location of biological significance.

The rapid growth of this lineage indicates the need for enhanced genomic and epidemiological surveillance worldwide and laboratory investigations of antigenicity and infectivity.

Background

The two earliest sampled genomes that belong to the B.1.1.7 lineage were collected on 20-Sept-2020 in Kent and another on 21-Sept-2020 from Greater London. B.1.1.7 infections have continued to be detected in the UK through early December 2020. Genomes belonging to lineage B.1.1.7 form a monophyletic clade that is well supported by a large number of lineage-defining mutations (Figure 1). As of 15th December, there are 1623 genomes in the B.1.1.7 lineage. Of these 519 were sampled in Greater London, 555 in Kent, 545 in other regions of the UK including both Scotland and Wales, and 4 in other countries.

Figure 1 | Phylogenetic tree of the B.1.1.7 lineage and its nearest outgroup sequences, for samples collected up until 30-Nov-2020. Tips from the same location have been collapsed into circles whose area is proportional to the number of genomes represented. Three large subclades are evident within the B.1.1.7 lineage, each defined by one nucleotide change. One of these clades is defined by a further stop codon in ORF8.

Lineage-defining mutations & rate of evolution

The B.1.1.7 lineage carries a larger than usual number of virus genetic changes. The accrual of 14 lineage-specific amino acid replacements prior to its detection is, to date, unprecedented in the global virus genomic data for the COVID-19 pandemic. Most branches in the global phylogenetic tree of SARS-CoV-2 show no more than a few mutations and mutations accumulate at a relatively

consistent rate over time. Estimates suggest that circulating SARS-CoV-2 lineages accumulate nucleotide mutations at a rate of about 1-2 mutations per month (Duchene et al. 2020).

A preliminary analysis of these observations is provided in Figure 2, which shows a regression of root-to-tip genetic distances against genome sampling date, for lineage B.1.1.7 and for a selection of related outgroup genomes. The rate of molecular evolution within lineage B.1.1.7 is similar to that of other related lineages. However, lineage B.1.1.7 is more divergent from the phylogenetic root of the pandemic, indicating a higher rate of molecular evolution on the phylogenetic branch immediately ancestral to B.1.1.7. Further, inferred nucleotide changes on this branch are predominantly amino acid-altering (14 non-synonymous mutations and 3 deletions). There are 6 synonymous mutations on the branch. This is suggestive of a process involving adaptive molecular evolution, although a role for increased fixation rates through relaxed selective constraint cannot be currently ruled out.

Figure 2 | Regression of root-to-tip genetic distances against sampling dates, for sequences belonging to lineage B.1.1.7 (blue) and those in its immediate outgroup in the global phylogenetic tree (brown). The regression lines are fitted to the two sets independently. The regression gradient is an estimate of the rate of sequence evolution. These rates are $5.6E^{-4}$ and $5.3E^{-4}$ nucleotide changes/site/year for the B.1.1.7 and outgroup data sets, respectively.

What evolutionary processes or selective pressures might have given rise to lineage B.1.1.7?

High rates of mutation accumulation over short time periods have been reported previously in studies of immunodeficient or immunosuppressed patients who are chronically infected with SARS-CoV-2 (Choi et al. 2020; Avanzato et al. 2020; Kemp et al. 2020). These infections exhibit detectable SARS-CoV-2 RNA for 2-4 months or longer (although there are also reports of long infections in some immunocompetent individuals). The patients are treated with convalescent plasma (sometimes more than once) and usually also with the drug remdesivir. Virus genome sequencing of these infections reveals unusually large numbers of nucleotide changes and deletion mutations and often high ratios of non-synonymous to synonymous changes. Convalescent plasma is often given when patient viral loads are high, and Kemp et al. (2020) report that intra-patient virus genetic diversity increased after plasma treatment was given.

Under such circumstances, the evolutionary dynamics of and selective pressures upon the intra-patient virus population are expected to be very different to those experienced in typical infection. First, selection from natural immune responses in immune-deficient/suppressed patients will be weak or absent. Second, the selection arising from antibody therapy may be strong due to high antibody concentrations. Third, if antibody therapy is administered after many weeks of chronic infection, the virus population may be unusually large and genetically diverse at the time that antibody-mediated selective pressure is applied, creating suitable circumstances for the rapid fixation of multiple virus genetic changes through direct selection and genetic hitchhiking.

These considerations lead us to hypothesise that the unusual genetic divergence of lineage B.1.1.7 may have resulted, at least in part, from virus evolution with a chronically-infected individual. Although such infections are rare, and onward transmission from them presumably even rarer, they are not improbable given the ongoing large number of new infections.

Although we speculate here that chronic infection played a role in the origins of the B.1.1.7 variant, this remains a hypothesis and we cannot yet infer the precise nature of this event.

Potential biological significance of mutations

Table 1 provides details of the B.1.1.7 lineage-specific non-synonymous mutations and deletions. We note that many occur in the virus spike protein. These include spike position 501, one of the key contact residues in the receptor binding domain (RBD), and experimental data suggests mutation N501Y can increase ACE2 receptor affinity (Starr et al. 2020) and P681H, one of 4 residues comprising the insertion that creates a furin cleavage site between S1 and S2 in spike. The S1/S2 furin cleavage site of SARS-CoV-2 is not found in closely related coronaviruses and has been shown to promote entry into respiratory epithelial cells and transmission in animal models (Hoffmann, Kleine-Weber, and Pöhlmann 2020; Peacock et al. 2020; Zhu et al. 2020). N501Y has been associated with increased infectivity and virulence in a mouse model (Gu et al. 2020). Both N501Y and P681H have been observed independently but not to our knowledge in combination before now.

Also present is the deletion of two amino acids at sites 69-70 in spike - this mutation is one of a number of recurrent deletions observed in the N terminal domain of Spike (McCarthy et al. 2020; Kemp et al. 2020) and has been seen in multiple lineages linked to several RBD mutations. For example, it arose in the mink-associated outbreak in Denmark on the background of the Y453F

RBD mutation, and in humans in association with the N439K RBD mutation, accounting for its relatively high frequency in the global genome data (~3000 sequences).

Table 1 | Non-synonymous mutations and deletions inferred to occur on the branch leading to lineage B.1.1.7 lineage.

gene	nucleotide	amino acid
ORF1ab	C3267T	T1001I

	G28048T	R52I
	A28111G	Y73C
N	28280 GAT->CTA	D3L
	C28977T	S235F

Outside of spike, the ORF8 Q27stop mutation truncates the ORF8 protein or renders it inactive and thus allows further downstream mutations to accrue. Early on during the pandemic multiple virus isolates with deletions leading to loss of ORF8 expression were isolated worldwide, including a large cluster in Singapore with a deletion leading to both a truncated Orf7b and ablated ORF8 expression. The Singaporean strain, which had a 382nt deletion, was associated with a milder clinical infection and less post-infection inflammation, however this cluster died out at the end of March after Singapore successfully implemented control measures (Young et al. 2020). Subsequent work has found that the ORF8 deletion has only a very modest effect on virus replication in human primary airway cells compared to viruses without the deletion, leading to a slight replication lag compared to viruses with the deletion (Gamage et al. 2020). As ORF8 is usually 121 amino acids long it is likely the stop codon at position 27 observed in lineage B.1.1.7 results in a loss of function.

Finally there are 6 synonymous mutations with 5 in ORF1ab (C913T, C5986T, C14676T, C15279T, T16176C), and one in the M gene (T26801C).

Conclusion

We report a rapidly growing lineage in the UK associated with an unexpectedly large number of genetic changes including in the receptor-binding domain and associated with the furin cleavage site. Given (i) the experimentally-predicted and plausible phenotypic consequences of some of these mutations, (ii) their unknown effects when present in combination, and (iii) the high growth rate of B.1.1.7 in the UK, this novel lineage requires urgent laboratory characterisation and enhanced genomic surveillance worldwide.

Interesting. Note that people with B-cell deficiencies (CVID in particular, but SIgA and I think others—these deficiencies are often not diagnosed until adulthood) are well known to have chronic OPV infections (more than 5 years in several cases), which evolve over time. The viruses are considered vaccine-derived polioviruses if they're more than 1% from the original Sabin virus, and are designated iVDPV. iVDPVs can often (usually, I think) be distinguished from circulating VDPVs (cVDPVs) by a high level of non-synonymous mutations in particular parts of the capsid. cVDPVs, by contrast, arise in populations with low vaccination coverage, where the virus (usually Sabin 2) is transmitted serially, presumably with little immune pressure. cVDPVs have a much higher percentage of synonymous mutations (as you'd expect). IVIG treatment of chronically infected people with CVID may also play a role. There have been instances, in countries where polio has been eliminated, of iVDPVs have been detected and identified in wastewater. In at least a couple of those cases, I believe they attempted (unsuccessfully) to trace the individual by following up the sewage lines and testing at the branches.

Note also that a chronically infected person also would be a setup for recombination.

Thank you for the great work.

I am concerned with the lack of monitoring of SARS-Cov-2 in animals.

COVID-19 is a zoonosis and other animals, including Syrian hamster are prone to infection .

Minks from different locations have been infected with a variant containing the S69-70deletion. It has been shown that minks can infect humans... but what was the origin of this new mink associated strain?

Now a new UK variant emerges with a mutation that increase the affinity of the spike to human and murine ACE2 ...

The mink associated SARS-CoV-2 variant has been found in wild minks...

This is not enough to take more seriously the One Health approach of this pandemics !? It's a zoonosis .

Why we still don't have monitoring plans for animals that cohabit with sars-Cov-2 positive persons ?

isabel

Dec '20

Does someone knows when the in vitro seroneutralization -SNT assays with samples obtained from vaccinated persons tested against this new strain will be available ? I am sure that they are already done. It is a pretty straightforward assay... and is a crucial assay to provide us an idea about the vaccine protection against this new strain ...

the major structural changes of the Spike could suggest a potencial failure of licensed vacines .

Do you agree ?

Or I am being too pessimist ...

isabel

Dec '20

Sorry for too many questions ... but I appreciate your work and opinion

One more ...

Faster evolutionary rate of the virus was reported in Mink associated SARS-CoV-2 in Netherlands by Munnink et al.

Do you think that spillover to new host species could speed up the evolutionary rate of SARS-CoV-2?

In HIV-1 and EIAV vaccine studies there are reports of the emergence of new variants for immune evasion. The same is associated to antivirals .

Why with SARS-CoV-2 everyone is betting in the lack of immune evasion responses to vaccines ?

What is the scientific evidence that we have that are indicating that we'll have stable and low evolutionary rates in SARS-COV-2?

Herd Immunity: Understanding COVID-19

Haley E. Randolph¹ and Luis B. Barreiro^{1,2,3,*}¹Genetics, Genomics, and Systems Biology, University of Chicago, Chicago, IL, USA²Department of Medicine, Section of Genetic Medicine, University of Chicago, Chicago, IL 60637, USA³Committee on Immunology, University of Chicago, Chicago, IL 60637, USA*Correspondence: lbarreiro@uchicago.edu<https://doi.org/10.1016/j.immuni.2020.04.012>

The emergence of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and its associated disease, COVID-19, has demonstrated the devastating impact of a novel, infectious pathogen on a susceptible population. Here, we explain the basic concepts of herd immunity and discuss its implications in the context of COVID-19.

Basic Concepts of Herd Immunity

Acquired immunity is established at the level of the individual, either through natural infection with a pathogen or through immunization with a vaccine. Herd immunity (Box 1) stems from the effects of individual immunity scaled to the level of the population. It refers to the indirect protection from infection conferred to susceptible individuals when a sufficiently large proportion of immune individuals exist in a population. This population-level effect is often considered in the context of vaccination programs, which aim to establish herd immunity so that those who cannot be vaccinated, including the very young and immunocompromised, are still protected against disease. Depending on the prevalence of existing immunity to a pathogen in a population, the introduction of an infected individual will lead to different outcomes (Figure 1). In a completely naive population, a pathogen will propagate through susceptible hosts in an unchecked manner following effective exposure of susceptible hosts to infected individuals. However, if a fraction of the population has immunity to that same pathogen, the likelihood of an effective contact between infected and susceptible hosts is reduced, since many hosts are immune and, therefore, cannot transmit the pathogen. If the fraction of susceptible individuals in a population is too few, then the pathogen cannot successfully spread, and its prevalence will decline. The point at which the proportion of susceptible individuals falls below the threshold needed for transmission is known as the herd immunity threshold (Anderson and May, 1985). Above this level of immunity, herd immunity begins to take effect, and susceptible individuals benefit from indirect protection from infection (Figure 1B).

Under the simplest model, the herd immunity threshold depends on a single parameter known as R_0 , or the basic reproduction number (Figure 2A). R_0 refers to the average number of secondary infections caused by a single infectious individual introduced into a completely susceptible population (Anderson and May, 1985). If we consider a hypothetical pathogen with an R_0 of 4, this means that, on average, one infected host will infect four others during the infectious period, assuming no immunity exists in the population. Mathematically, the herd immunity threshold is defined by $1 - 1/R_0$ (e.g., if $R_0 = 4$, the corresponding herd immunity threshold is 0.75) (Anderson and May, 1985). Therefore, the more communicable a pathogen, the greater its associated R_0 and the greater the proportion of the

population that must be immune to block sustained transmission (Figure 2B). A similar parameter important for understanding population-level immunity is the effective reproduction number (R_e or R_t). R_e is defined as the average number of secondary cases generated by a single index case over an infectious period in a partially immune population (Delamater et al., 2019). Unlike R_0 , R_e does not assume a completely susceptible population and, consequently, will vary depending on a population's current immune state, which will change dynamically as an outbreak event or vaccination campaign unfolds. Ultimately, the goal of vaccination programs is to bring the value of R_e below 1. This occurs when the proportion of the population with immunity exceeds the herd immunity threshold. At this point, pathogen spread cannot be maintained, so there is a decline in the number of infected individuals within the population.

Establishing Herd Immunity within Populations

The above interpretation of R_0 and its relation to the herd immunity threshold is the simplest understanding of these terms. It relies on several key assumptions, including homogeneous mixing of individuals within a population and that all individuals develop sterilizing immunity—immunity that confers lifelong protection against reinfection—upon vaccination or natural infection. In real-world situations, these epidemiological and immunological assumptions are often not met, and the magnitude of indirect protection attributed to herd immunity will depend on variations in these assumptions.

R_0 is defined by both the pathogen and the particular population in which it circulates. Thus, a single pathogen will have multiple R_0 values depending on the characteristics and transmission dynamics of the population experiencing the outbreak (Delamater et al., 2019). This inherently implies that the herd immunity threshold will vary between populations, which is a well-documented occurrence (Delamater et al., 2019). For any infectious disease, communicability depends on many factors that impact transmission dynamics, including population density, population structure, and differences in contact rates across demographic groups, among others (Anderson and May, 1985). All of these factors will directly or indirectly impact R_0 and, consequently, the herd immunity threshold.

To establish herd immunity, the immunity generated by vaccination or natural infection must prevent onward

Box 1. Glossary

Herd immunity: the indirect protection from infection conferred to susceptible individuals when a sufficiently large proportion of immune individuals exist in a population

Herd immunity threshold: the point at which the proportion of susceptible individuals in a population falls below the threshold needed for transmission

R_0 : the average number of secondary infections caused by a single infectious individual introduced into a completely susceptible population

R_e : the average number of secondary infections generated by a single infectious individual over an infectious period in a partially immune population

Onward transmission: the effective transmission of a pathogen from an infected individual to susceptible host(s)

Case Fatality Rate (CFR): proportion of deaths attributed to a certain disease among all individuals diagnosed with that disease

Infection Fatality Rate (CFR): proportion of deaths attributed to a certain disease among all infected individuals

transmission, not just clinical disease. For certain pathogens, such as severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), clinical manifestations are a poor indicator of transmissibility, as asymptomatic hosts can be highly infectious and contribute to the spread of an epidemic. Once the herd immunity threshold is reached, the efficacy of herd immunity largely depends on the strength and duration of the immunity acquired. For pathogens in which lifelong immunity is induced, as is the case for measles vaccination or infection, herd immunity is highly effective and can prevent pathogen spread within a population. However, this situation is relatively rare, as immunity for many other infectious diseases, such as pertussis and rotavirus, wanes over time. As a consequence, herd immunity is less effective, and periodic outbreaks can still occur. Finally, if immunity is unevenly distributed within a population, clusters of susceptible hosts that frequently contact one another may remain. Even if the proportion of immunized individuals in the population as a whole surpasses the herd immunity threshold, these pockets of susceptible individuals are still at risk for local outbreaks.

Herd Immunity and SARS-CoV-2

The ongoing SARS-CoV-2 pandemic has caused over 3.5 million clinically confirmed cases of COVID-19 and has claimed more than 250,000 lives worldwide (as of May 4, 2020). Numerous clinical trials to evaluate novel vaccine candidates and drug repurposing strategies for the prevention and treatment of SARS-CoV-2 infection are currently ongoing. However, it is unknown whether these trials will produce effective interventions, and it is unclear how long these studies will take to establish efficacy and safety, although an optimistic estimate for any vaccine trial is at least 12–18 months. In the absence of a vaccine, building up SARS-CoV-2 herd immunity through natural infection is theoretically possible. However, there is no straightforward, ethical path to reach this goal, as the societal consequences of achieving it are devastating.

Since the onset of SARS-CoV-2 spread, various studies have estimated the basic reproductive number (R_0) of the virus to be in the range of 2 to 6. From an initial cohort of 425 confirmed cases in Wuhan, China, an R_0 of approximately 2.2 was estimated, meaning that, on average, each infected individual gives rise to 2.2 other infections (Li et al., 2020). More recent estimates place the R_0 higher at 5.7, although many estimates fall within this range (Sanche et al., 2020). This variation reflects the difficulty of obtain-

ing accurate R_0 estimates in an ongoing pandemic, and the current estimated SARS-CoV-2 R_0 values likely do not indicate a complete picture of the transmission dynamics across all countries.

Assuming an R_0 estimate of 3 for SARS-CoV-2, the herd immunity threshold is approximately 67%. This means that the incidence of infection will start to decline once the proportion of individuals with acquired immunity to SARS-CoV-2 in the population exceeds 0.67. As discussed above, this model relies on simplifying assumptions, such as homogeneous population mixing and uniform sterilizing immunity in recovered individuals across demographic groups, which are unlikely to hold true. Nevertheless, this basic model can give us a rough idea of the number of individuals that would need to be infected to achieve herd immunity in the absence of a vaccine given an approximate herd immunity threshold and a country's population.

Consequences of Reaching the SARS-CoV-2 Herd Immunity Threshold in the Absence of a Vaccine

One important measure to evaluate the impact of SARS-CoV-2 spread is the overall case fatality rate (CFR). The CFR is the proportion of deaths attributed to a certain disease among all individuals diagnosed with that disease (i.e., cases) over a specified period of time. It is worth noting that there is still significant uncertainty in the CFR for COVID-19 due to variation in the testing capacity per country, selection bias for which individuals receive testing, and differences in how deaths are officially attributed to COVID-19. Further, CFR is also sensitive to variation in the underlying age structure and distribution of comorbidities among populations. Consequently, CFRs may differ considerably over time and between countries. In the case of COVID-19, the initial estimate of the CFR in a small cohort of 41 individuals with laboratory-confirmed SARS-CoV-2 infection was high (15%) (Huang et al., 2020). However, this number has markedly decreased as more data have become available. Using data from all laboratory-confirmed and clinically diagnosed cases from mainland China, Verity et al. obtained an estimated overall CFR of 1.38%, adjusted for censoring, under-ascertainment, and the underlying demography in China, and similar estimates have been obtained from other groups (Verity et al., 2020; Wu et al., 2020a). Like many other infectious diseases, a non-uniform COVID-19 CFR has been reported across age groups, with the vast majority of deaths occurring among individuals 60 years old or greater.

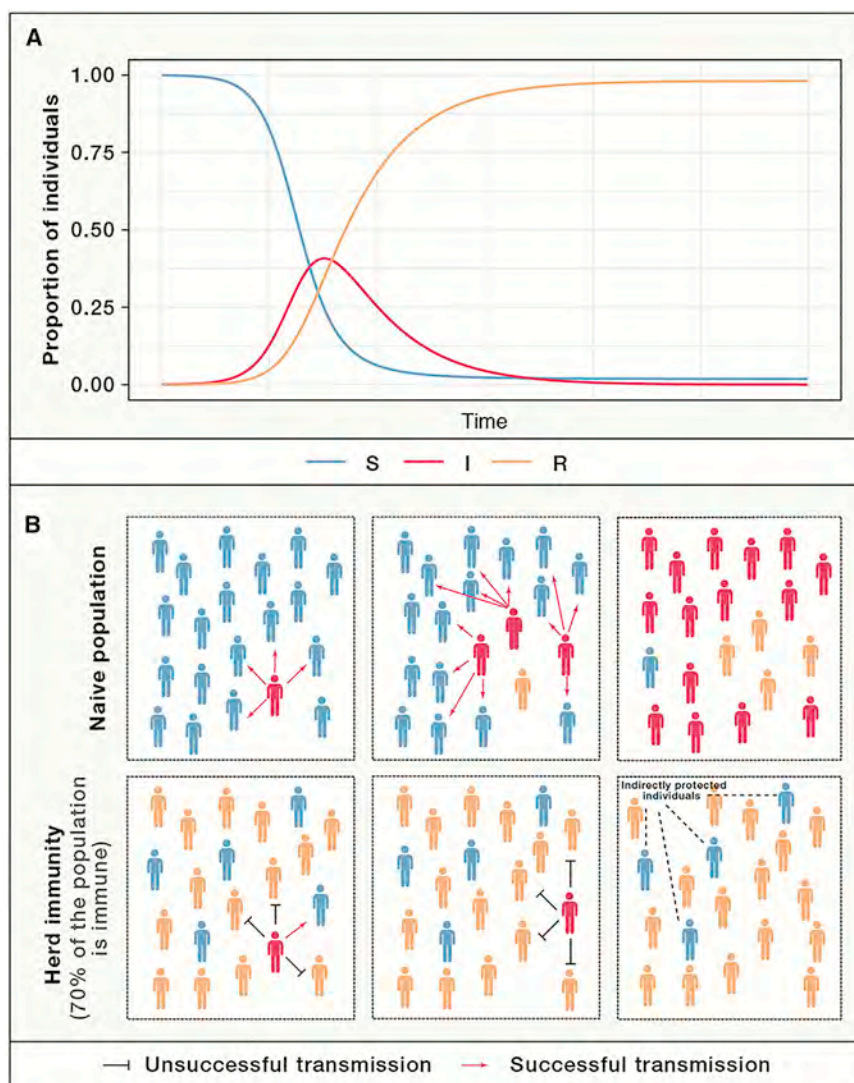

Figure 1. Herd Immunity

(A) SIR (susceptible, infectious, recovered) model for a completely immunizing infection with an $R_0 = 4$. The model assumes a closed population in which no people leave and no new cases are introduced. Following the introduction of a single infected individual, the proportion of infected individuals (red line) increases rapidly until reaching its peak, which corresponds to the herd immunity threshold. After this point, newly infected individuals infect fewer than one susceptible individual, as a sufficient proportion of the population has become resistant, preventing further spread of the pathogen (orange line).

(B) Schematic depiction of the disease propagation dynamics when one infected individual is introduced into a completely susceptible population (top panel) versus a situation in which an infected individual is introduced into a population that has reached the herd immunity threshold (bottom panel). In the naive population, an outbreak quickly emerges, whereas under the scenario of herd immunity, the virus fails to spread and persist in the population.

not vary across countries, and it does not consider factors that lead to heterogeneity in IFRs, including differences in access to healthcare resources and variation in the prevalence of comorbidities.

In reality, CFRs and IFRs vary dramatically across countries, as highlighted by the current estimates of unadjusted CFRs across the globe (Italy, 13.7%; United States, 5.77%; South Korea, 2.33%; [The Centre for Evidence-Based Medicine, 2020](#)). Although testing biases and differences in age demographics across countries account in part for these elevated regional CFRs, additional factors likely play a role, most notably a strain on

The most relevant measure to evaluate the societal cost of achieving global SARS-CoV-2 herd immunity is the overall infection fatality rate (IFR). The IFR is defined as the proportion of deaths caused by a certain disease among all infected individuals. Because some cases will not be reported, especially among asymptomatic hosts or individuals with mild symptoms, the IFR will inherently be lower than the CFR. If we combine infection fatality data with an estimate of the number of individuals that need to develop immunity to reach the herd immunity threshold, we can project the expected number of deaths as a consequence of meeting this threshold. Because of the uncertainty in the COVID-19 IFR, we use three different point estimates in our analysis: (1) an IFR of 0.2%, (2) an IFR of 0.6% that is in line with the IFR determined by Verity et al., and (3) an IFR of 1% ([Figure 2C](#)). Assuming a uniform herd immunity threshold of 67% ($R_0 = 3$) and an IFR of 0.6%, the absolute number of expected deaths across the globe would exceed 30 million people ([Figure 2C](#)). Notably, this analysis assumes that IFRs do

local healthcare systems. In Italy, a sudden influx of COVID-19 patients in March led to a shortage of intensive care unit beds and other essential medical resources, causing a substantial burden on hospitals. This outbreak underscores the importance of taking into account the limits of local healthcare infrastructure and how exceeding these limits can exacerbate negative outcomes of COVID-19.

Particularly in the context of attaining herd immunity to SARS-CoV-2, a regard for finite healthcare resources cannot be overstated, as this policy inherently relies on allowing a large fraction of the population to become infected. Unchecked, the spread of SARS-CoV-2 will rapidly overwhelm healthcare systems. A depletion in healthcare resources will lead not only to elevated COVID-19 mortality but also to increased all-cause mortality. This effect will be especially devastating for countries in which hospitals have limited surge capacity, where minimal public health infrastructure exists, and among vulnerable communities, including prison and homeless populations.

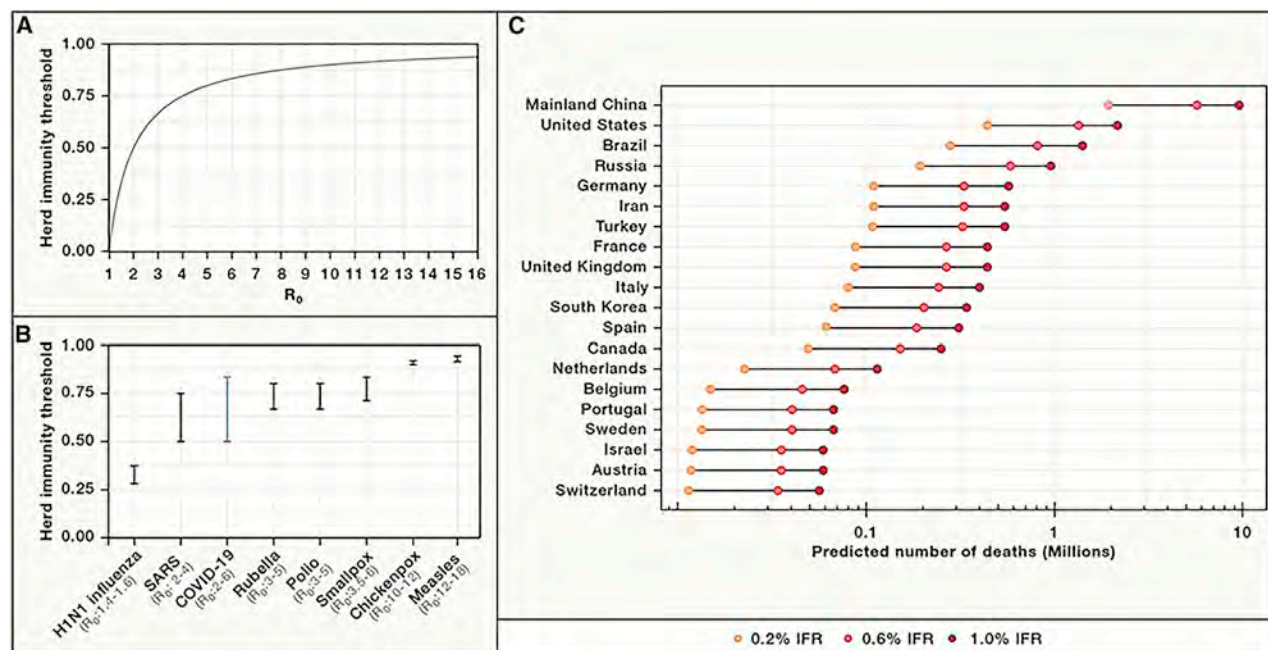

Figure 2. The Potential Health Burden of COVID-19 if Herd Immunity Is Achieved in the Absence of Vaccination

(A) Relationship between R_0 —the basic reproduction number (Box 1)—and the herd immunity threshold, which corresponds to the proportion of individuals in the population that would need to become immune for herd immunity to be established (y axis). As R_0 increases, the proportion of the population that must be immune to generate herd immunity increases ($1 - 1/R_0$).

(B) Basic reproduction numbers (R_0) and the corresponding herd immunity thresholds for various infectious diseases. R_0 estimates represent the commonly accepted R_0 range for each of the pathogens reported.

(C) Expected number of absolute deaths for the top 20 countries with the highest incidence of COVID-19 as of April 10, 2020, assuming herd immunity is established at a uniform threshold of 67% ($R_0 = 3$) in each country. Overall COVID-19 infection fatality rates (IFR) of 0.2%, 0.6%, and 1.0% are considered. We note that these numbers are necessarily underestimates given that, even after the herd immunity threshold is reached, it will take a long time until there are no more new cases, and therefore, no new deaths.

Epidemiological Considerations for SARS-CoV-2 Herd Immunity

Because SARS-CoV-2 is a novel pathogen, many features of its transmission and infection dynamics are not well characterized. Thus, our above analysis provides only a sense of the potential ramifications given a scenario in which we attain herd immunity via natural infection. We do not consider numerous complexities of viral spread and infectivity, including variation in R_0 across time and populations, heterogeneity in the attack and contact rates across demographic groups, and inter-individual variation in communicability and disease severity, although these aspects are essential to understand the full picture of SARS-CoV-2 community spread. While these epidemiological factors have important implications in the context of herd immunity, currently, they are difficult to estimate given the limited data available.

Differences in population density, cultural behaviors, population age structure, underlying comorbidity rates, and contact rates across groups influence transmission dynamics within communities, so the assumption of a uniform R_0 across populations is not realistic. Further, variation in transmissibility between individuals may play a major role in SARS-CoV-2 spread. Superspreading events occur when circumstances favorable for high rates of transmission arise. These events involve a single index case infecting a large number of secondary contacts and are known to be important in driving outbreaks of infectious diseases, including SARS, Middle East respiratory syndrome (MERS), and measles

(Lloyd-Smith et al., 2005). Reports of SARS-CoV-2 superspreading events have been documented, suggesting that heterogeneity in infectivity may significantly impact the dynamics of its transmission (Liu et al., 2020). Finally, the factors that influence inter-individual heterogeneity in COVID-19 susceptibility, clinical pathology, and disease outcome are not well understood. Reported differences in sex- and ethnicity-specific CFRs suggest that genetic, environmental, and social determinants likely underlie variation in susceptibility to COVID-19 and the severity of COVID-19 complications, although future studies are needed to explore this further (Nasiri et al., 2020).

Immunological Considerations for SARS-CoV-2 Herd Immunity

The ability to establish herd immunity against SARS-CoV-2 hinges on the assumption that infection with the virus generates sufficient, protective immunity. At present, the extent to which humans are able to generate sterilizing immunity to SARS-CoV-2 is unclear. A recent study assessing the possibility of SARS-CoV-2 reinfection in a small cohort of rhesus macaques found that reinfection was not able to occur 1 month after the first viral challenge, suggesting at least short-term sterilizing immunity in these animals (Bao et al., 2020). In a cohort of 175 recovered COVID-19 patients, SARS-CoV-2-specific serum neutralizing antibodies (NAbs) were detected at considerable, albeit variable, titers in most ($n = 165$) individuals (Wu et al., 2020b),

indicating that the production of NAb against SARS-CoV-2 is relatively common.

Whereas these findings are promising, other important questions to consider are whether NAb titers will wane over time and how long acquired immunity will last. Previous studies in confirmed SARS patients have demonstrated that NAb responses against SARS-CoV persisted for several months to 2 years, although all individuals displayed low titers after about 15 months (Mo et al., 2006). Further, elevated concentrations of specific antibodies to coronavirus 229E, one of the viruses responsible for the common cold, were found 1 year after infection, although these titers were not sufficient to prevent reinfection in all individuals (Callow et al., 1990). Together, these studies suggest that protection against reinfection with coronavirus species tends to diminish given sufficient time, although longitudinal serological studies are needed to assess the duration of SARS-CoV-2 immunity. If this proves to also be true for SARS-CoV-2, persistent herd immunity may never be attained in the absence of recurrent vaccination. Indeed, modeling of the transmission dynamics of SARS-CoV-2 predicts that short-term immunity (~10 months) would give rise to annual outbreaks, while longer-term immunity (~2 years) would lead to biennial outbreaks (Kissler et al., 2020). Mass serological testing is now needed to determine how many individuals have been infected, how many individuals are immune, and how far we are from reaching the herd immunity threshold. That said, even if reinfection can occur after sterilizing immunity wanes, enduring memory cells of the adaptive immune system would likely facilitate immune control of the virus and limit disease pathology, which would hopefully decrease the clinical severity of subsequent infections.

Recap

In a sufficiently immune population, herd immunity provides indirect protection to susceptible individuals by minimizing the probability of an effective contact between a susceptible individual and an infected host. In its simplest form, herd immunity will begin to take effect when a population reaches the herd immunity threshold, namely when the proportion of individuals who are immune to the pathogen crosses $1 - 1/R_0$. At this point, sustained transmission cannot occur, so the outbreak will decline. However, in real-world populations, the situation is often much more complex. Epidemiological and immunological factors, such as population structure, variation in transmission dynamics between populations, and waning immunity, will lead to variation in the extent of indirect protection conferred by herd immunity. Consequently, these aspects must be taken into account when discussing the establishment of herd immunity within populations. There are two possible approaches to build widespread SARS-CoV-2 immunity: (1) a mass vaccination campaign, which requires the development of an effective and safe vaccine, or (2) natural immunization of global populations with the virus over time. However, the consequences of the latter are serious and far-reaching—a large fraction of the human population would need to become infected with the virus, and millions would succumb to it. Thus, in the absence of a vaccination program, establishing herd immunity should not be the ultimate goal. Instead, an emphasis should be placed on policies that protect the most vulnerable groups in the hopes that herd immunity will eventually be achieved as a byproduct of such measures, although not the primary objective itself.

Summary

On December 9th, the Brazilian Ministry of Health (MoH) recognised the first case of reinfection in the country. A 37-years-old healthcare worker resident in Northeast Brazil presented two clinical episodes of COVID-19 in June and October 2020, that were confirmed by RT-PCR in samples

collected 116 days apart. Whole-genome sequencing revealed that the two infections were caused, respectively, by the two most prevalent SARS-CoV-2 Brazilian lineages B.1.1.33 (primo-infection) and B.1.1.28 (reinfection). Bayesian analysis indicates that the reinfection probably occurred between September 14th to October 11th, a few days before the second confirmed clinical episode of COVID-19, thus excluding the possibility of viral co-infection followed by long-term viral persistence. Notably, the B.1.1.28 virus detected at reinfection corresponds to a new emergent Brazilian viral lineage, initially detected in the Rio de Janeiro state, containing the mutation E484K in the Spike protein. We found this new viral variant, hereafter designated B.1.1.28(E484K), in several states from the South, Northeast, and North Brazilian regions and date its origin at August 27th, 2020 (July 14th - September 18th). These findings documented a classical SARS-CoV-2 reinfection case with the emerging Brazilian lineage B.1.1.28(E484K). Additionally, we provide evidence of this emerging Brazilian clade's geographic dissemination outside the Rio de Janeiro state.

Keywords: COVID-19; SARS-CoV-2; reinfection; secondary infection.

Introduction

The efficiency and persistence of protective immunity naturally caused by the coronavirus disease (COVID-19) or vaccination are currently unknown. Some reinfection cases have been reported in different countries **(1)**, but the differentiation between reinfection and viral persistence cases remains a challenge. The detection of two COVID-19 episodes months apart and caused by two different lineages of SARS-CoV-2 remains the most reliable evidence of a reinfection case. On December 9th, the Brazilian MoH recognised the first case of reinfection in the country **(2)**. Here, we describe this classical reinfection case and highlight details about the genomic features of the two COVID-19 episodes. Additionally, we demonstrate that the second episode's virus was related to the new viral variant, hereafter designated B.1.1.28 (E484K), circulating in several states from the South, Northeast, and North Brazilian regions.

Results

Case description

A 37-years-old woman without pre-existing comorbidities, healthcare worker (medical doctor) in Paraíba and resident in Rio Grande do Norte, neighbouring States in Brazilian Northeastern region, reported two clinical episodes of COVID-19. The first one in June and the second one in October 2020, comprising 116 days between the two episodes. On June 17th, the healthcare worker presented symptoms such as headache, runny nose, diarrhea, and myalgia, being classified as a mild COVID-19 case with no complications. The upper respiratory specimen (nasopharyngeal swabs - NPS) was collected from this patient six days later (June 23th). A second NPS was collected on 16th September as follow-up procedure. On October 11th, the patient presented new symptoms such as intense headache, ageusia, anosmia, and fatigue. This second infection was mild and evolved without complications as in the first episode, and a third NPS was collected two days later (October 13th).

This study was approved by the FIOCRUZ-IOC Ethics Committee (68118417.6.0000.5248 and CAAE 32333120.4.0000.5190) and the Brazilian Ministry of Health SISGEN (A1767C3). In addition, the patient reinfected with SARS-CoV-2 read and signed the free and informed consent form.

Diagnostic Laboratory findings

The three NPS samples collected were processed locally; the viral RNA was extracted and tested for SARS-CoV-2 using the real-time RT-PCR for the targets E (3) or N1 and N2 (4). After the diagnostic, Paraíba State Central Public Health Laboratory (LACEN-PB) sent the positive NPS and the serum specimens to the Respiratory Viruses and Measles Laboratory (LVRS) at Fiocruz (MoH National Reference Laboratory and WHO Reference Laboratory for Coronavirus) for confirmation and complementary analysis. Briefly, both positive samples were confirmed using the real-time RT-PCR protocol and the Ag-RDT Panbio COVID-19 Antigen Test (Abbott) directly from the clinical sample. According to the Brazilian MoH Technical Note, to confirm SARS-CoV-2 reinfection, two positive RT-PCR results separated by at least 90 days, independent of clinical conditions are necessary (5). The first and third clinical specimens collected on June 23th and October 13th, 2020, from the healthcare worker were positive for SARS-CoV-2 by real-time RT-PCR, while the second specimen collected on September 16th was negative. Both NPS positive specimens presented a high viral load, presumed by the low cycle threshold (Ct) values in the real time RT-PCR shown in **Table 1**.

Genomic findings

To distinguish between reinfection and long-term viral persistent hypothesis, we recovered the SARS-CoV-2 whole-genomes from the two positive NPS samples (EPI_ISL_792561 and EPI_ISL_792562) from the suspected reinfection case and 76 SARS-CoV-2 positive cases detected in the same state of Paraíba from April 6th to November 27th, 2020 (EPI_ISL_792563 to EPI_ISL_792638). The whole-genomes were recovered using Illumina or ONT Nanopore sequencing protocols previously established and used by Genomic Coronavirus Fiocruz Network to recover high-quality genomes (6,7). The FASTQ reads obtained were imported into the CLC Genomics Workbench version 20.0.4 (Qiagen A/S, Denmark), trimmed, and mapped against the reference sequence EPI_ISL_402124 available in EpiCoV database in the GISAID (<https://www.gisaid.org/>). The alignment was refined using the InDels and Structural Variants module, followed by the Local Realignment module and the final consensus obtained. Maximum Likelihood (ML) phylogenetic analysis of all SARS-CoV-2 whole-genomes from Paraíba was conducted using PhyML8 and revealed two different viral lineages in the two COVID-19 episodes. In the first episode, the lineage B.1.1.33 was detected, whereas lineage B.1.1.28 was detected in the third (second positive) one (**Figure 1**), according to Pangolin lineage classification (9). These SARS-CoV-2 lineages were also detected in other samples from Paraíba state (**Figure 1**) and represent the most prevalent viral variants circulating in Brazil during the early epidemic phase (10,11). Of note, the B.1.1.28 sequences recovered from the reinfection case and from two additional cases in the Paraíba state harbor the E484K substitution (G23012A) in the Spike protein that was recently associated with a novel SARS-CoV-2 B.1.1.28 lineage circulating in Rio de Janeiro state (12).

To better characterize the B.1.1.28 virus present in the second NPS positive sample of the reinfection case, we aligned it against all B.1.1.28 whole-genomes available in the EpiCoV database in GISAID by December 20th, 2020. Additionally, we also selected eight B.1.1.28 whole-genomes from Alagoas (n = 2), Amazonas (n = 1), and Parana (n = 5) states available at the Genomic Coronavirus Fiocruz Network database that also harbor the E484K substitution (EPI_ISL_792560, EPI_ISL_792639, EPI_ISL_792642, EPI_ISL_792645, EPI_ISL_792646, EPI_ISL_792650 to EPI_ISL_792652). The new ML phylogenetic tree revealed that the B.1.1.28

virus from the reinfection case branched in a highly supported (aLRT = 1) sub-clade with two sequences from Paraiba and 44 additional sequences recently sampled (October-December, 2020) in Brazil: 36 sequences from Rio de Janeiro recovered from the EpiCoV database in GISAID and the eight sequences from Alagoas, Parana, and Amazonas states that harbours the mutation S-E484K (Figure 2A). We identified five lineage-defining SNPs: C100U (5'UTR), T10667G (NSP5_L205V), C11824T (NSP6), G23012A (Spike_E484K), and G28628T (N_A119S) that distinguish sequences from the novel B.1.1.28 sub-clade from all other Brazilian B.1.1.28 sequences available. Because of the potential impact of the spike mutation E484K on viral phenotype (**13-16**), we designated this new emerging clade as B.1.1.28(E484K).

To further investigate the spatiotemporal emergence of the novel B.1.1.28(E484K) clade and the viral strain detected in the reinfection case, we conducted a Bayesian phylogeographic analysis of all 47 SARS-CoV-2 Brazilian sequences that branched within such clade. Time-scaled trees were estimated using a strict molecular clock model with a uniform substitution rate prior ($8-10 \times 10^{-4}$ substitutions/site/year), a GTR+I+G nucleotide substitution model, and the Bayesian skyline coalescent prior as implemented in BEAST 1.10 (**17**). Bayesian reconstructions traced the origin of the emerging B.1.1.28(E484K) lineage in the Rio de Janeiro State (PSP = 0.97) on August 27th (95% High Posterior Density [HPD]: July 14th – September 18th) and its subsequent dispersion from Rio de Janeiro to other States from the South (Parana) and Northeast (Alagoas and Paraiba) regions (**Figure 2B**). This phylogeographic reconstruction also supports a dissemination event from Paraiba State to Amazonas State and the branching of the B.1.1.28(E484K) sequence from the reinfection case with that from Amazonas with high support (PP = 1) (**Figure 2B**). The most recent common ancestor of B.1.1.28(E484K) sequences from the reinfection case and the Amazonas state was dated to September 29th (95% HPD: September 14th – October 11th), a few days earlier before the onset of reinfection symptoms (October 11th).

Discussion

We demonstrate that the first case of reinfection recognised by the Brazilian MoH on December 9th corresponds to a primoinfection with the Brazilian lineage B.1.1.33 and a reinfection with a novel emerging B.1.1.28 lineage harboring the mutation E484K in the Spike protein. The age of the common ancestor of the B.1.1.28(E484K) virus present in the second positive sample of the reinfection case and a non-related virus sampled in the Amazonas state provide a maximum limit for the reinfection episode between September 14th and October 11th, thus excluding the possibility of long-term persistence of the B.1.1.28(E484K) virus since primoinfection (before June 23rd, 2020).

Notably, the reinfection case reported here coincides with a recently reported case in the Bahia state that also described a primoinfection and reinfection with the B.1.1.33 and B.1.1.28(E484K) viral variants, respectively (**18**). These studies also confirm that the B.1.1.28(E484K) emerging variant initially described in the Rio de Janeiro state (**12**) is more widely distributed across different Brazilian states. Our analysis supports that the B.1.1.28(E484K) lineage probably emerged in the state of Rio de Janeiro around late August, but defining the precise location and time of emergence of this novel lineage will require a denser sampling from different Brazilian states during the second half of 2020.

The mutation E484K is located in the receptor-binding domain (RBD) and has also been recently described in an independent SARS-CoV-2 lineage rapidly spreading in South Africa (**19**). The rapid dissemination of these variants, combined with the ability of viruses harboring the mutation E484K to escape from neutralizing antibodies (**13-16**), and the recent cases of reinfection with the

B.1.1.28(E484K) lineage detected in Brazil should raise concern about the potential impact of this mutation on infectivity, immune escape, and reinfection.

The findings presented here support that previous exposure to SARS-CoV-2 might not guarantee immunity in all cases. It reinforces the need to maintain the non-pharmacologic protective measures not only by individuals who tested negative, but also for those who already tested positive for SARS-CoV-2. Characterization of the immune response in individuals who presented reinfection with SARS-CoV-2 will be crucial to understand better the role of viral and host factors on this, apparently, rare phenotype.

Acknowledgment

We want to thank the funding support from CGLab/MoH (General Laboratories Coordination of Brazilian Ministry of Health), CVSLR/FIOCRUZ (Coordination of Health Surveillance and Reference Laboratories of Oswaldo Cruz Foundation), CNPq COVID-19 MCTI 402457/2020-0 and 403276/2020-9; INOVA Fiocruz VPPCB-005-FIO-20-2 and VPPCB-007-FIO-18-2-30; FAPERJ: E26/210.196/2020; FAPEAM (PCTI-EmergeSaude/AM call 005/2020 and Rede Genomica de Vigilancia em Saude - REGESAM). We also appreciate the support of all Genomic Coronavirus Fiocruz Network members, the Multi-user Research Facility of Biosafety Level 3 Platform of the Oswaldo Cruz Institute (IOC), Fiocruz, and the CGLab/MoH and Secretary of Surveillance and Health of the Brazilian MoH (SVS-MS). Additionally, we are thankful for all that contribute to the EpiCoV database from the GISAID initiative with high-quality SARS-CoV-2 genomes. All genomes used in this study are described in the acknowledgment **Supplementary Table 1**.

Figures and Tables

Table 1. Epidemiological and laboratorial data of the reinfection SARS-CoV-2 case detected in Northeast of Brazil.

NPS = naso-oropharyngeal swab; Ct = cycle threshold, E = envelope protein, N1 and N2 = nucleoprotein, RP = human RNase P, NA = not applicable; ND = Not detectable.

Figure 01: ML of SARS-CoV-2 whole-genomes sequences from Paraiba. ML phylogenetic tree showing the branching pattern of SARS-CoV-2 whole genome sequences (29779 nt), from Paraiba (n = 77) classified within lineages B.1.1.28 (red), B.1.1.33 (blue), and others B.1.1 (black). Sequences derived from the primo-infection and reinfection are both highlighted with different colors as indicate in the legend at left. Nodes with high statistical (aLRT ≥ 9.0) support are marked by circular shapes.

Figure 02: Emergence of the B.1.1.28(E484K) clade. **A.** ML phylogenetic tree of B.1.1.28 SARS-CoV-2 whole genome sequences (29779 nt) from Brazil (n = 376). Shaded box highlights the B.1.1.28(E484K) clade (n = 47) and its statistical support (aLRT = 1.0) is indicated in the cladogram. Sequences from Paraíba and the reinfection case are marked in orange and green, respectively. **B.** Time-scaled Bayesian MCC tree of SARS-CoV-2 whole genome sequences from the B.1.1.28(E484K) clade (n = 47). Branches are colored according to the most probable location state of their descendent nodes as indicated in the legend at right. The five lineage-defining SNPs are indicated at the MCCT root node. Circular shapes mark nodes with high statistical support (PP ≥ 9.0) and a square tip shape indicates the sequence from reinfection case.

SARS-CoV-2 is transmitted via contact and via the air between ferrets

Mathilde Richard ¹, Adinda Kok ¹, Dennis de Meulder¹, Theo M. Bestebroer¹, Mart M. Lamers ¹, Nisreen M. A. Okba ¹, Martje Fentener van Vlissingen ², Barry Rockx ¹, Bart L. Haagmans ¹, Marion P. G. Koopmans ¹, Ron A. M. Fouchier ¹ & Sander Herfst ¹✉

SARS-CoV-2, a coronavirus that emerged in late 2019, has spread rapidly worldwide, and information about the modes of transmission of SARS-CoV-2 among humans is critical to apply appropriate infection control measures and to slow its spread. Here we show that SARS-CoV-2 is transmitted efficiently via direct contact and via the air (via respiratory droplets and/or aerosols) between ferrets, 1 to 3 days and 3 to 7 days after exposure respectively. The pattern of virus shedding in the direct contact and indirect recipient ferrets is similar to that of the inoculated ferrets and infectious virus is isolated from all positive animals, showing that ferrets are productively infected via either route. This study provides experimental evidence of robust transmission of SARS-CoV-2 via the air, supporting the implementation of community-level social distancing measures currently applied in many countries in the world and informing decisions on infection control measures in healthcare settings.

In late December 2019, clusters of patients in China presenting with pneumonia of unknown etiology were reported to the World Health Organization (WHO)¹. The causative agent was rapidly identified as being a virus from the *Coronaviridae* family, closely related to the severe acute respiratory syndrome coronavirus (SARS-CoV)^{2–4}. The SARS-CoV epidemic affected 26 countries and resulted in more than 8000 cases in 2003. The newly emerging coronavirus, named SARS-CoV-2⁵, rapidly spread worldwide and was declared pandemic by the WHO on March 11, 2020⁶. The first evidence suggesting human-to-human transmission came from the descriptions of clusters among the early cases^{7,8}. Based on epidemiological data from China before measures were taken to control the spread of the virus, the reproductive number R_0 (the number of secondary cases directly generated from each case) was estimated to be between 2 and 3^{9–11}. In order to apply appropriate infection control measures to reduce the R_0 , the modes of transmission of SARS-CoV-2 need to be elucidated. Respiratory viruses can be transmitted via direct and indirect contact (via fomites), and through the air via respiratory droplets and/or aerosols. Transmission via respiratory droplets ($>5\ \mu\text{m}$) is mediated by expelled particles that have a propensity to settle quickly and is therefore reliant on close proximity between infected and susceptible individuals, usually within 1 m of the site of expulsion. Transmission via aerosols ($<5\ \mu\text{m}$) is mediated by expelled particles that are smaller in size than respiratory droplets and can remain suspended in the air for prolonged periods of time, allowing infection of susceptible individuals at a greater distance from the site of expulsion¹². Current epidemiological data suggest that SARS-CoV-2 is transmitted primarily via respiratory droplets and contact^{7–9,13,14}, which is used as the basis for mitigation of spread through physical and social distancing measures. However, scientific evidence that SARS-CoV-2 can be efficiently transmitted via the air is weak.

Previous studies have shown that ferrets were susceptible to infection with SARS-CoV^{15–19}, and that SARS-CoV was efficiently transmitted to co-housed ferrets via direct contact¹⁵. Here, we use a ferret transmission model to show that SARS-CoV-2 spreads through direct contact and through the air (via respiratory droplets and/or aerosols).

Results

Transmission of SARS-CoV-2 between ferrets. Individually housed donor ferrets were inoculated intranasally with a strain of SARS-CoV-2 isolated from a German traveller returning from China. Six hours post-inoculation (hpi), a direct contact ferret was added to each of the cages. The next day, indirect recipient ferrets were placed in adjacent cages, separated from the donor cages by two steel grids, 10 cm apart, allowing viruses to be transmitted only via the air (Fig. 1). On alternating days to prevent cross-contamination, throat, nasal and rectal swabs were collected from each ferret in the inoculated and direct contact groups and from the indirect recipient group, followed by SARS-CoV-2 detection by RT-qPCR and virus titration.

Ferrets were productively infected by SARS-CoV-2 upon intranasal inoculation, as demonstrated by the robust and long-term virus shedding from the donor ferrets (Fig. 2, Supplementary Fig. 1). SARS-CoV-2 RNA levels peaked at 3 days post-inoculation (dpi) and were detected up to 11 dpi in two animals and up to 15 and 19 dpi in the other two animals (Fig. 2, Supplementary Fig. 1). SARS-CoV-2 was transmitted to direct contact ferrets in four out of four independent experiments between 1 and 3 days post-exposure (dpe) and viral RNA was detected up to 13–15 days (i.e. 13–17 dpe) (Fig. 2, Supplementary Fig. 1). Interestingly, SARS-CoV-2 was also transmitted via the air to three out of four indirect

recipient ferrets. SARS-CoV-2 RNA was detected from 3 to 7 dpe onwards these indirect recipient ferrets and for 13–19 days (Fig. 2, Supplementary Fig. 1).

Whereas donor ferrets were inoculated with a high virus dose, direct contact and indirect recipient ferrets are likely to have received a low infectious dose via direct contact or via the air. In spite of this, the pattern of virus shedding from the direct contact and indirect recipient ferrets was similar to that of the inoculated donor ferrets, both in terms of duration and SARS-CoV-2 RNA levels, corroborating robust replication of SARS-CoV-2 upon transmission via direct contact and via the air, independent of the infectious dose. In general, higher SARS-CoV-2 RNA levels were detected in the throat swabs as compared to the nasal swabs. SARS-CoV-2 RNA levels in the rectal swabs were overall the lowest. From each SARS-CoV-2 RNA positive animal, infectious virus was isolated in VeroE6 cells from throat and nasal swabs for at least two consecutive days (Supplementary Fig. 2 and Supplementary Table 1). In contrast, no infectious virus was isolated from the rectal swabs. Infectious virus titers ranged from $10^{0.75}$ to $10^{2.75}$ TCID₅₀/ml (median tissue culture infectious dose per ml) in the donor ferrets, from $10^{0.75}$ to $10^{3.5}$ TCID₅₀/ml in the direct contact ferrets and from $10^{0.75}$ to $10^{4.25}$ TCID₅₀/ml in the indirect recipient ferrets. All SARS-CoV-2 positive ferrets seroconverted 21 dpi/dpe, and the antibody levels detected using a receptor binding domain (RBD) enzyme-linked immunosorbent assay (ELISA) were similar in donor, direct contact and indirect recipient ferrets (Fig. 3a). Plaque reduction neutralization titers (PRNT) in sera from indirect recipient ferrets were lower than that of donor and direct contact ferrets, which is probably due to the later onset of virus replication upon transmission via the air and thus a relatively earlier collection of serum after infection (Fig. 3b). The indirect recipient ferret, in which no SARS-CoV-2 was detected, did not seroconvert as expected.

Sequence analysis of viruses isolated from ferrets. MinION (Nanopore) sequencing was used to determine the whole genome consensus sequences of viruses in throat swabs collected from the four donor (all 3 dpi), the four direct contact (all 5 dpe) and three indirect recipient ferrets (7, 9 or 11 dpe). Two substitutions were detected in the consensus sequence of viruses collected from all ferrets as compared to the sequence of the original virus isolate: N501T and S686G, both in the spike protein. Residue 501 is part of the receptor binding motif that mediates contact with angiotensin-converting enzyme 2 (ACE2), the receptor of SARS-CoV-2. A threonine at position 501 (as present in the majority of SARS-CoV viruses) was previously shown to decrease the affinity of the spike protein with the receptor²⁰. Perhaps this substitution emerged in ferrets as a result of adaptation to efficient binding to ferret ACE2. Residue 686 is the first residue after the furin cleavage site. The serine to glycine substitution has not been found in human SARS-CoV-2 sequences, hence the effect of this substitution is unknown. In addition, a L260F substitution in Nsp6 was observed in the throat swab of a direct contact ferret, and two synonymous substitutions (C2910T and C7235T) were detected in an indirect recipient ferret and a direct contact ferret respectively. In order to understand whether the N501T and S686G substitutions were either positively selected in ferrets from existing minority variants in the virus isolate or had mutated in ferrets, Illumina next-generation sequencing was performed on sequential samples from the donor ferrets and on the virus stocks (Supplementary Table 2). Single nucleotide polymorphisms (SNPs) which were present in $>5\%$ of the total number of reads were called (Supplementary Table 2A). The N501T substitution was already present in all donor ferrets at 1 dpi in 14.7%–49.6% of the reads and percentages rapidly increased to 86.4%–98.7% on

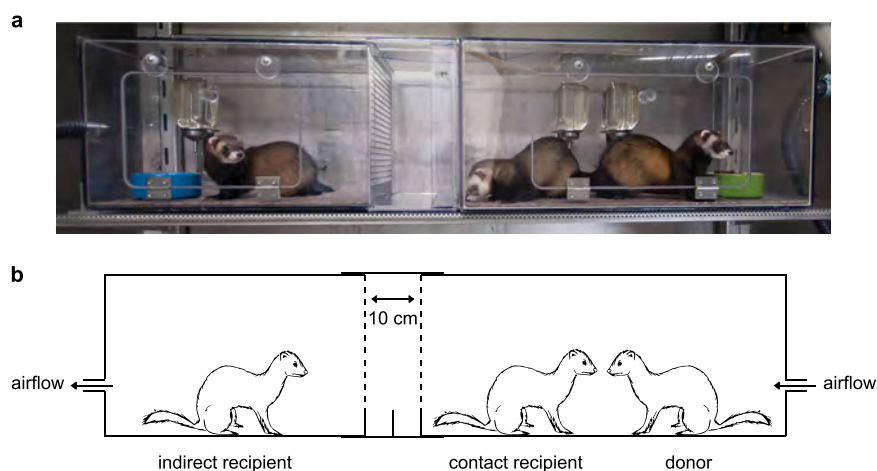

Fig. 1 The ferret transmission experimental set-up. Picture (a) and schematic representation (b) of one independent experimental set-up to assess direct contact transmission and indirect transmission via the air. One inoculated donor ferret is housed in a cage (right-hand side of the picture). Six hours later, a direct contact ferret is added to the same cage as the donor ferret. The next day, an indirect recipient ferret is placed in an opposite cage (left-hand side of the picture) separated by two steel grids, 10 cm apart, to avoid contact transmission. The direction of the air flow (100 L min^{-1}) is indicated by the arrows. The ferret transmission set-ups are placed in class III isolators in a biosafety level 3+ laboratory.

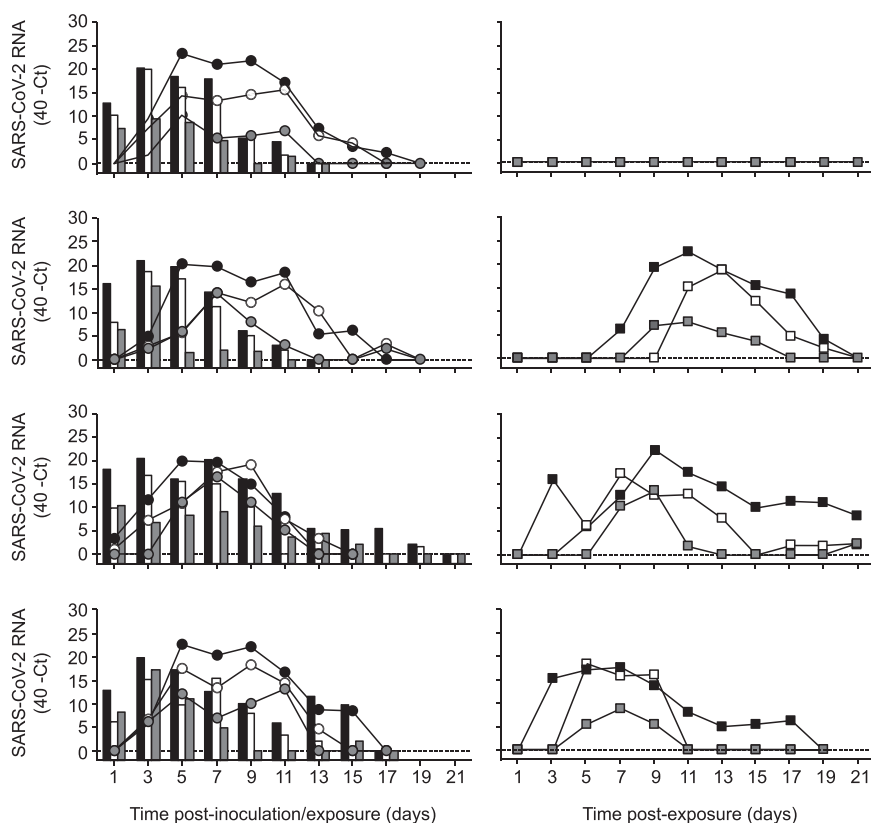

Fig. 2 SARS-CoV-2 shedding in ferrets in the transmission experiment. SARS-CoV-2 viral RNA was detected by RT-qPCR in throat (black), nasal (white) and rectal (grey) swabs collected from inoculated donor ferrets (bars; left panels), direct contact ferrets (circles; left panels) and indirect recipient ferrets housed in separate cages (squares; right panels). Swabs were collected from each ferret every other day until no viral RNA was detected in any of the three swabs. The dotted line indicates the detection limit.

3 dpi. At 7 dpi, the percentages of reads with the N501T substitution were still high, albeit lower in donor ferret 4 (66.2%). A similar trend was observed for the S686G substitution. In addition, an R685H substitution in the spike protein was detected in two ferrets and L207F and L260F substitutions in Nsp6 were detected in individual ferrets, all at low percentages (Supplementary Table 2A). SNP analysis of the virus isolates

demonstrated that S686G was the only substitution that was present in more than 5% of the reads: 8.1% in the passage 3 virus stock used to inoculate donor ferrets and 15.2% in the passage 1 virus isolate from Germany (Supplementary Table 2B). Among the other substitutions observed in the ferret samples, only the R685H substitution was detected at >1% of the reads in the original virus isolate (Supplementary Table 2B).

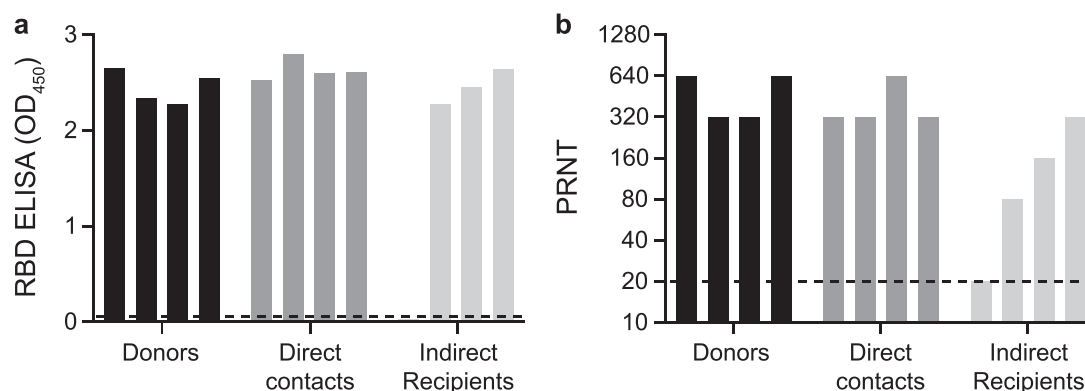

Fig. 3 Antibody responses in donor, direct contact and indirect recipient ferrets 21 dpi/dpe. Sera were collected from the donor, direct contact and indirect recipient ferrets 21 dpi/dpe and IgG responses were assessed using a SARS-CoV-2 receptor binding site (RBD) ELISA (a) and using a plaque reduction neutralization assay (b). The dotted lines indicate the detection limit of the assays. PRNT: plaque reduction neutralization titer. OD: optic density. All presera were tested negative by RBD ELISA and plaque reduction neutralization assay (OD₄₅₀ 0.02–0.05; PRNT < 20).

Discussion

Here, we show that SARS-CoV-2 is transmitted via contact and via the air between ferrets. SARS-CoV-2 transmission in experimental animal models has recently also been described by others. SARS-CoV-2 direct contact transmission between ferrets²¹ and hamsters²² was reported, with similar efficiency as observed in our study. In addition, SARS-CoV-2 was also found to be transmitted via the air in two out of six ferrets²¹, and in two out of six cats²³. However, only low levels of SARS-CoV-2 RNA were detected in nasal washes and feces of the indirect recipient ferrets, and no infectious virus was isolated²¹. Furthermore, virus shedding was shorter as compared to the donor animals and only one out of the two SARS-CoV-2 RNA positive indirect recipient ferrets seroconverted. Similarly, the transmission via the air between cats was not efficient. SARS-CoV-2 RNA was detected in the feces and tissues of one cat at 3 and 11 dpi, respectively and in nasal washes of another cat, but no infectious virus was isolated. Both SARS-CoV-2 RNA positive indirect recipient cats seroconverted. In contrast, the present study showed that SARS-CoV-2 was efficiently transmitted via the air between ferrets, as demonstrated by long-term virus shedding and the presence of infectious virus in the indirect recipient animals, which is comparable to the transmissibility of pandemic influenza viruses in the ferret model²⁴.

To date, there is no evidence of fecal-oral transmission of SARS-CoV-2 in humans. However, the prolonged detection of RNA in consecutive stool samples²⁵ and the environmental contamination of sanitary equipment²⁶ may suggest that the fecal-oral route could be a potential route of transmission of SARS-CoV-2. Here, no infectious virus was retrieved from any of the rectal swabs. Despite this, it cannot be fully excluded that SARS-CoV-2 was also transmitted from donors to direct contact ferrets partly via the fecal-oral route. In the study by Kim et al., ferret fecal material was used to inoculate ferrets, resulting in a productive infection, indicating that infectious SARS-CoV-2 was shed in fecal specimens²¹.

Our experimental system does not allow to assess whether SARS-CoV-2 was transmitted via the air through respiratory droplets, aerosols or both, as donor and indirect recipient ferret cages are placed only 10 cm apart from each other. In a recent study, SARS-CoV-2 remained infectious in aerosols for at least 3 h after aerosolization at high titers in a rotating drum, comparable to SARS-CoV²⁷. Although it is informative to compare the stability of different respiratory viruses in the air, our study provides the additional information that infectious SARS-CoV-2 particles can actually be expelled in the air and subsequently

infect recipients. In two other studies, the presence of SARS-CoV-2 in air samples collected in hospital settings was investigated. However, no SARS-CoV-2 RNA was detected in the air sampled in three isolation rooms²⁶, or 10 cm from a symptomatic patient who was breathing, coughing or speaking²⁸. Nevertheless, RNA was detected on the air exhaust outlet of one of the isolation rooms in the first study, suggesting that virus-laden droplets may be displaced by airflows²⁶.

Here we provide the first experimental evidence that SARS-CoV-2 can be transmitted efficiently via the air between ferrets, resulting in a productive infection and the detection of infectious virus in indirect recipients, as a model for human-to-human transmission. Although additional experiments on the relative contribution of respiratory droplets and aerosols to the transmission of SARS-CoV-2 are warranted, the results of this study corroborate the WHO recommendations about transmission precautions in health care settings and the social distancing measures implemented in many countries around the globe to mitigate the spread²⁹. The ferret transmission model will also be useful to understand transmission dynamics and the molecular basis of the transmissibility of SARS-CoV-2 and other betacoronaviruses, which, in the context of the current SARS-CoV-2 pandemic and future pandemic threats, is clearly of utmost importance.

Methods

Virus and cells. SARS-CoV-2 (isolate BetaCoV/Munich/BavPat1/2020; GISAID ID EPI_ISL_406862; kindly provided by Prof. Dr. C. Drosten) was propagated to passage 3 on VeroE6 cells (ATCC) in Opti-MEM I (1×) + GlutaMAX (Gibco), supplemented with penicillin (10,000 IU mL⁻¹, Lonza) and streptomycin (10,000 IU mL⁻¹, Lonza) at 37 °C in a humidified CO₂ incubator. VeroE6 cells were inoculated at an moi of 0.01. Supernatant was harvested 72 hpi, cleared by centrifugation and stored at -80 °C. The virus stock was tested mycoplasma negative and contained 3.15 × 10⁸ genome copies/ml (RdRp gene).

VeroE6 cells were maintained in Dulbecco modified Eagle medium (DMEM, Gibco) supplemented with 10% foetal calf serum (Greiner), 2 mM of L-glutamine (Gibco), 10 mM Hepes (Lonza), 1.5 mg mL⁻¹ sodium bicarbonate (NaHCO₃, Lonza), penicillin (10,000 IU/mL) and streptomycin (10,000 IU/mL) at 37 °C in a humidified CO₂ incubator. All work was performed in a Class II Biosafety Cabinet under BSL-3 conditions at the Erasmus Medical Center.

Ferret transmission experiment. All relevant ethical regulations for animal testing have been complied with. Animals were housed and experiments were performed in strict compliance with the Dutch legislation for the protection of animals used for scientific purposes (2014, implementing EU Directive 2010/63). Influenza virus, SARS-CoV-2 and Aleutian Disease Virus seronegative 6 month-old female ferrets (*Mustela putorius furo*), weighing 700–1000 g, were obtained from a commercial breeder (TripleF (USA)). Research was conducted under a project license from the Dutch competent authority (license number AVD1010020174312) and the study protocol was approved by the institutional Animal Welfare Body

(Erasmus MC permit number 17-4312-02). Animal welfare was monitored on a daily basis. Virus inoculation of ferrets was performed under anesthesia with a mixture of ketamine/medetomidine (10 and 0.05 mg kg⁻¹, respectively) antagonized by atipamezole (0.25 mg kg⁻¹). Swabs were taken under light anesthesia using ketamine to minimize animal discomfort.

Four donor ferrets were inoculated intranasally with 6×10^5 TCID₅₀ of SARS-CoV-2 virus diluted in 500 µl of phosphate-buffered saline (PBS) (250 µl instilled dropwise in each nostril) and were housed individually in a cage. Six hpi, direct contact ferrets were placed in the same cage as the donor ferrets. One day later, indirect recipient ferrets were placed in an opposite cage separated by two steel grids, 10 cm apart, to avoid contact transmission (Supplementary Fig. S1). The air flow rate from the donor to the recipient ferret was ~100 L min⁻¹ and the temperature of the room was between 21 and 22 °C. Throat, nasal and rectal swabs were collected using dry swabs (Coban, cat. 155CS01) every other day, to prevent cross-contamination, until they were negative for SARS-CoV-2 RNA or maximum for 21 dpi/dpe by determined by real-time RT-qPCR as described below. Swabs were stored at -80 °C in transport medium (Minimum Essential Medium Eagle with Hank's BSS (Lonza), 5 g L⁻¹ lactalbumine enzymatic hydrolysate (Sigma-Aldrich), 10% glycerol (Sigma-Aldrich), 200 U ml⁻¹ of penicillin, 200 mg ml⁻¹ of streptomycin, 100 U ml⁻¹ of polymyxin B sulfate (Sigma-Aldrich), and 250 mg ml⁻¹ of gentamicin (Life Technologies)) for end-point titration in VeroE6 cells as described below. Ferrets were euthanized at 21 dpi/dpe by heart puncture under anaesthesia. Therefore, the exposure duration of direct contact and indirect recipient ferrets was 21 and 20 days respectively. Blood was collected in serum-separating tubes (Greiner) and processed according to the manufacturer's instructions. Sera were heated for 1 h at 60 °C and used for the detection of specific antibodies against SARS-CoV-2 as described below. All animal experiments were performed in class III isolators in a negatively pressurized ABSL3+ facility.

RNA isolation and RT-qPCR. RNA was isolated using an in-house developed high-throughput method in a 96-well format. Sixty µl of sample were added to 90 µl of MagNA Pure 96 External Lysis Buffer (Roche). A known concentration of phocine distemper virus (PDV) was added to the sample as internal control for the RNA extraction³⁰. The 150 µl of sample/lysis buffer was added to a well of a 96-well plate containing 50 µl of magnetic beads (AMPure XP, Beckman Coulter). After thorough mixing by pipetting up and down at least 10 times, the plate was incubated for 15 minutes (min) at room temperature. The plate was then placed on a magnetic block (DynaMag™-96 Side Skirted Magnet (ThermoFisher Scientific)) and incubated for 3 min to allow the displacement of the beads towards the side of the magnet. Supernatants were carefully removed without touching the beads and beads were washed three times for 30 seconds (sec) at room temperature with 200 µl/well of 70% ethanol. After the last wash, a 10 µl multi-channel pipet was used to remove residual ethanol. Plates were air-dried for 6 min at room temperature. Plates were removed from the magnetic block and 30 µl of PCR grade water was added to each well and mixed by pipetting up and down 10 times. Plates were incubated for 5 min at room temperature and then placed back on the magnetic block for 2 min to allow separation of the beads. Supernatants were pipetted in a new plate and RNA was kept at 4 °C. Eight µl of RNA were directly pipetted into a mix for RT-qPCR, containing 0.4 µl of primers and probe mix targeting the E gene of SARS-CoV-2 (forward primer: 5'-ACAGGTACGTTAATAGTTAATAGCGT-3'; reverse primer: 5'-ATATTGCAGCAGTACGCACACA-3'; probe: 5'-FAM-ACACTAGCCATCCTTACTGCGCTTCG-BHQ-3')³¹, 0.4 µl of primers and probe mix targeting the HA gene of PDV (forward primer: 5'-CGGGTGCCCTTTTACAAGAAC-3'; reverse primer: 5'-TTCCTTCCTCAACCTCGTCC-3'; probe: 5'-Cy5-ATGCAAGGGCCAATTCTTCCAAGTT-BHQ-3'), 4 µl of TaqMan™ Fast Virus 1-Step Master Mix (ThermoFisher Scientific) and 6.2 µl of PCR grade water. Amplification and detection was performed on an ABI7700 (ThermoFisher Scientific) using the following program: 5 min 50 °C, 20" 95 °C, [3" 95 °C, 31" 58 °C] × 45 cycles.

Virus titrations. Throat, nasal and rectal swabs were titrated in quadruplicates in VeroE6 cells. Briefly, confluent VeroE6 cells were inoculated with 10-fold serial dilutions of sample in Opti-MEM I (1×) + GlutaMAX, supplemented with penicillin (10,000 IU mL⁻¹), streptomycin (10,000 IU mL⁻¹). At one hpi, the first three dilutions were washed twice with media and fresh media was subsequently added to the whole plate. At six dpi, virus positivity was assessed by reading out cytopathic effects. Infectious virus titers (TCID₅₀/ml) were calculated from four replicates of each throat, nasal and rectal swabs and from 24 replicates of the virus stock using the Spearman-Kärber method.

Serology. Pre-sera (collected before the start of the experiment) and sera collected at 21 dpi/dpe were tested for SARS-CoV-2 antibodies using a receptor binding domain (RBD) enzyme-linked immunosorbent assay (ELISA)³². ELISA plates were coated overnight at 4 °C with 100 ng/well of in-house produced SARS-CoV-2 RBD diluted in PBS. After blocking with Blocker™ BLOTTO in TBS (Life technologies) + 0.01% of Tween-20 (Sigma-Aldrich), heat-inactivated sera (diluted 1:100) were added and incubated for 1 h at 37 °C. Bound antibodies were detected using horseradish peroxidase (HRP)-labelled goat anti-ferret IgG (1:10,000; ab112770, Abcam) and 3,3',5,5'-Tetramethylbenzidine (TMB, Life Technologies) as a substrate. The absorbance of each sample was measured at 450 nm.

Additionally, pre-sera and sera collected at 21 dpi/dpe were tested for the presence of SARS-CoV-2 neutralizing antibodies using a plaque reduction neutralization test (PRNT)³². Heat-inactivated sera were two-fold serially diluted in DMEM supplemented with NaHCO₃, HEPES buffer, penicillin, streptomycin, and 1% fetal bovine serum, starting at a dilution of 1:10 in 50 µL. Fifty µL of diluted virus suspension (400 plaque-forming units) were added and the mixture was incubated for 1 h at 37 °C. The mixtures were then placed on VeroE6 cells and incubated for 8 h. After incubation, cells were fixed with 4% formaldehyde/phosphate-buffered saline (PBS) and stained with a monoclonal mouse anti-SARS-CoV nucleocapsid antibody (1:10,000; 40143-MM05, Sino Biological), and a secondary HRP-labeled goat anti-mouse IgG1 (1:2000; 1071-05, Southern Biotech). HRP was revealed using the 3,3',5,5'-tetramethylbenzidine substrate (True Blue; Kirkegaard and Perry Laboratories) and the number of infected cells per well was assessed by using ImmunoSpot Image Analyzer (CTL Europe GmbH). The plaque reduction neutralization titer (PRNT) was determined as the reciprocal of the highest dilution resulting in a reduction of >90% of the number of infected cells. The detection limit of the assay was <20.

Whole genome sequencing using MinION. A SARS-CoV-2 specific multiplex PCR was performed as recently described³³. In short, primers for 86 overlapping amplicons spanning the entire genome were designed using primal scheme (<http://primal.zibraproject.org/>) (for primer sequences, see Supplementary Table 3). The amplicon length was set to 500 bp with 75 bp overlap between the different amplicons. The libraries were generated using the native barcode kits from Nanopore (EXP-NBD104 and EXP-NBD114 and SQK-LSK109) and sequenced on a MinION R9.4 flow cell multiplexing up to 24 samples per sequence run according to the manufacturer's instructions.

The resulting raw sequence data were demultiplexed using Porechop (<https://github.com/rrwick/Porechop>). FASTQ files were then imported to the CLC Genomics Workbench v20.0.3 (QIAGEN) for analysis. First, sequences were trimmed off 33 base pairs on both the 3' and 5' ends to remove primer sequences and also using a Phred quality score threshold of 8. The trimmed sequences were mapped to the reference sequence (GISAID ID EPI_ISL_406862) with the following default parameters (match score = 1, mismatch cost = 2, insertion cost = 3, length fraction = 0.5 and similarity fraction = 8) and consensus genomes were extracted.

Next-generation sequencing. Amplicons were generated by a SARS-CoV-2 specific multiplex PCR as described above for the whole genome sequencing. Amplicons were purified with 0.8x AMPure XP beads (Beckman Coulter) and 100 ng of DNA was converted into paired-end Illumina sequencing libraries using KAPA HyperPlus library preparation kit (Roche), following the manufacturer's recommendations, to enable subsequent sequencing of multiple libraries in a single Illumina V3 MiSeq flowcell (2×300 cycles). Multiplex Adaptors (KAPA Unique Dual-Indexed Adapters Kit (Roche)) with indexes were used. FASTQ files were then imported to the CLC Genomics Workbench v20.0.3 (QIAGEN) for analysis. First, sequences were trimmed off 33 base pairs on both the 3' and 5' ends to remove primer sequences and also using a Phred quality score threshold of 20. The trimmed sequences were mapped to the reference sequence (GISAID ID EPI_ISL_406862) with the following default parameters (match score = 1, mismatch cost = 2, insertion cost = 3, length fraction = 0.5 and similarity fraction = 8). Variants were called with the Basic Variant Detection tool. Single nucleotide polymorphisms that were present in both the forward and reverse reads with a 200x minimum coverage and a minimum variant count of 10 (5%) were called.

Reporting summary. Further information on research design is available in the Nature Research Reporting Summary linked to this article.

Data availability

All data are available from the corresponding author (S.H.) on reasonable request. Porechop, which was used to demultiplex data from the MinION and Illumina sequencing, is available on github at: <https://github.com/rrwick/Porechop>. The source data underlying Figs. 2, 3, Supplementary Figs. 2 and 3 are provided as a Source data file. The sequencing raw data were deposited in the NCBI Sequence Read Archive (SRA) under the BioProject PRJNA641813. Source data are provided with this paper.

Children's emotion inferences from masked faces: Implications for social interactions during COVID-19

Abstract

To slow the progression of COVID-19, the Centers for Disease Control (CDC) and the World Health Organization (WHO) have recommended wearing face coverings. However, very little is known about how occluding parts of the face might impact the emotion inferences that children make during social interactions. The current study recruited a racially diverse sample of school-aged (7- to 13-years) children from publicly funded after-school programs. Children made inferences from facial configurations that were not covered, wearing sunglasses to occlude the eyes, or wearing surgical masks to occlude the mouth. Children were still able to make accurate inferences about emotions, even when parts of the faces were covered. These data suggest that while there may be some challenges for children incurred by others wearing masks, in combination with other contextual cues, masks are unlikely to dramatically impair children's social interactions in their everyday lives.

Introduction

COVID-19 is one of the worst pandemics in modern history. To slow the spread of the virus, both the Centers for Disease Control and the World Health Organization have recommended wearing face coverings in public spaces. This recommendation has led to speculation and concern about the ramifications of mask wearing on emotion communication [1, 2]. Of particular concern for parents and teachers is how wearing masks might impact children's social interactions [3, 4]. While much research has documented how children infer emotions from facial configurations and how this ability predicts children's social and academic competence [5–7], uncertain is how children make these inferences when part of the face is occluded by a mask. The current study explores how children draw emotional inferences from faces partially occluded by surgical masks and, as a comparison, sunglasses.

Paper and cloth “surgical” masks cover the lower half of the face, allowing the eyes, eyebrows, and forehead to remain visible. When asked to infer emotions from stereotypical facial configurations, adults tend to look at the eyes first and more frequently than other facial features (e.g., mouth, nose) [8–10], although scan patterns vary across cultures [11, 12]. Adults

also show above-chance accuracy at inferring emotions from stereotypical facial configurations when only the eyes are visible [13–15]. (Note: Across most studies, “accuracy” refers to whether participants select the label/emotion typically associated with a particular facial configuration, such as “anger” for a face with furrowed brows and a tight mouth). Humans are particularly sensitive to eyes [16], and thus, eye musculature may convey sufficient information for adults to make reasonably accurate emotional inferences, even when masks cover the mouth and nose.

Nevertheless, focusing on the eyes alone may be insufficient for some emotion inferences [11, 17]. When facial configurations are ambiguous or subtle, adults (and children) shift their attention between the eyes and other facial features that may provide additional diagnostic information [18]. For instance, to make inferences about whether wide eyes indicate “fear” or “surprise,” adults attend to both the eyes and the mouth [19, 20]. Adults also tend to fixate on specific facial features that characterize specific emotion stereotypes, such as the mouth for happiness and the nose for disgust [8–10, 21]. Inferring emotions from these characteristic facial features (e.g., labeling a smile as “happy”) is also influenced by other parts of the face [10, 22–24]. In short, adults scan facial configurations in a holistic manner [19, 25], allowing for information to be gleaned from the mouth, nose, and other parts of the face, which are not accessible when wearing a mask.

While this research suggests how adults infer emotions when parts of the face are obscured, much less is known about how this process emerges in early childhood [7]. In the first year of life, infants shift from configural to holistic processing of faces [26, 27] and demonstrate heightened attention to eyes associated with positive affective states [28–30]. By 3-years of age, children show above-chance accuracy at inferring emotions from the eyes alone [31]. However, compared to when other parts of the face are also visible, 5- to 10-year-olds are less accurate at inferring emotions from the eyes only [32–35], although results for specific emotions have been inconsistent across studies [32, 33]. One study even found that 3- to 4-year-olds were *more accurate* at inferring happiness, sadness, and surprise from faces when the eyes were *covered* by sunglasses [35]. With respect to emotion inferences with masks, only one study has obscured the mouth (with a dark circle). Roberson et al. (2012) found that 9- to 10-year-old children and adults showed more accurate emotion inferences for uncovered faces than when the mouth was covered. However, 3- to 8-year-olds did not show these impairments. Similarly, when facial configurations are presented within a background emotion context, 12-year-olds show heightened visual attention to faces compared to 4- and 8-year-olds [18]. Thus, there may be developmental differences in children's reliance on and use of specific facial features to make emotional inferences and the impact of mask wearing on these inferences.

Current study

The current study examines how 7- to 13-year-old children draw emotional inferences from facial configurations that are partially occluded. This age range was selected because there is a shift during this time in children's use of eye information to infer others' emotions [33, 35]. Facial configurations associated with different negative emotions (i.e., sadness, anger, fear) were presented via a Random Image Structure Evolution (RISE) paradigm [36]. Facial configurations were initially presented in a highly degraded format in which children only had access to partial facial information. In a dynamic sequence, the images became less degraded at regular intervals. After each interval, children selected from an array of emotion labels to indicate their belief about how the person displaying the facial configuration was feeling. Thus, this paradigm allows for the assessment of children's emotion inferences from incomplete through

more complete facial information. This approach is more similar to daily experiences with the unfolding of others' emotions compared to a single presentation of a facial configuration at full intensity [37].

We examined how children perceived others' emotions as partial information about the face was presented, to evaluate whether masks meaningfully changed the types of inferences children made. We included sunglasses as a comparison for other types of coverings that children regularly encounter on faces in their daily lives. Together, these results shed light on how mask wearing during COVID-19 might—or might not—influence children's inferences about others' emotions and their related social interactions.

Methods

Participants

Procedures were approved by the University of Wisconsin—Madison Institutional Review Board. To test a racially diverse sample of children, participants were recruited from publicly funded after-school programs associated with the Dane County (Wisconsin) Department of Human Services. The final sample included 81 7- to 13-year-old children (37 female, $M = 9.86$ years, $SD = 1.84$ years, range = 7.06–12.98 years). Parents identified their children as Black (53%, $n = 43$), White (41%, $n = 33$), and Multi-racial (6%, $n = 5$). Three additional children participated in the study but were excluded from final analyses due to missing or corrupt data files. A power analysis confirmed that this sample size would be sufficient to detect reliable differences in a within-subjects design, assuming a medium effect size ($f = .25$) at the .05 level [36].

Stimuli

Stimuli, selected from the Matsumoto and Ekman (1988) database, were pictures of stereotypical facial configurations associated with sadness, anger, and fear posed by male and female models. These three emotions were selected given that adults tend to fixate predominantly on the eyes for these facial configurations, rather than other parts of the face (e.g., the mouth and nose, as with happiness and disgust) [8, 20]. Further, negative emotions are complex and rich in informational value [38]; yet, these emotions have received limited empirical attention in the literature on emotion perception development [39–41]. Pictures were presented in unaltered format (i.e., with no covering) or digitally altered to be (a) covered with a surgical face mask that obscured the mouth and nose, or (b) covered with sunglasses that obscured the eyes and eyebrows (see Fig 1). Pictures of each emotion (sad, anger, fear) paired with each covering type (none, mask, shades) were presented twice in a random order (i.e., 18 stimuli total). Half of the presentations were on male faces and half were on female faces.

Procedure

Parents provided written consent and children provided verbal assent prior to participation. Children were tested in a modified Random Image Structure Evolution (RISE) paradigm [36]. RISE performs pairwise exchanges of pixels in an image until the target image dissolves into an unstructured random field. These exchanges are presented in reverse order such that participants begin viewing a random visual display that gradually transforms into a fully formed, clear image (see Fig 2). Importantly, the RISE protocol holds the low-level perceptual attributes of the original image (e.g., luminance, color) constant.

Children viewed these image sequences on a high-resolution touch-sensitive color monitor. Faces were initially presented in a highly degraded format. At 14 regular 3.3-s intervals, the images became less degraded and easier to discern. After each interval, children were

Fig 1. Example stimuli by covering. From top to bottom: none, mask, shades. From left to right: sad, anger, fear. The image is from a set of photographs entitled *Japanese and Caucasian Facial Expressions of Emotion (JACFEE)* by D. Matsumoto and P. Ekman, University of California, San Francisco, 1988. Copyright 1988 by D. Matsumoto and P. Ekman. Reprinted by permission.

<https://doi.org/10.1371/journal.pone.0243708.g001>

prompted to identify the emotion depicted on the face by selecting one of the following emotion labels: “happy,” “sad,” “angry,” “surprised,” “afraid,” or “disgusted.” Labels were presented in this order on the screen, and children touched a label to indicate their response. A total of 252 responses were collected for each child (i.e., 14 trials each of 18 stimuli). Responses were coded as “accurate” if the child selected the label/emotion typically associated with a particular facial configuration (i.e., “anger” for a face with furrowed brows).

Results

All analyses were conducted in *R* [42], and figures were produced using the package *ggplot2* [43]. Alpha was set at $p < .05$. The raw data and analysis code are available on OSF: doi.org/10.17605/OSF.IO/7FYX9. Children's accuracy scores were analyzed in a 3 (Emotion: sad / anger / fear) x 3 (Covering: none / mask / shades) x 14 (Trial: 1 to 14) repeated-measures ANCOVA with child Gender as a between-subjects factor and child Age as a covariate. All significant main effects and interactions are explored below.

Fig 2. Example test sequence. Anger (no covering) is pictured. The image is from a set of photographs entitled *Japanese and Caucasian Facial Expressions of Emotion (JACFEE)* by D. Matsumoto and P. Ekman, University of California, San Francisco, 1988. Copyright 1988 by D. Matsumoto and P. Ekman. Reprinted by permission.

Are children more accurate with anger, sadness, or fear?

The main effect of Emotion, $F(2, 154) = 30.46, p < .001, \eta_p^2 = .28$, showed that children were more accurate with facial configurations associated with sadness ($M = .36, SD = .48$) compared to anger ($M = .27, SD = .44, t(80) = 4.10, p < .001, d = .46, CI_{95\%} [.04, .13]$), or fear ($M = .19, SD = .39, t(80) = 7.39, p < .001, d = .82, CI_{95\%} [.12, .21]$). Children were also more accurate with facial configurations associated with anger compared to fear, $t(80) = 3.68, p < .001, d = .41, CI_{95\%} [.04, .12]$.

A similar pattern of results was seen in the Emotion x Trial interaction, $F(14, 1091) = 5.35, p < .001, \eta_p^2 = .06$, which was explored with 95% confidence intervals (estimated with bootstrapping, Fig 3). Unsurprisingly, children became more accurate with each emotion as the images became less obscured. In earlier trials, there were few differences between the stimuli. In later trials, children were more accurate with facial configurations associated with sadness compared to anger and fear, and children were more accurate with facial configurations associated with anger compared to fear.

Are children less accurate with the eyes or mouth covered?

The primary question addressed by this study is whether masks meaningfully degraded children's ability to infer others' emotions. The main effect of Covering, $F(2, 154) = 27.19, p < .001, \eta_p^2 = .26$, showed that children were more accurate when faces were uncovered ($M = .34, SD = .47$) compared to when the faces wore a mask ($M = .24, SD = .43, t(80) = 6.57, p < .001, d = .73, CI_{95\%} [.07, .13]$), or shades ($M = .24, SD = .43, t(80) = 6.24, p < .001, d = .69, CI_{95\%} [.07, .13]$). Accuracy between the faces that wore masks and shades did not differ, $t(80) = .20, p >$

Fig 3. Linear regression and means for emotion x trial and covering x trial interactions. The dotted line indicates chance responding (1/6). Confidence intervals (95%) were estimated with bootstrapping (1,000 bootstrap estimates resampled 81 times from mean participant accuracy).

<https://doi.org/10.1371/journal.pone.0243708.g003>

.25, $d = .02$, $CI_{95\%}[-.03, .03]$. A similar pattern of results was seen in the Covering x Trial interaction, $F(18, 1372) = 10.27$, $p < .001$, $\eta_p^2 = .12$, which was also explored with 95% confidence intervals (estimated with bootstrapping, Fig 3). Yet, the overall effect of face coverings on accuracy was relatively small, especially as children gained more visual information.

How do different coverings impact children's inferences for specific emotions?

To explore the Emotion x Covering interaction, $F(4, 284) = 3.58$, $p = .009$, $\eta_p^2 = .04$, paired t -tests were conducted between each covering type, separated by emotion (Fig 4). Further, to examine if children's performance was greater than chance ($m = 1/6$) for each emotion-covering pair, additional one-sample t -tests were conducted. Bonferroni-holm corrections were applied for multiple comparisons (reported p -values are corrected).

For facial configurations associated with sadness, children were less accurate when the faces wore masks ($M = .28$, $SD = .45$) compared to when the faces had no covering ($M = .43$, $SD = .49$), $t(80) = 4.60$, $p < .001$, $d = .51$, $CI_{95\%} [.08, .21]$. Children's accuracy did not differ when the faces wore shades ($M = .37$, $SD = .48$) compared to when the faces had no covering, $t(80) = 1.91$, $p = .12$, $d = .21$, $CI_{95\%} [.00, .12]$, or wore masks $t(80) = 2.47$, $p = .063$, $d = .27$, $CI_{95\%} [.02, .16]$. Children responded with above-chance accuracy for all coverings: none, $t(80) = 10.30$, $p < .001$, $d = 1.14$, $CI_{95\%} [.38, .47]$; mask, $t(80) = 4.77$, $p < .001$, $d = .53$, $CI_{95\%} [.23, .33]$, shades, $t(80) = 7.23$, $p < .001$, $d = .80$, $CI_{95\%} [.31, .42]$.

For facial configurations associated with anger, children were less accurate when the faces wore masks ($M = .27$, $SD = .44$) compared to when the faces had no covering ($M = .34$, $SD = .48$), $t(80) = 2.72$, $p = .041$, $d = .30$, $CI_{95\%} [.02, .13]$. Children were also less accurate when the faces wore shades ($M = .20$, $SD = .40$) compared to when the faces had no covering, $t(80) = 5.01$, $p < .001$, $d = .56$, $CI_{95\%} [.09, .20]$. Children's accuracy when the faces wore masks or shades did not differ, $t(80) = 2.16$, $p = .10$, $d = .24$, $CI_{95\%} [.01, .13]$. Children only responded

Fig 4. Boxplots for the emotion x covering interaction. * indicates comparisons between covering types for each emotion (* $p < .05$, *** $p < .001$, + $p < .10$, NS = not significant with Bonferroni-Holm corrections). The dotted line indicates chance responding (1/6). Δ indicates that accuracy was significantly greater than chance ($p < .05$ with Bonferroni-Holm corrections).

<https://doi.org/10.1371/journal.pone.0243708.g004>

with above-chance accuracy when the faces had no covering, $t(80) = 7.28, p < .001, d = .81$, $CI_{95\%} [.30, .39]$, or when the faces wore masks, $t(80) = 4.50, p < .001, d = .50$, $CI_{95\%} [.22, .31]$. Children did not respond with above-chance accuracy when the faces wore shades, $t(80) = 1.77, p = .24, d = .20$, $CI_{95\%} [.16, .24]$.

For facial configurations associated with fear, children were less accurate when the faces wore masks ($M = .18, SD = .38$) compared to when the faces had no covering ($M = .25, SD = .43$), $t(80) = 2.91, p = .028, d = .32$, $CI_{95\%} [.02, .12]$. Children were also less accurate when the faces wore shades ($M = .15, SD = .35$) compared to when the faces had no covering, $t(80) = 3.96, p < .001, d = .44$, $CI_{95\%} [.05, .16]$. Children's accuracy when the faces wore masks or shades did not differ, $t(80) = 1.09, p > .25, d = .12$, $CI_{95\%} [-.02, .09]$. Children only responded with above-chance accuracy when the faces had no covering, $t(80) = 3.85, p < .001, d = .43$, $CI_{95\%} [.21, .30]$. Children did not reach above-chance accuracy when the faces wore masks, $t(80) = .50, p > .25, d = .06$, $CI_{95\%} [.13, .22]$, or shades, $t(80) = .94, p > .25, d = .10$, $CI_{95\%} [.11, .19]$.

Thus, across all emotions, children were less accurate with faces that wore a mask compared to faces that were not covered. However, children were only less accurate with faces that wore sunglasses compared to uncovered for two emotions: anger and fear. This suggests that children inferred whether the face displayed sadness from mouth shape alone, whereas the information from the eye region was necessary for forming inferences about anger and fear (see below). Ultimately, accuracy differences between the masks and shades did not significantly differ for any emotion. Thus, while both types of coverings negatively impacted children's emotion inferences, the strongest impairments were observed for facial configurations associated with fear.

What inferences did children make for each stimulus? To further investigate why children did not reach above-chance responding for the *anger-shades*, *fear-mask*, and *fear-shades* stimuli, we examined children's responses to each stimulus. As seen in Fig 5, children tended to interpret facial configurations associated with fear as "surprised." This effect was particularly pronounced when the faces were covered by a mask. Children also tended to interpret facial configurations associated with anger as "sad" when the faces were covered by shades. In contrast, children interpreted facial configurations associated with sadness as "sad," regardless of covering.

How does children's accuracy differ based on age?

The main effect of Age, $F(1, 78) = 5.85, p = .018, \eta_p^2 = .07$, showed that accuracy improved as child age increased. The Age x Trial, $F(6, 474) = 2.40, p = .027, \eta_p^2 = .03$, interaction was explored with a simple slopes analysis. This analysis revealed that older children showed enhanced performance over the course of the experiment compared to younger children (Fig 6).

How does children's accuracy differ based on gender?

Although there was not a significant main effect of Gender, $F(1, 78) = .54, p > .25, \eta_p^2 = .01$, a Gender x Emotion interaction emerged, $F(2, 154) = 3.20, p = .044, \eta_p^2 = .04$. Follow-up comparisons showed that male participants were significantly more accurate with facial configurations associated with anger ($M = .30, SD = .46$) compared to female participants ($M = .24, SD = .42$), $t(79) = 2.28, p = .025, d = .51$, $CI_{95\%} [.01, .12]$. Accuracy for facial configurations associated with sadness, $t(79) = 1.25, p = .22, d = .28$, $CI_{95\%} [-.03, .11]$, or fear, $t(79) = .53, p > .25, d = .12$, $CI_{95\%} [-.08, .05]$, did not differ based on participant gender.

Discussion

These results highlight how children's social interactions may be minimally impacted by mask wearing during the COVID-19 pandemic. Positive social interactions are predicated on the

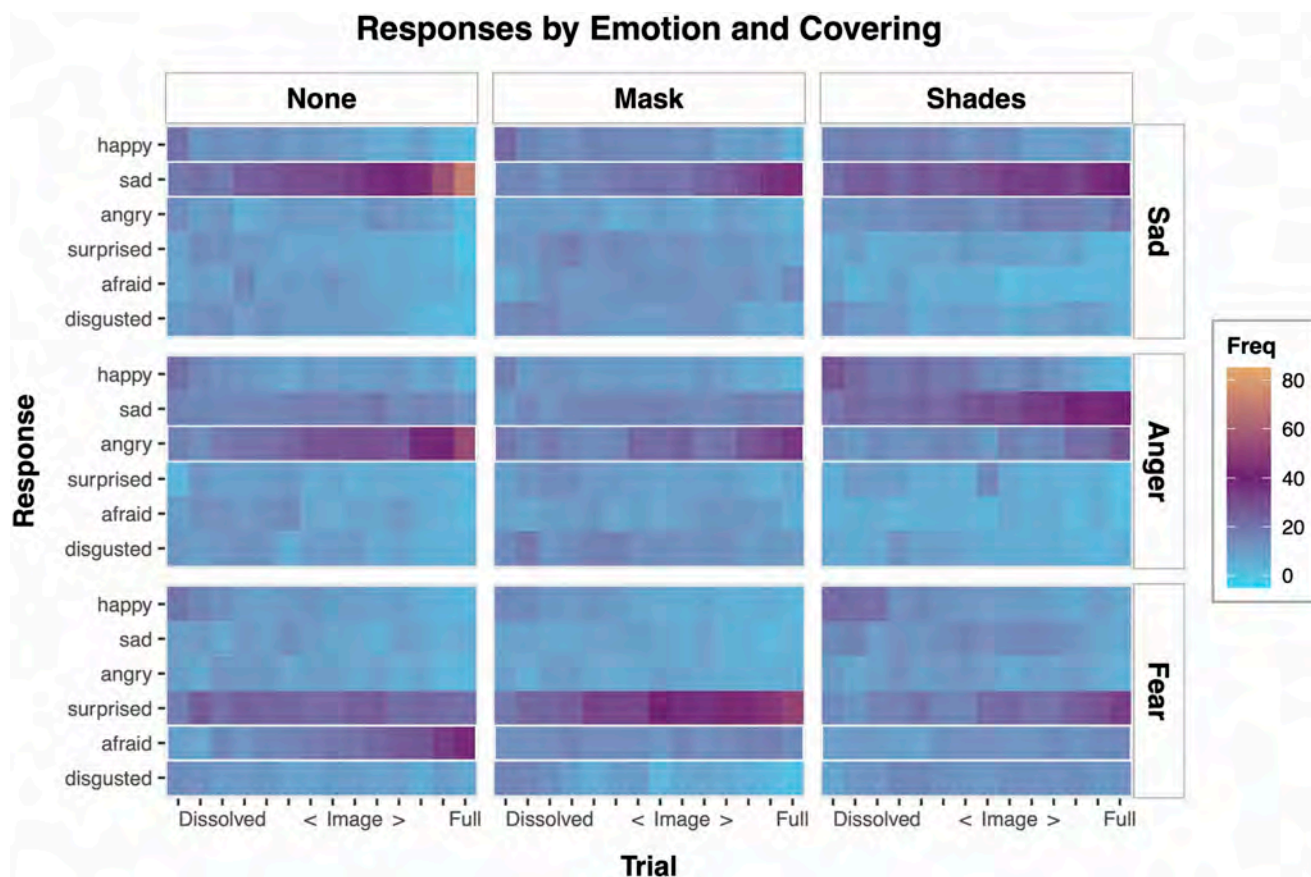

Fig 5. Average frequency of responses for each emotion and covering as a function of trial. The expected ("accurate") response for each stimulus is outlined in white.

<https://doi.org/10.1371/journal.pone.0243708.g005>

Fig 6. Simple slopes analysis for age x trial interaction. The dotted line indicates chance responding (1/6).

<https://doi.org/10.1371/journal.pone.0243708.g006>

ability to accurately infer and respond to others' emotions. In the current study, children's emotion inferences about faces that wore masks compared to when faces were not covered were still above chance. Masks seem to have the greatest effect on children's inferences about facial configurations associated with "fear," which were commonly identified as "surprised" when the mouth and nose were covered. Thus, although children may require more visual facial information to infer emotions with masks, children may reasonably infer whether someone wearing a mask is sad or angry, based on the eye region alone. In addition, children's accuracy with masked facial configurations did not significantly differ from their accuracy with facial configurations that wore sunglasses—a common accessory that children encounter in their everyday lives. Thus, it appears that masks do not negatively impact children's emotional inferences to a greater degree than sunglasses. In sum, children's ability to infer and respond to another person's emotion, and their resulting social interactions, may not be dramatically impaired by mask wearing during the COVID-19 pandemic.

Furthermore, in everyday life, it is unlikely that children draw emotional inferences from facial configurations alone. For instance, the same facial configuration may be inferred as either "anger" or "disgust" depending on background context, body posture, and facial coloration [18, 44, 45]. In addition, dynamic facial configurations and faces that are vocalizing are scanned differently than silent, static pictures of faces [46–48]. Ultimately, facial configurations displayed in everyday life are more dependent on context, less consistent, and less specific than pictures of stereotyped emotions commonly used in laboratory tasks [37]. The current paradigm improves upon these standard laboratory tasks by assessing children's emotion inferences from incomplete facial information. However, the key to children's emotional inferences is the ability to learn about and navigate the tremendous variability inherent in human emotion [7, 49]. In everyday life, children may be able to use additional contextual cues to make reasonably accurate inferences about others' variable emotional cues, even if others are wearing masks.

Future research should take these considerations into account when designing and interpreting findings on mask wearing during the COVID-19 pandemic. While the current study assessed whether children made "accurate" emotion inferences, a single facial configuration can be interpreted in many ways that are "accurate" given a particular context [37]. Researchers could explore how children make emotion inferences from a wider variety of non-stereotyped emotional cues that are presented in context. Although we did not find many age effects in the current study, future research could also explore how younger children's social interactions are impacted by mask wearing, particularly infants who are actively learning about others' emotions [50]. To conclude, while there may be some loss of emotional information due to mask wearing, children can still infer emotions from faces, and likely use many other cues to make these inferences. This suggests that children, and adults, may be able to adapt to the new reality of mask wearing to have successful interactions during this unprecedented health crisis.

Medical News & Perspectives

As Their Numbers Grow, COVID-19 “Long Haulers” Stump Experts

Rita Rubin, MA

For 32-year-old Hanna Lockman of Louisville, Kentucky, it all started March 12. She was at work when she suddenly felt a stabbing pain in her chest.

“It just got worse and worse and worse, to the point I was crying from the pain,” she recalled in a recent interview. At 3 AM, the pain sent her to the emergency department. “I had developed a dry cough, maybe a mild fever. I don’t remember.”

Five months, 16 emergency department trips, and 3 short hospitalizations later, Lockman can’t remember a lot of things. She places the blame squarely on coronavirus disease 2019 (COVID-19).

“I joke, ‘Well, COVID has eaten my brain, because I can’t remember how to remember words, keep track of medication,’” she said. “My brain just feels like there’s a fog.”

Lockman considers herself to be a “long hauler,” someone who still hasn’t fully recovered from COVID-19 weeks or even months after symptoms first arose. She serves as an administrator of 2 “Long Haul COVID Fighters” Facebook groups, whose members now number more than 8000.

The longer the pandemic drags on, the more obvious it becomes that for some patients, COVID-19 is like the unwelcome houseguest who won’t pack up and leave.

“Anecdotally, there’s no question that there are a considerable number of individuals who have a postviral syndrome that really, in many respects, can incapacitate them for weeks and weeks following so-called recovery and clearing of the virus,” Anthony Fauci, MD, director of the National Institute of Allergy and Infectious Diseases, said in July during a COVID-19 webinar organized by the International AIDS Society.

That appeared to be the case with the first severe acute respiratory syndrome (SARS), which emerged in 2002 and was also caused by a coronavirus. Some people who were hospitalized with SARS still had impaired lung function 2 years after their symptoms began, according to a prospective study of 55 patients in Hong Kong. But only 8096 people were diagnosed with SARS worldwide—a fraction of the COVID-19 cases reported each day in the US alone.

In a recent *JAMA* research letter, 125 of 143 Italian patients ranging in age from 19 to 84 years still experienced physician-confirmed COVID-19-related symptoms an average of 2 months after their first symptom emerged. All had been hospitalized, with their stays averaging about 2 weeks; 80% hadn’t received any form of ventilation.

Physicians at a Paris hospital recently reported that they saw an average of 30 long haulers every week between mid-May, when the COVID-19 lockdown ended in France, and late July. The patients’ average age was around 40 years, and women outnumbered men 4 to 1.

As with SARS, many COVID-19 long haulers are health care workers who had massive exposure to the virus early in the pandemic, neuroimmunologist Avindra Nath, MD, of the National Institute of Neurological Disorders and Stroke (NINDS), noted in a recent editorial.

Overall, approximately 10% of people who’ve had COVID-19 experience prolonged symptoms, a UK team estimated in a recently published *Practice Pointer* on postacute COVID-19 management. And yet, the authors wrote, primary care physicians have little evidence to guide their care.

Puzzling Persistence

Adults with severe illness who spend weeks in intensive care, often intubated, can experience long-lasting symptoms, but that’s not unique to patients with COVID-19. What’s unusual about the long haulers is that many initially had mild to moderate symptoms that didn’t require lengthy hospitalization—if any—let alone intensive care.

“Most of the patients that I see who are suffering from [post-COVID-19] syndrome were not hospitalized,” Jessica Dine, MD, a pulmonary specialist at the University of Pennsylvania Perelman School of Medicine, said in an interview. “They were pretty sick, but still at home.”

Why some previously healthy, often young, adults still haven’t recovered from the disease has stymied physicians.

“We in the medical field are very accustomed to taking care of respiratory syncytial virus and other pneumoviruses in young adults,” Wesley Self, MD, MPH, an emergency medicine physician at Vanderbilt University Medical Center, said in an interview. With those infections, “people feel pretty sick for 2 to 3 days, and then they feel markedly better.”

But COVID-19 is another matter, Self and his coauthors found in a recent study of 292 individuals with the disease who did not require hospitalization. “One of the goals of this particular study was to understand those with mild symptoms,” Self said. “This was an understudied group.”

More than a third of them hadn’t returned to their usual state of health 2 to 3 weeks after testing positive, the researchers wrote in the *Morbidity and Mortality Weekly Report*. The older the patients, the more likely they were to say they their pre-COVID-19 health hadn’t come back. But even a quarter of the youngest, those aged 18 to 34 years, said they had not yet regained their health.

“That certainly was a surprise to us,” Self’s coauthor and Vanderbilt colleague William Stubblefield, MD, an emergency medicine specialist, said in an interview.

Self and others say they suspect that severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection triggers long-lasting changes in the immune system. In some organs, especially the lungs, those changes persist far past the point at which patients have stopped shedding the virus, Self said. “Frankly, we don’t know how long that lasts.” To help answer that question, Self and his coauthors are conducting a follow-up study to assess

outpatients' health 6 months after their COVID-19 diagnosis.

Sorting Through Symptoms

Just as acute COVID-19 has been found to affect every part of the body, so, apparently, do its persistent symptoms.

In the study of Italian patients, the most common symptoms reported at follow-up were fatigue, shortness of breath, joint pain, and chest pain, in that order. None of the patients had a fever or other sign or symptom of acute illness, but about 44% of them had a worsened quality of life. As the authors pointed out, though, patients with community-acquired pneumonia can also have persistent symptoms, so the findings might not be exclusive to COVID-19.

Less formal surveys have also turned up wide-ranging lingering effects. When the [Body Politic COVID-19 Support Group](#) conducted an online survey in the spring, about 91% of 640 respondents said they hadn't fully recovered and were on day 40 of symptoms, on average. Most reported ongoing fatigue, chills and sweats, body aches, headaches, brain fog, and gastrointestinal issues. Anecdotally, some people have reported feeling better for days or weeks before relapsing with old or new symptoms, according to the organization, which started as a small Instagram group chat and has grown to more than 14 000 members.

Francis Collins, MD, PhD, director of the National Institutes of Health (NIH), [blogged](#) about the survey in September. "Because COVID-19 is such a new disease, little is known about what causes the persistence of symptoms, what is impeding full recovery, or how to help the long-haulers," Collins wrote, noting that the Body Politic and its international Patient-Led Research for COVID-19 group are now conducting a [second survey](#) of long haulers.

A recent [survey](#) by the grassroots group COVID-19 "[Survivor Corps](#)" found that fatigue was the most common of the top 50 symptoms experienced by the more than 1500 long haulers who responded, followed by muscle or body aches, shortness of breath or difficulty breathing, and difficulty concentrating.

Cough is the most common persistent symptom seen at the new [COVID-19 Recovery Clinic](#) (CORE) at Montefiore Medical Center in New York, codirector Aluko Hope, MD, MSCE, said in an interview. Between Hope, a pulmonary and critical care

specialist, and the clinic's other director, general internist Seth Congdon, MD, the clinic sees a wide range of patients, including some who were never hospitalized. What the CORE patients have in common is that they haven't yet returned to their pre-COVID-19 health. At least a few of them have been sick for 4 or 5 months, Hope said. Besides the persistent cough, which can also occur with other viruses, loss of taste and smell lingers for many long haulers.

Many of the clinic's patients are also still short of breath. This could be due to the deconditioning seen with any lengthy illness, Hope said, or to infection-specific conditions, such as postviral reactive airways disease, lung fibrosis, or viral myocarditis. Hope said that he's seen at least one patient with no history of heart disease who developed postviral heart failure.

Dine first noticed that some patients weren't getting better through Penn's [COVID Watch](#) outreach program, which texts those who are home sick with the disease twice a day until they've been symptom-free for a week to 10 days. She now sees so many people with persistent issues that she's developed a flowchart to try to narrow down the reasons for their ill health: Is this a new symptom unrelated to COVID-19? Is it a complication of the disease, like a blood clot? Or is it a side effect of treatment? If she rules those out, she said there are just 2 options left: Either the patient is still infected with SARS-CoV-2 or they have postviral syndrome.

When the Fog Doesn't Lift

Lockman and many other long haulers describe their most debilitating persistent symptom as impaired memory and concentration, often with extreme fatigue.

The effects are different from the cognitive impairment patients might experience after a critical illness, according to Hope. When it comes to COVID-19, "I do think there's a subset of patients [who] weren't even in the hospital who have a post-viral brain fog," he said.

At the end of May, Lockman took a 6-week leave of absence from her job at a human resources management company. Since that ended, she has been working part-time—4 hours on a good day. She moved her home office to her living room so she can rest on the couch. After a recent trip to the emergency department, she was so exhausted that she slept all but 3 hours the next day.

An intriguing idea is taking shape. During the July webinar, Fauci noted that some long haulers' symptoms like brain fog and fatigue are "highly suggestive" of [myalgic encephalomyelitis/chronic fatigue syndrome](#) (ME/CFS).

New York-based psychiatrist Mady Hornig, MD, a member of Columbia University Medical Center's epidemiology faculty, has long studied the role of microbial, immune, and toxic factors in the development of brain conditions such as ME/CFS, whose etiology and pathogenesis are unknown. Now she's looking at these relationships not only as a physician and scientist but also as a long hauler.

Hornig wrote off a throat tickle and cough in March as allergies. And she assumed that walking around her home shoeless caused the chilblains that later developed on her toes. It wasn't until a 4 AM fever awoke her on April 24 that she suspected she had contracted COVID-19. Although she takes 650 mg of aspirin daily for another condition, the fever persisted for 12 days, a longer stretch than any she had experienced since she had her tonsils removed at age 14, nearly 50 years ago.

Despite all the indicators, Hornig's April 27 nasal swab test was negative for SARS-CoV-2. That's likely because it was performed either [too soon or too late](#)—depending on whether the late April fever or the earlier cough or "COVID toes" were the first sign.

Her doctors told her they didn't have a better explanation than COVID-19 for her symptoms, which have also included oxygen saturation levels as low as 88% and 8- to 10-minute tachycardia episodes that still send her heart rate to 115 to 135 beats per minute at least once a day and leave her breathless, even if she's sitting down. Before COVID-19, Hornig was used to working 12- to 14-hour days. For weeks after becoming ill, tachycardia would leave her so fatigued that "I felt like I could not do anything further—my brain was just empty," she said in an interview.

About 3 out of 4 people diagnosed with ME/CFS report that it began with what appeared to be an infection, often infectious mononucleosis caused by [Epstein-Barr virus](#) (EBV), Hornig noted. One ME/CFS [International Classification of Diseases diagnosis code](#) even calls the condition "post-viral fatigue syndrome." Although EBV is a herpesvirus, not a coronavirus, Hornig speculated

that SARS-CoV-2 infection might reactivate latent EBV, triggering the fatigue.

To explore the idea, she has designed prospective studies with the Solve ME/CFS Initiative. The nonprofit in July launched a [registry](#) and biobank, funded in part by the NIH, to collect data from COVID-19 long haulers, as well as people diagnosed with ME/CFS and healthy controls.

"Because of the large number of COVID-19 cases occurring simultaneously, we have a unique scientific window and a huge responsibility to investigate any long-term consequences and disabilities that COVID-19 survivors may face," Hornig said in a [statement](#) announcing the registry and biobank. "Doing so will provide clues and potential treatment candidates for the millions of Americans already diagnosed with ME/CFS."

Hornig and other scientists point to autonomic nervous system dysregulation as the possible explanation for long-haulers' tachycardia, extreme fatigue, and other persistent symptoms. The system controls involuntary physiologic processes such as heart rate, blood pressure, respiration, and digestion.

Stanford University neurologist Mitchell Miglis, MD, who specializes in autonomic nervous system disorders such as postural orthostatic tachycardia syndrome (POTS), recently coauthored a [case report](#) about a previously healthy, 26-year-old emergency department nurse who developed classic POTS symptoms—fatigue, tachycardia—that hadn't resolved 5.5 months after she was diagnosed with COVID-19 in March.

"One of the most common symptoms of POTS is brain fog," Miglis noted. "It's not clearly related to blood flow to the brain. It's something else."

With Lauren Stiles, JD, president of [Dysautonomia International](#) and research assistant professor of neurology at Stony Brook University School of Medicine, Miglis has developed an online survey that is being shared with COVID-19 survivor social media groups to gather more infor-

mation about autonomic symptoms. He plans to resurvey respondents every 3 months for the next year to see how they progress. Miglis speculated that POTS, ME/CFS, and persistent COVID-19 may be different names for the same disorder, and patients' diagnoses depend on their physicians' subspecialty.

Nath, chief of the Section of Infections of the Nervous System at NINDS, is planning a prospective study of persistent ME/CFS-type symptoms among people who've had COVID-19. "I think we need to assure the public that we are aware of the syndrome," he said in an interview. "We're very keen to understand what it's about."

"Medical Gaslighting"

Many long haulers never had laboratory confirmation of COVID-19, which, they say, adds to some health care professionals' skepticism that their persistent symptoms have a physiological basis.

Only about a quarter of the Body Politic survey's respondents had tested positive for COVID-19, while nearly half were never tested—often because their request was denied. But everyone's answers were included in the analysis. The main difference between those who received a positive or negative result was how early in their illness they were tested. "We believe future research must consider the experiences of all people with COVID-19 symptoms, regardless of testing status, in order to better understand the virus and underscore the importance of early and widespread testing," the report's authors wrote.

Lockman was not one of the survey respondents, but she exemplifies the Body Politic's point. At her first trip to the emergency department, she was diagnosed with pneumonia and admitted to the hospital, where she received supplemental oxygen and intravenous antibiotics for 3 days. She suspected it was COVID-19 from the beginning. But she was told she wasn't sick enough or old enough to get one of the then-scarce tests for SARS-CoV-2.

Three weeks after her symptoms began, and after testing negative for influenza and respiratory syncytial virus, Lockman was finally given a SARS-CoV-2 nasal swab test. She tested negative, likely because she had low virus levels by then, she said. In June, she was hospitalized again, this time with pulmonary emboli. A physician who reviewed her chart said she had no doubt that COVID-19 explained her symptoms.

Body Politic has acknowledged that its survey sample wasn't representative of all people with COVID-19. But the organization expressed hope that the findings would inform public health professionals and future research. Toward that end, the founders of the Long Haul COVID Fighters recently launched a [Medical and Scientific Collaboration](#) group on Facebook, giving patients and researchers a place to exchange information.

One thing that's clear, Miglis said, is that "these mystery diagnoses are real, and they're not just in patients' heads."

Long haulers say they aren't always taken seriously, though, especially if they're women, harkening back to the era when "female troubles" were written off as hysteria.

"There is definitely gender bias," Dine said. Women with persistent symptoms are more likely than men to be viewed as "dramatic and anxious," she said. "One of the first steps is believing them and making them feel heard. That alone helps."

"We've experienced so much medical gaslighting, basically doctors telling us, 'That's not what you have. It's just anxiety,'" Lockman said. Despite her frustrations, she remains hopeful that her health will continue to improve, although she recognizes that there likely will be bumps along the way.

"I definitely feel better than I did a month ago," she said in early August. "But I still wake up not knowing what I'm going to deal with today." ■

Resurgence of COVID-19 in Manaus, Brazil, despite high seroprevalence

Published Online
January 27, 2021
[https://doi.org/10.1016/S0140-6736\(21\)00183-5](https://doi.org/10.1016/S0140-6736(21)00183-5)

After initially containing severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), many European and Asian countries had a resurgence of COVID-19 consistent with a large proportion of the population remaining susceptible to the virus after the first epidemic wave.¹ By contrast, in Manaus, Brazil, a study of blood donors indicated that 76% (95% CI 67–98) of the population had been infected with SARS-CoV-2 by October, 2020.² High attack rates of SARS-CoV-2 were also estimated in population-based samples from other locations in the Amazon Basin—eg, Iquitos, Peru 70% (67–73).³ The estimated SARS-CoV-2 attack rate in Manaus would be above the theoretical herd immunity threshold (67%), given a basic case reproduction number (R_0) of 3.⁴

In this context, the abrupt increase in the number of COVID-19 hospital admissions in Manaus during January, 2021 (3431 in Jan 1–19, 2021, vs 552 in Dec 1–19, 2020) is unexpected and of concern (figure).^{5–10} After a large epidemic that peaked in late April, 2020,

COVID-19 hospitalisations in Manaus remained stable and fairly low for 7 months from May to November, despite the relaxation of COVID-19 control measures during that period (figure).

There are at least four non-mutually exclusive possible explanations for the resurgence of COVID-19 in Manaus. First, the SARS-CoV-2 attack rate could have been overestimated during the first wave, and the population remained below the herd immunity threshold until the beginning of December, 2020. In this scenario, the resurgence could be explained by greater mixing of infected and susceptible individuals during December. The 76% estimate of past infection² might have been biased upwards due to adjustments to the observed 52.5% (95% CI 47.6–57.5) seroprevalence in June, 2020, to account for antibody waning. However, even this lower bound should confer important population immunity to avoid a larger outbreak. Furthermore, comparisons of blood donors with census data showed no major

difference in a range of demographic variables,² and the mandatory exclusion of donors with symptoms of COVID-19 is expected to underestimate the true population exposure to the virus. Reanalysis and model comparison¹¹ by independent groups will help inform the best-fitting models for antibody waning and the representativeness of blood donors.

Second, immunity against infection might have already begun to wane by December, 2020, because of a general decrease in immune protection against SARS-CoV-2 after a first exposure. Waning of anti-nucleocapsid IgG antibody titres observed in blood donors² might reflect a loss of immune protection, although immunity to SARS-CoV-2 depends on a combination of B-cell and T-cell responses.¹² A study of UK health-care workers¹³ showed that reinfection with SARS-CoV-2 is uncommon up to 6 months after the primary infection. However, most of the SARS-CoV-2 infections in Manaus occurred 7–8 months before the resurgence in January, 2021; this is longer than the period covered by the UK study,¹³ but nonetheless suggests that waning immunity alone is unlikely to fully explain the recent resurgence. Moreover, population mobility in Manaus decreased from mid-November, 2020, with a sharp reduction in late December, 2020,¹⁴ suggesting that behavioural change does not account for the resurgence of hospitalisations.

Third, SARS-CoV-2 lineages might evade immunity generated in response to previous infection.¹⁵ Three recently detected SARS-CoV-2 lineages (B.1.1.7, B.1.351, and P.1), are unusually divergent and each possesses a unique constellation of mutations of potential biological importance.^{16–18} Of these, two are circulating in Brazil (B.1.1.7 and P.1) and one (P.1) was detected in Manaus on Jan 12, 2021.¹⁶ One case of SARS-CoV-2 reinfection has been associated with the P.1 lineage in Manaus¹⁹ that accrued ten unique spike protein mutations, including E484K and N501K.¹⁶ Moreover, the newly classified P.2 lineage (sublineage of B.1.128 that independently accrued the spike E484K mutation) has now been detected in several locations in Brazil, including Manaus.²⁰ P.2 variants with the E484K mutation have been detected in two people who have been reinfected with SARS-CoV-2 in Brazil,^{21,22} and there is in-vitro evidence that the presence of the E484K mutation reduces neutralisation by polyclonal antibodies in convalescent sera.¹⁵

Figure: COVID-19 hospitalisations, excess deaths, and R_t in Manaus, Brazil, 2020–21

(A) Dark lines are the 7-day rolling averages and lighter lines are the daily time series of COVID-19 hospitalisations and excess deaths. Hospitalisation data are from the Fundação de Vigilância em Saúde do Amazonas.⁵ Total all-cause deaths for 2020–21 were reported initially by the Prefeitura de Manaus⁶ and subsequently in the daily COVID-19 bulletin of the Fundação de Vigilância em Saúde do Amazonas.⁷ All-cause deaths from 2019 were from Arpen/AM (Associação dos Registradores Cíveis das Pessoas Naturais do Amazonas).⁸ The compiled excess death data are from Bruce Nelson from the Instituto Nacional de Pesquisas da Amazônia.⁹ (B) R_t was calculated using the time series of COVID-19 hospitalisations after removal of the past 14 days to account for delays in notification. R_t was calculated using the EpiFilter method.¹⁰ Lines are median R_t estimates; shaded areas are the 95% CIs. R_t =Effective reproduction number. SARS-CoV-2=severe acute respiratory syndrome coronavirus 2.

Fourth, SARS-CoV-2 lineages circulating in the second wave might have higher inherent transmissibility than pre-existing lineages circulating in Manaus. The P.1 lineage was first discovered in Manaus.¹⁶ In a preliminary study, this lineage reached a high frequency (42%, 13 of 31) among genome samples obtained from COVID-19 cases in December, 2020, but was absent in 26 samples collected in Manaus between March and November, 2020.¹⁶ Thus far, little is known about the transmissibility of the P.1 lineage, but it shares several independently acquired mutations with the B.1.1.7 (N501Y) and the B.1.325 (K417N/T, E484K, N501Y) lineages circulating in the UK and South Africa, which seem to have increased transmissibility.¹⁸ Contact tracing and outbreak investigation data are needed to better understand relative transmissibility of this lineage.

The new SARS-CoV-2 lineages may drive a resurgence of cases in the places where they circulate if they have increased transmissibility compared with pre-existing circulating lineages and if they are

associated with antigenic escape. For this reason, the genetic, immunological, clinical, and epidemiological characteristics of these SARS-CoV-2 variants need to be quickly investigated. Conversely, if resurgence in Manaus is due to waning of protective immunity, then similar resurgence scenarios should be expected in other locations. Sustained serological and genomic surveillance in Manaus and elsewhere is a priority, with simultaneous monitoring for SARS-CoV-2 reinfections and implementation of non-pharmaceutical interventions. Determining the efficacy of existing COVID-19 vaccines against variants in the P.1 lineage and other lineages with potential immune escape variants is also crucial. Genotyping viruses from COVID-19 patients who were not protected by vaccination in clinical trials would help us to understand if there are lineage-specific frequencies underlying reinfection. The protocols and findings of such studies should be coordinated and rapidly shared wherever such variants emerge and spread.

Since rapid data sharing is the basis for the development and implementation of actionable disease control measures during public health emergencies, we are openly sharing in real-time monthly curated serosurvey data from blood donors through the Brazil-UK Centre for Arbovirus Discovery, Diagnosis, Genomics and Epidemiology (CADDE) Centre GitHub website and will continue to share genetic sequence data and results from Manaus through openly accessible data platforms such as GISAID and Virological.

Long COVID guidelines need to reflect lived experience

Since May, 2020,¹ increasing attention has been given to the experiences of people with COVID-19 whose symptoms persist for 4 or more weeks. According to the Office for National Statistics (ONS), an estimated 186 000 people (95% CI 153 000–221 000) in private households in England currently have COVID-19 symptoms 5–12 weeks or longer after acute infection.² The ONS estimate that one in five people have symptoms that persist after 5 weeks, and one in ten have symptoms for 12 weeks or longer after acute COVID-19 infection.² Research on long COVID is growing, including into the underlying pathology, consequences, and sequelae, as well as rehabilitation for patients. Evidence suggests that a considerable proportion of people with long COVID have severe complications.^{3–5}

We have lived experiences of long COVID, with a range of symptoms lasting for more than 6 months. Staff in the UK National Health Service (NHS) have been variously supportive or disbelieving of our ongoing, often worsening, symptoms. Before our illness we were fit, healthy, and working in demanding roles, including as doctors, nurses, and other health professionals. Our symptoms of acute COVID-19 included dyspnoea, dry cough, fever, anosmia, and debilitating fatigue. Throughout 2020 we also experienced other symptoms and conditions, never experienced before our acute illnesses (panel). All of these conditions began during, or shortly after, acute COVID-19. We each are experiencing different patterns and varied severity of symptoms; we all share difficulties accessing adequate health-care services; some of us have received misguided assessment and treatment in some of the UK's recently established long COVID clinics and encountered dismissive behaviour from some health professionals.^{6–8} We share these experiences with thousands of people we engage with in rapidly growing online support groups.

We were encouraged by the announcement, on Oct 5, 2020, that the National Institute for Health and Care Excellence (NICE), the Scottish Intercollegiate Guidelines Network (SIGN), and the Royal College of General Practitioners (RCGP) were developing “a guideline on persistent effects of COVID-19 (long COVID) on patients”,⁹ consulting with a broad range of professional groups and some people with long COVID.

The final NICE–SIGN–RCGP guideline, published on Dec 18, 2020,¹⁰ should provide clear information on what is and is not known about the natural history of long COVID, provide guidance for health-care workers to identify cases, and inform clinical practice for the correct management of people with symptoms. Accurate assessment, diagnosis, treatment, and rehabilitation are especially important given the increasing evidence of organ pathology

Keywords: SARS-CoV-2, COVID-19, intra-host variant, microbiota, transmission

Summary

An elevated level of viral diversity was found in some SARS-CoV-2 infected patients, indicating the risk of rapid evolution of the virus. Although no evidence for the transmission of intra-host variants was found, the risk should not be overlooked.

Abstract:

Background A novel coronavirus (SARS-CoV-2) has infected more than 75,000 individuals and spread to over 20 countries. It is still unclear how fast the virus evolved and how the virus interacts with other microorganisms in the lung.

Methods We have conducted metatranscriptome sequencing for the bronchoalveolar lavage fluid of eight SARS-CoV-2 patients, 25 community-acquired pneumonia (CAP) patients, and 20 healthy controls.

Results The median number of intra-host variants was 1-4 in SARS-CoV-2 infected patients, which ranged between 0 and 51 in different samples. The distribution of variants on genes was similar to those observed in the population data (110 sequences). However, very few intra-host variants were observed in the population as polymorphism, implying either a bottleneck or purifying selection involved in the transmission of the virus, or a consequence of the limited diversity represented in the current polymorphism data. Although current evidence did not support the transmission of intra-host variants in a person-to-person spread, the risk should not be overlooked. The microbiota in SARS-CoV-2 infected patients was similar to those in CAP, either dominated by the pathogens or with elevated levels of oral and upper respiratory commensal bacteria.

Conclusion SARS-CoV-2 evolves *in vivo* after infection, which may affect its virulence, infectivity, and transmissibility. Although how the intra-host variant spreads in the population is still elusive, it is necessary to strengthen the surveillance of the viral

evolution in the population and associated clinical changes.

Abbreviations: COVID-19: Coronavirus disease 2019; CAP: Community-acquired pneumonia; SARS: Severe acute respiratory syndrome; CoV: Coronavirus; Healthy: Healthy controls; BALF: Bronchoalveolar lavage fluid; nCoV: COVID-19 patients; NC: Negative controls.

Introduction

Since the outbreak of a novel coronavirus (SARS-CoV-2) in Wuhan, China, the virus had spread to more than 20 countries, resulting in over 75,000 cases and more than 2,300 deaths (Until Feb 22, 2020) [1, 2]. The basic reproduction number was estimated to range from 2.2 to 3.5 at the early stage[3], making it a severe threat to public health. Recent studies have identified bat as the possible origin of SARS-CoV-2, and the virus likely uses the same cell surface receptor as SARS-CoV [4], namely ACE2. These studies have advanced our understanding of SARS-CoV-2. However, our knowledge of the novel virus is still limited.

The virus undergoes a strong immunologic pressure in humans, and may thus accumulate mutations to outmaneuver the immune system [5]. These mutations could result in changes in viral virulence, infectivity, and transmissibility [6]. Therefore, it is imperative to investigate the pattern and frequency of mutations occurred. Aside from the pathogen, microbiota in the lung is associated with disease susceptibility and severity [7]. Alterations of lung microbiota could potentially modify immune response against the viral and secondary bacterial infection [8, 9]. Thus, understanding the microbiota, which comprises bacteria that could cause secondary infection or exert effects on the mucosal immune system, might help to predict the outcome and reduce complications.

In our study, we conducted metatranscriptome sequencing on bronchoalveolar lavage fluid (BALF) samples from 8 subjects with Coronavirus disease 2019 (COVID-19, the disease caused by SARS-CoV-2) patients. We found that the number of intra-

host variants ranged from 0 to 51 with a median number of 4, suggesting a high evolution rate of the virus. By investigating a person-to-person spread event, we found no evidence for the transmission of intra-host variants. Meanwhile, we found no specific microbiota alteration in the BALF of COVID-19 patients comparing to CAP patients with other suspected viral causes.

Results

Data summary

By metatranscriptome sequencing, more than 20 million reads were generated for each BALF of COVID-19 patients (nCoV) as well as a negative control (nuclease-free water, NC). For comparison, the metatranscriptome sequencing data with similar number of reads from 25 virus-like community-acquired pneumonia patients (CAP, determined by at least 100 viral reads and 10-fold higher than those in the NC), 20 healthy controls without any known pulmonary diseases (Healthy), and two extra NCs (two saline solutions passing through the bronchoscope) were used in this study. Demographic and clinical information was collected and summarized in Supplementary Table 1.

After quality control, a median number of 55,571 microbial reads were generated for each sample. nCoV had the highest proportion of microbial reads compared to CAP and Healthy (nCov: median proportion of 7%, CAP: 0.8%, Healthy:0.1%, $p < 0.001$, Figure 1A), and 49% of the microbial reads could be mapped to SARS-CoV-2, which was not different from the viral proportion in CAP (Figure 1B). Only SARS-CoV-2 was identified in nCoV, and no read was mapped to other species belonging to

Betacoronavirus. Moreover, besides the detection of HCoV-OC43 in one Healthy and HCoV-NL63 in a CAP, no other samples showed any signal of *Betacoronavirus*, which proved the authenticity of the data and methods used in our analysis.

Intra-host variants in the genome of SARS-CoV-2

The sequencing depth of SARS-CoV-2 ranged from 18-fold in nCoV-5 to 32,291-fold in nCoV1, with more than 80% of the genome covered by at least 50-fold in five samples (Figure 2A, Supplementary Table 2). In total, 84 intra-host variants were identified with minor allele frequency (MAF) greater than 5%, and 25 variants were with MAF greater than 20% (Supplementary Table 3, Figure 2B, nCoV5 was excluded from the analysis due to large gaps on its genome coverage). Notably, the number of variants was not associated with the sequencing depth (Supplementary Figure 1). The overall Ka/Ks ratio was significantly smaller than 1, which was similar for intra-host variants and the polymorphisms observed in the population data, suggesting a purifying selection acting on both types of mutations (Table 1). The numbers of variants observed in the gene were proportional to gene lengths ($\text{cor} = 0.950$, $p = 8\text{E-}06$ for the intra-host variant; $\text{cor} = 0.957$, $p = 4\text{E-}06$ for the polymorphisms). Although only a small fraction of the variants was observed in multiple patients (2 out of 84, Figure 2C), some positions were more prone to mutate or variants were transmitting in the population, such as position 10779, where the mutant allele A was observed in all seven patients, with the frequency ranging from 15% to 100% (Figure 2D).

The number of intra-host variants per individual showed a large variation (0 to 51, median 4 for variants with $\text{MAF} \geq 5\%$; 0 to 19, median 1 for variants with $\text{MAF} \geq 20\%$),

which could not be explained by the batch effect, coverage variance, or contamination (Supplementary Figure 1; nCoV1-4 were in one batch, nCoV5-8 were in another batch; most mutations were not observed in the population data). We also noted that the number of variations was not relevant to the days after symptom onset or the age of patients (Supplementary Figure 2). Collectively, we did not find any reason for the extremely high level of variants in nCoV6 (51 variants). A larger population size is needed to investigate how frequent such outliers are, and whether they are associated with the level of host immune response or the viral replication rate. We also noted similar outliers for other viruses [11]. Of note, the origin of variants could be either mutation occurred *in vivo* after infection or multiple transmitted SARS-CoV-2 strains.

No evidence for transmission of intra-host variants between samples

Among the eight COVID-19 patients, nCoV4 and nCoV7 were from the same household, with dates of symptom onset differing by five days; thus a transmission from nCoV4 to nCoV7 is highly suspected, especially considering that only nCoV4 had been to the Huanan seafood market in Wuhan, which is the starting point of the outbreak and suspected to be the source. First, the consensus sequence of the virus was the same for two samples, and all four intra-host variants passing the selection criteria in nCoV4 were not detected in nCoV7 (Table 2). We further expanded the investigation to all variants with $\text{MAF} \geq 2\%$ and supported by at least 3 reads. By doing so, we detected seven variants (out of 25) shared between the two samples. However, the MAF in both nCoV4 and nCoV7 were similar to those in other samples, suggesting that these positions were either error-prone or mutation-prone; hence they cannot support the

transmission of these variants.

Meanwhile, among all 84 intra-host variants, only three of them were found to be polymorphic in the population data (position 7866 G/T; 27493 C/T; 28253 C/T). This small number of overlap also suggests that intra-host variants were rarely transmitted to other samples. However, we cannot rule out the possibility that the sequence diversity in the population is underestimated by the current database.

Missing microbiota signature associated with SARS-CoV-2 infection

Metatranscriptome data also enabled us to profile the transcriptionally active microbiota in different types of pneumonia, which is associated with the immunity response in the lung [12, 13]. In general, a significant difference in microbiota composition was observed among the nCoV, CAP, and Healthy groups ($R^2 = 0.07$, $p = 0.001$; Figure 3A). However, the clustering of some samples with NC indicated a barren microbiota in some samples. After removing the problematic samples and ambiguous components, we still found that nCoV and CAP were both different from the healthy controls (nCoV *vs.* Healthy: $R^2 = 0.45$, $p = 0.001$; CAP *vs.* Healthy: $R^2 = 0.10$, $p = 0.002$), implying a dysbiosis occurred in their lung microbiota. Microbiota could be classified into three different types (Figure 3B). In particular, the microbiota in cluster I was dominated by the possible pathogens, whereas the microorganisms in other clusters were more diverse. By further inspecting the species belonging to each cluster (Supplementary Table 4-5), we found that bacteria in Type III were mainly commensal species frequently observed in the oral and respiratory tract, whereas bacteria in Type II were mostly environmental organisms, thereby contamination was highly suspected.

Therefore, the microbiota was either pathogen-enriched (Type I) or commensal-enriched (Type III) or undetermined due to low microbial load (Type II).

The microbiota in six nCoV samples were pathogen-enriched, and the other two were commensal-enriched (Figure 3B). Moreover, two nCoV samples (2, 6) with an excess number of intra-host SARS-CoV-2 variants both possessed the pathogen-enriched microbiota. The overwhelming proportion of the virus may associate with a higher replication rate, and could also potentially stimulate the intense immune response against the virus, under which circumstance, an excess number of intra-host mutations would be expected. However, as only eight nCoV patients were included in this analysis, and the absolute microbial load was unknown, more data is needed for further investigation.

Discussion

RNA viruses have a high mutation rate due to the lack of proofreading activity of polymerases. Consequently, RNA viruses are prone to evolve resistance to drugs and escape from immune surveillance. The mutation rate of SARS-CoV-2 is still unclear. However, considering that the median number of pairwise sequence differences was 4 (Interquartile Range: 3-6) for 110 sequences collected between Dec 24, 2019 and Feb 9, 2020, the mutation rate should be at the same order of magnitude in SARS-CoV ($0.80\text{-}2.38\times 10^{-3}$ nucleotide substitution per site per year)[14]. The high mutation rate also results in a high level of intra-host variants in RNA viruses [11, 15]. The median number of intra-host variant in COVID-19 patients was 4 for variant with frequency $\geq 5\%$, and this incidence was not significantly different from that reported in a study on

Ebola (655 variants with frequency $\geq 5\%$ in 134 samples) ($p > 0.05$) [11], suggesting that the mutation rate of SARS-CoV-2 was also comparable to Ebola virus. An exoribonuclease (ExoN) has been proposed to provide proofreading activity in SARS-CoV [16, 17], and we noted that all three key motifs in the gene were identical between SARS-CoV and SARS-CoV-2 (Supplementary Figure 3). In addition, neither polymorphism nor intra-host variant was detected in these motifs, suggesting that the gene is highly conserved, and thereby it could be a potential target for antiviral therapy. Although we did not find any mutation hotspot genes in either polymorphism or intra-host variants, the observation of shared intra-host variants among different individuals implied the possibility of adaptive evolution of the virus in patients, which could potentially affect the antigenicity, virulence, and infectivity of the virus [6].

It is worth noting that the SARS-CoV-2 genome in patients could be highly diverse, which was also observed in other viruses [11]. The high diversity could potentially increase the fitness of the viral population, making it hard to be eliminated [15]. Further studies are needed to explore how this may influence the immune response towards the virus and whether there is a selection acting on different strains in the human body or during the transmission. In a single transmission event investigated in this study, we found no evidence for the transmission of multiple strains. However, it is unclear whether these intra-host variants occurred before the transmission or after the transmission, which would result in different conclusions. Additionally, a bottleneck may be involved in the transmission, which could also result in the loss of diversity [18]. Nevertheless, the observation of high mutation burden in some patients

emphasized the possibility of rapid-evolving of this virus.

Recent studies have shown that the microbiota in the lung contributed to the immunological homeostasis and potentially altered the susceptibility to viral infection. Meanwhile, the lung microbiota could also be regulated by invading viruses [9, 19]. However, besides the feature that the microbial diversity was significantly lower in pneumonia than that in healthy controls (Figure 3B), we did not identify any specific microbiota pattern shared among COVID-19 patients, neither for CAP patients. A possible reason for this could be the use of antibiotics in pneumonia patients. However, this was not true for all pneumonia samples, as a substantial proportion of bacteria were observed in some samples, including two COVID-19 patients. It is well known that a common complication of viral infection, especially for respiratory viruses, secondary bacterial infection often results in a significant increase in morbidity [20]. Thus, the elevated level of bacteria in the BALF of some COVID-19 patients might increase the risk of secondary infection. In the clinical data, the secondary infection rate for COVID-19 was between 1%-10% [2, 21]. However, the quantitative relationship between bacterial relative abundance/titer and infection is unclear.

Overall, our study has revealed the evolution of SARS-CoV-2 in the patient, a common feature shared by most RNA viruses. How these variants influence the fitness of viruses and genetic diversity in the population awaits further investigation. Currently, only limited sequences are shared in public databases (Supplementary Table 6); hence there is an urgent need to accumulate more sequences to trace the evolution of the viral genome and associate the changes with clinical symptoms and outcomes.

Methods.

Subjects and samples collection

Eight COVID-19 pneumonia samples were collected from hospitals in Wuhan from December 18 to 29, 2019; 25 virus-like community-acquired pneumonia (CAP) samples were collected from Beijing Peking University People's Hospital, The Shenzhen Third People's Hospital, Fujian Provincial Hospital, and The First-affiliated hospital of Xi'an Jiaotong University between 2014 and 2018. CAP was diagnosed following the guidelines of the Infectious Diseases Society of America and the American Thoracic Society [22]. Pneumonia patients with chronic pulmonary diseases were excluded. Meanwhile, BALF from 20 healthy volunteers were collected and used as healthy controls. Demographic information and clinical information were included in Supplementary Table 1.

For each patient, BALF samples were collected using a bronchoscope as part of normal clinical management. The volume of BALF samples ranged between 5ml and 30ml, most of which were used for bacterial culture and the remnant were aliquoted and stored at -80 °C before processing.

Metatranscriptome sequencing

A 200 ul aliquot of each SARS-CoV-2 infected whole-BALF sample was used to extract RNA using Direct-zol RNA Miniprep kit (Zymo Research, Irvine, CA, USA) and Trizol LS (Thermo Fisher Scientific, Carlsbad, CA, USA) in biosafety III laboratory, and the rest samples were operated following the same protocol in biosafety II laboratory. The

RNA was then reverse transcribed, and amplified using an Ovation Trio RNA-Seq library preparation kit (NuGEN, CA, USA) and was sequenced on an Illumina HiSeq 2500/4000 platform (Illumina, United Kingdom).

Data availability

The raw sequencing data reported in this paper have been deposited in the Genome Warehouse in National Genomics Data Center [23], under project number PRJCA002202 that is publicly accessible at <https://bigd.big.ac.cn/gsa>. Meanwhile, the data have also been submitted to NCBI Sequence Read Archive (SRA) database under project number PRJNA605907.

Data processing and taxonomic assignments

Quality control processes included adapter trimming, low quality reads removal, short reads removal by fastp (-l 70, -x, --cut-tail, --cut_tail_mean_quality 20, version: 0.20.0)[24], low complexity reads removal by Komplexity (-F, -k 8, -t 0.2, version: Nov 2019)[25], host removal by bmtagger (<ftp://ftp.ncbi.nlm.nih.gov/pub/agarwala/bmtagger>)[26, 27], and ribosomal reads removal by SortMeRNA (version:2.1b)[28].

The resultant reads were mapped against NCBI nt database (version: Jul 1 2019) using BLAST+ (version:2.9.0)(-task megablast, -evalue 1e-10, -max_target_seqs 10, -max_hsps 1, -qcov_hsp_perc 60, -perc_identity 60)[29]. Taxonomic assignment was done by MEGAN using lowest common ancestor algorithm (-ms 100, -supp 0, -me 0.01, -top 10, -mrc 60, version: 6.11.0)[30]. After performing an overall PCoA and Permanova test, samples and microorganisms were filtered for further analyses with the

following criteria. Samples with less than 5000 microbial reads were discarded. Microorganisms satisfying the following criteria were considered in the microbiota analysis, 1) archaea, bacteria, fungi, or virus; 2) with relative abundance $\geq 1\%$ in the raw data and filtered data; 3) supported by at least 100 reads; 4) abundance higher than 10-fold of that in the negative control; 5) no batch effect; 6) abundance was not negatively correlated with bacteria titer; 7) not known contamination.

Intra-individual variants detection

Clean reads were mapped to the reference genome of SARS-CoV-2 (GenBank: MN908947.3) using BWA mem (version:0.7.12)[31]. Duplicate reads were removed by Picard (<http://broadinstitute.github.io/picard>; version: 2.18.22) [32]. Mpileup file was generated by samtools (version 1.8)[33], and intra-host variants were called using VarScan (version: 2.3.9)[34] and an in-house scripts. All variants had to satisfy the following requirements: 1) Sequencing depth ≥ 50 ; 2) Minor allele frequency $\geq 5\%$; 3) Minor allele frequency $\geq 2\%$ on each strand; 4) Minor allele count ≥ 5 on each strand; 5) The minor allele was supported by the inner part of the read (excluding 10 bp on each end); 6) Both alleles could be identified in at least 3 reads that specifically assigned to genus *Betacoronavirus*.

For comparison with the polymorphism in the population, we obtained 110 sequences from GISAID (www.gisaid.org)[35, 36]. The accession number and acknowledgment were included in Supplementary Table S6.

Statistical analysis.

Pearson's chi-square test or Fisher's exact test was used for categorical variables, and

the Mann-Whitney U test or Kruskal-Wallis rank sum test was used for continuous variables that do not follow a normal distribution. A comparison of microbiota was done by Permanova test.

Ethics statement.

The study was approved by the Institutional Review Board of Beijing Peking University People's Hospital, The Shenzhen Third People's Hospital, Fujian Provincial Hospital, and The First-affiliated hospital of Xi'an Jiaotong University. The data collection for the COVID-19 patients were deemed by the National Health Commission of the People's Republic of China as the contents of the public health outbreak investigation. Written informed consent was obtained from other pneumonia patients and healthy controls.

Acknowledgments

We thank Dr. Xue Yongbiao and colleagues from National Genomics Data Center for helpful discussion and computational resource support. We thank Dr. Huang Yanyi (Peking University, Beijing, China) and Wang Jianbin (Tsinghua University, Beijing, China) for providing the sequencing platform. We also thank Dr. Huang Chaolin for assist in sample collection. We gratefully acknowledge the Authors, the Originating and Submitting Laboratories for their sequence and metadata shared through GISAID, on which some of our analysis is based, a full name list of all submitters was given in Table S6.

Funding

This work was supported by grants from Innovation Fund for Medical Sciences [2016-I2M-1-014], the National Major Science & Technology Project for Control and Prevention of Major Infectious Diseases in China [2017ZX10103004, 2018ZX10305409, 2018ZX10301401, 2018ZX10732401]; National Natural Science Foundation of China [31670169, 31871263]; and the Open Project of Key Laboratory of Genomic and Precision Medicine, Chinese Academy of Sciences.

- ^{1.} The four intra-host variant positions with MAF \geq 5% and passing selection criteria were highlighted in bold.
- ^{2.} Number of reads supporting the reference allele.
- ^{3.} Number of reads supporting the alternative (mutant) allele.
- ^{4.} P-value indicates whether the difference of allele frequency between nCoV4 and nCoV7 is significant or not (Fisher Exact test).

Figure legends

Figure 1. Overview of the sequencing data. (A) The proportion of microbial reads in different groups; (B) Proportion of the viral read in patients infected with different viruses.

Figure 2. Intra-host variants in SARS-CoV-2 genome. (A) Genome coverage for SARS-CoV-2. A dash line indicates coverage of 50; (B) Frequency distribution of all intra-host variants, and the frequency of different mutations in polymorphism data was shown on the right side; (C) Distribution of the intra-host variations and polymorphisms on the genome of SARS-CoV-2. The outer ring displays the structure of the genome, following by the polymorphisms distribution on the genome. The length of each bar represents the number of sequences with this mutation. Due to a large variation of the number (1-27), 5% of the bar length was added for each additional sequence. The inner rings represent the distribution of intra-host variants in different patients (ID of each patient was labeled on each ring). Red bar indicates a synonymous mutation, and blue bar indicates a nonsynonymous mutation; (D) Frequency of the mutant allele at each high level (with frequency $\geq 20\%$) intra-host variant position. Nucleotides at the position (reference allele/alternative allele), mutation type (nonsynonymous, synonymous, noncoding), gene name, amino acid change were labeled on the right side of the heatmap. The total number of variants (with frequency $\geq 20\%$) in each sample was labeled on top of the heatmap. The name of five samples with more than 80% of the genome covered by at least 50-fold was labeled in blue. An open circle was added if the sample had a sequencing depth less than 50-fold at this position.

Figure 3. Microbiota in the BALF of COVID-19 patients, CAP patients, and healthy controls. A. Principal Coordinates Analysis (PCoA) of all samples. B. Heatmap of microbiota composition after QC filter (filters were described in Methods). The CAP samples were labeled as virus names followed by numbers. COVID-19 patients were highlighted by black rectangles, and two co-occurring bacterial clusters were highlighted by red rectangles. The names of all viruses are labeled in blue, and contaminant genera reported by Salter and colleagues are labeled in red[38].

Reproduction number

ABSTRACT

Objectives: Since the first case of 2019 novel coronavirus (COVID-19) identified on Jan 20, 2020, in South Korea, the number of cases rapidly increased, resulting in 6284 cases including 42 deaths as of Mar 6, 2020. To examine the growth rate of the outbreak, we present the first study to report the reproduction number of COVID-19 in South Korea.

Methods: The daily confirmed cases of COVID-19 in South Korea were extracted from publicly available sources. By using the empirical reporting delay distribution and simulating the generalized growth model, we estimated the effective reproduction number based on the discretized probability distribution of the generation interval.

Results: We identified four major clusters and estimated the reproduction number at 1.5 (95% CI: 1.4–1.6). In addition, the intrinsic growth rate was estimated at 0.6 (95% CI: 0.6, 0.7), and the scaling of growth parameter was estimated at 0.8 (95% CI: 0.7, 0.8), indicating sub-exponential growth dynamics of COVID-19. The crude case fatality rate is higher among males (1.1%) compared to females (0.4%) and increases with older age.

Conclusions: Our results indicate an early sustained transmission of COVID-19 in South Korea and support the implementation of social distancing measures to rapidly control the outbreak.

Introduction

A novel coronavirus (SARS-CoV-2) that emerged out of the city of Wuhan, China, in December 2019 has already demonstrated its potential to generate explosive outbreaks in confined settings and cross borders following human mobility patterns (Mizumoto et al., 2020). While COVID-19 frequently induces mild symptoms common to other respiratory infections, it has also exhibited an ability to generate severe disease among certain groups, including older populations and individuals with underlying health issues such as cardiovascular disease and diabetes (Adler, 2020). Nevertheless, a clear picture of the epidemiology of this novel coronavirus is still being elucidated.

The number of cases of COVID-19 in the province of Hubei, the disease epicenter, quickly climbed following an exponential growth trend. The total number of COVID-19 cases is at 80,859, including 3100 deaths in China as of Mar 8, 2020 (WHO, 2020).

Fortunately, by Feb 15, 2020, the daily number of newly reported cases in China started to decline across the country, although Hubei Province reported 128 cases on average per day in the week of March 2–8, 2020 (WHO, 2020). While the epidemic continues to decline in China, 24,727 COVID-19 cases have been reported in more than 100 countries outside of China, including South Korea, Italy, Iran, Japan, Germany, and France (WHO, 2020). In particular, South Korea quickly became one of the hardest-hit countries with COVID-19, exhibiting a steadily increasing number of cases over the last few days. Hence, it is crucial to monitor the progression of these outbreaks and assess the effects of various public health measures, including the social distancing measures in real-time.

The first case in South Korea was identified on Jan 20, 2020, followed by the detection of one or two cases on average in the subsequent days. However, the number of confirmed cases of SARS-CoV-2 infection started to increase rapidly on Feb 19, 2020, with a total of 6284 confirmed COVID-19 cases including 42 deaths reported as of Mar 6, 2020, according to the Korea Centers for Disease Control and Prevention (KCDC) (KCDC, 2020) (Table 1). The epicenter of the South Korean COVID-19 outbreak has been identified in Daegu, a city of 2.5 million people, approximately 150 miles South East of Seoul. The rapid spread of COVID-19 in South Korea has been attributed to one case linked to a superspreading

event that has led to more than 3900 secondary cases stemming from church services in the city of Daegu (Kuhn, 2020; Ryall, 2020). This has led to sustained transmission chains of COVID-19, with 55% of the cases associated with the church cluster in Daegu (Bostock, 2020).

Moreover, three other clusters have been reported, including one set in Chundo Daenam hospital in Chungdo-gun, Gyeong-sangbuk-do (118 cases), one set in the gym in Cheonan, Chungcheongnam-do (92 cases), and one Pilgrimage to Israel cluster in Gyeongsangbuk-do (49 cases). These few clusters have become the primary driving force of the infection. A total of 33 cases were imported, while the four major clusters are composed of local cases, as described in Table 2.

The transmission of SARS-CoV-2 in Korea is exacerbated by amplified transmission in confined settings, including a hospital and a church in the city of Daegu. The hospital-based outbreak alone involves 118 individuals, including 9 hospital staff (News, 2020), which is reminiscent of past outbreaks of SARS and MERS (Chowell et al., 2015). To respond to the mounting number of cases of COVID-19, the Korean government has raised the COVID-19 alert level to the highest (Level 4) on Feb 23, 2020, to facilitate the implementation of comprehensive social distancing measures including enhanced infection control measures in hospitals, restricting public transportation, canceling of social events, and delaying the start of school activities (Kim, 2020).

While the basic reproduction number, denoted by R_0 , applies at the outset of an exponentially growing epidemic in the context of an entirely susceptible population and in the absence of public health measures and behavior changes, the effective reproduction number (R_t) quantifies the time-dependent transmission potential. This key epidemiological parameter tracks the average number of secondary cases generated per case as the outbreak progresses over time. Steady values of R_t above 1 indicate sustained disease

transmission, whereas values of $R_t < 1$ do not support sustained transmission, and the number of new cases is expected to follow a declining trend. In this report, using a mathematical model parameterized with case series of the COVID-19 outbreak in Korea, we investigated the transmission potential and severity of COVID-19 in Korea using preliminary data of local and imported cases reported up until Feb 26, 2020.

Methods

Data

We obtained the daily series of confirmed cases of COVID-19 in South Korea from Jan 20, 2020, to Feb 26, 2020, that are publicly available from the Korea Centers for Disease Control and Prevention (KCDC) (KCDC, 2020). Our data includes the dates of reporting for all confirmed cases, the dates of symptom onsets for the first 28 reported cases, and whether the case is autochthonous (local transmission) or imported. We also summarize the case clusters comprising one or more cases according to the source of infection, according to the field investigations conducted by the KCDC (KCDC, 2020). Accordingly, four major clusters were identified. The total number of confirmed and suspected cases as of Mar 6, 2020, as well as the crude case and fatality rate distribution by gender and age, are presented in Table 1.

Imputing the date of onset

To estimate the growth rate of the epidemic, it is ideal to characterize the epidemic curve according to dates of symptoms onset rather than dates of reporting. For the COVID-19 data in Korea, the symptom onset dates are available for only the first 28 reported cases. Moreover, all of the dates of symptoms onset are

Table 2

Characteristics of the largest COVID-19 clusters in South Korea as of Mar 8, 2020.

Cluster name	Cluster location	Cluster size	Reporting date for the first case linked to cluster	Reporting date for the last case linked to cluster
Shinchunji Church of Jesus	81, Daemyeong-ro, Nam-gu, Daegu, Republic of Korea	4482	2/18/2020	3/08/2020
Chundo Daenam hospital	79-7, Cheonghwa-ro, Hwayang-eup, Cheongdo-gun, Gyeongsangbuk-do, Republic of Korea	118	2/20/2020	2/29/2020
Cluster related to the gym in Cheonan	667, Dujong-dong, Seobuk-gu, Cheonan-si, Chungcheongnam-do, Republic of Korea	92	2/25/2020	3/08/2020
Pilgrimage to Israel	31, Guncheong-gil, Uiseong-eup, Uiseong-gun, Gyeongsangbuk-do, Republic of Korea	49	2/22/2020	3/02/2020

available for the imported cases. Therefore, we utilize this empirical distribution of reporting delays from the onset to diagnosis to impute the missing dates of onset for the remainder of the cases with missing data. For this purpose, we reconstruct 300 epidemic curves by dates of symptoms onset from which we derive a mean incidence curve of local case incidence and drop the last three data points from the analysis to adjust for reporting delays in our real-time analysis (Tariq et al., 2019).

Estimation of reproduction number from daily case incidence

We assess the effective reproduction number, R_t , which quantifies the time-dependent variations in the average number of secondary cases generated per case during an outbreak due to intrinsic factors (decline in susceptible individuals) and extrinsic factors (behavior changes, cultural factors, and the implementation of public health measures) (Anderson and May, 1991; Chowell et al., 2015; Nishiura et al., 2010). Using the Korean incidence curves for imported and local cases, we estimate the evolution of R_t for COVID-19 in Korea. First, we characterize daily local case incidence using a generalized growth model (GGM) (Viboud et al., 2016). This model describes the growth profile via two parameters: the growth rate parameter (r) and the scaling of the growth rate parameter (p). The model captures diverse epidemic profiles ranging from constant incidence ($p = 0$), sub-exponential or polynomial growth ($0 < p < 1$), and exponential growth ($p = 1$) (Viboud et al., 2016). The generation interval is assumed to follow a gamma distribution with a mean of 4.41 days and a standard deviation of 3.17 days (Nishiura et al., 2020; You et al., 2020).

Next, to estimate the most recent estimate of R_t , we simulate the progression of incident cases from GGM and apply the discretized probability distribution (ρ_i) of the generation interval

using the renewal equation (Nishiura and Chowell, 2009; Nishiura and Chowell, 2014; Paine et al., 2010) given by

$$R_{t_i} = \frac{I_i}{\sum_{j=0}^i (I_{i-j} + \alpha J_{i-j}) \rho_i}.$$

In the renewal equation, we denote the local incidence at calendar time t_i by I_i , and the raw incidence of imported cases at calendar time t_i by J_i . The parameter $0 \leq \alpha \leq 1$ quantifies the relative contribution of imported cases to secondary disease transmission (Nishiura and Roberts, 2010). The denominator represents the total number of cases that contribute to the incidence cases at time t_i . Next, we estimate R_t for 300 simulated curves assuming a Poisson error structure to derive the uncertainty bounds around the curve of R_t (Chowell, 2017).

Results

Reconstructed incidence of COVID-19

The reconstructed daily incidence curve of COVID-19 after imputing the onset dates for the Korean cases is shown in Figure 1. Between Jan 20 and Feb 18, 2020, an average of two new cases were reported each day, whereas, between February 19–26, 2020, 154 new cases were reported on average each day.

Effective reproduction number (R_t) from daily case incidence

Under the empirical reporting delay distribution from early Korean cases with available dates of onset, the intrinsic growth rate (r) was estimated at 0.6 (95% CI: 0.6, 0.7) and the scaling of growth parameter (p) was estimated at 0.8 (95% CI: 0.7, 0.8), indicating sub-exponential growth dynamics of COVID-19 in Korea (Figure 2, Table 3). The mean reproduction number R_t was estimated at 1.5

Figure 1. Reconstructed epidemic curve for the local Korean COVID-19 cases by the dates of onset as of February 26, 2020. The blue triangles represent the local cases, red triangles represent the imported cases and the gray curves correspond to the uncertainty in the local cases because of missing onset dates.

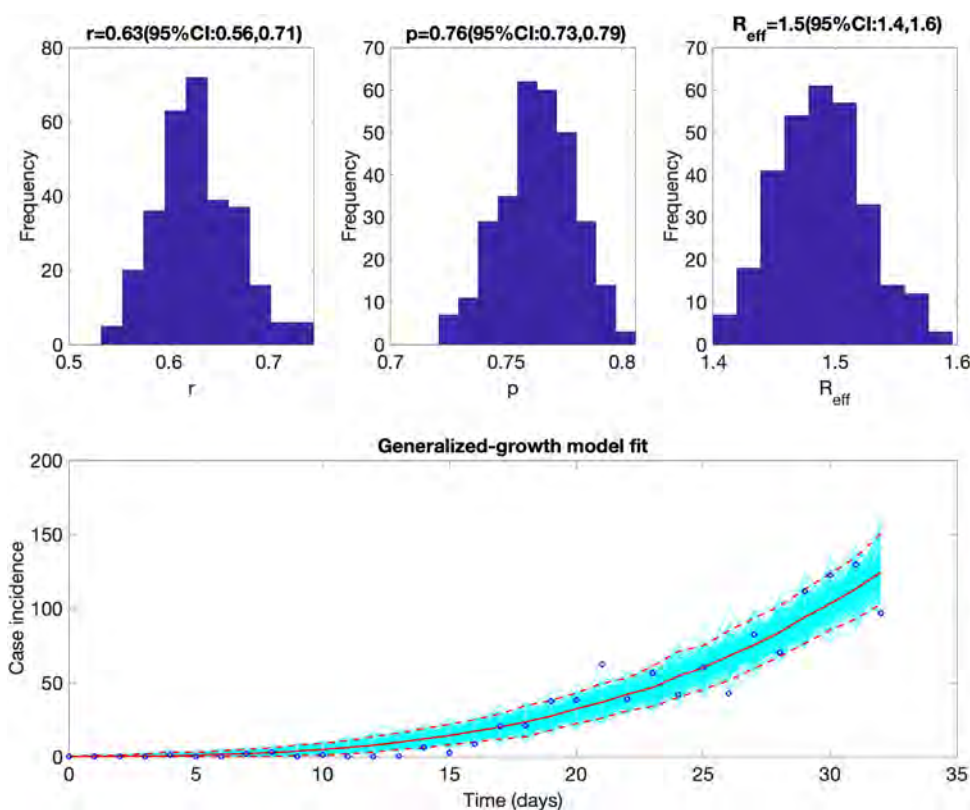

Figure 2. The mean reproduction number with 95% CI estimated by adjusting for the imported cases with $\alpha = 0.15$. Estimates for growth rate (r) and the scaling of the growth rate parameter (p) are also provided. The plot at the bottom depicts the fit of the Generalized Growth Model to the Korean data assuming Poisson error structure as of February 26, 2020.

Table 3

Mean estimates and the corresponding 95% confidence intervals for the effective reproduction number, growth rate, and the scaling of growth parameter during the early growth phase as of Feb 26, 2020.

Parameters	Estimated values
Reproduction number	1.5 (95% CI: 1.4, 1.6)
Growth rate, r	0.6 (95% CI: 0.6, 0.7)
Scaling of growth parameter, p	0.8 (95% CI: 0.7, 0.8)

(95% CI: 1.4, 1.6) as of Feb 26, 2020. Our estimates of R_t are not sensitive to changes in the parameter that modulates the contribution of the imported cases to transmission (α).

The crude case fatality rate

The crude case fatality rate is higher among males (1.1%) compared to females (0.4%) and increases with older age, from 0.1% among those 30–39 yrs to 6% among those ≥ 80 yrs as of Mar 6, 2020.

Transmission clusters

The spatial distribution of the Korean clusters is shown in Figure 3, and the characteristics of each cluster are presented in Table 2 as of Mar 8, 2020.

Shincheonji Church of Jesus cluster

As of Mar 8, 2020, 4482 confirmed cases of COVID-19 are linked to this cluster, according to the KCDC (KCDC, 2020). This largest cluster is associated with the Shincheonji Church of Jesus, with the first case (the 31st patient in the country) confirmed on Feb 18. It is

unclear how this case contracted the illness, as she does not present a recent history of travel or contact with another infected patient. However, before becoming a symptomatic case of COVID-19, she visited the hospital in Cheongdo after a minor car accident. After becoming a symptomatic case of COVID-19, she attended the Shincheonji Church of Jesus in Daegu twice. According to the KCDC, the patient had contact with 166 people, primarily at the Shincheonji Church and the hospital in Cheongdo; all those with whom the patient had contact, now placed themselves into self-quarantine. The Shincheonji church of Jesus has temporarily closed its facilities and halted the church activities as of Feb 18, 2020.

Chungdo Daenam hospital cluster

This cluster comprising 118 local cases and seven deaths is associated with Chungdo Daenam hospital, where South Korea's first coronavirus-associated case fatality occurred. Of the 118 cases, 92 were confirmed on Feb 22, 2020 (KCDC, 2020). A 63-year-old man who died of pneumonia at the hospital on Feb 19 was posthumously tested positive for COVID-19. On Feb 21, another patient at Daenam Hospital died from COVID-19, followed by another death on Feb 23. The confirmed cases were mainly from the psychiatric ward and include nine medical staff persons. The exact route of the infection is not yet known.

Cluster related to the gym in Cheonan

In the central cities of Cheonan, 92 COVID-19 patients were associated with a Zumba dance class after an instructor became the 5th confirmed case in Cheonan on Feb 25, 2020. According to the provincial government of South Chungcheong Province, everyone who attended the class in Cheonan was tested, and 27 cases were

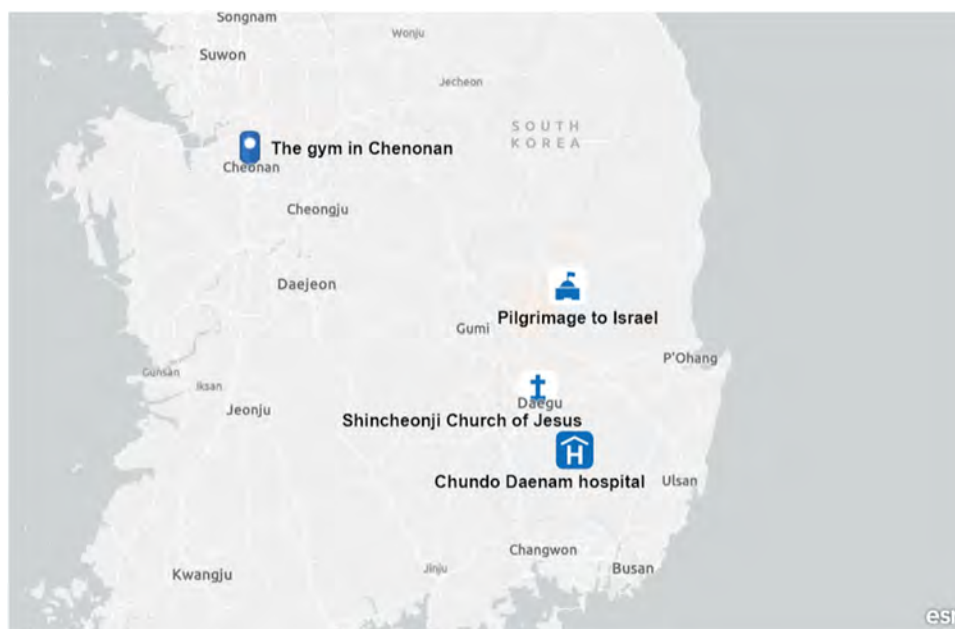

Figure 3. Map depicting the spatial distribution of the four largest clusters of COVID-19 in Korea as of March 8, 2020.

confirmed on Feb 28, 2020, with most of the cases being women in their 30's and 40's (KCDC, 2020). As of Mar 8, 2020, a total of 92 individuals were infected, including Zumba instructors and students, as well as their families and acquaintances (KCDC, 2020).

Pilgrimage tour to Israel related cluster

This cluster comprised 49 cases as of Mar 8, 2020. This cluster was identified when 31 Catholic pilgrims visited Israel between Feb 8, 2020, and Feb 16, 2020, and were subsequently confirmed to have COVID-19 (2020). Eleven individuals were diagnosed on Feb 17, 2020; twenty others were confirmed positive between February 21–25, 2020, and immediately quarantined. Of the 31 infected pilgrims, 19 came from Eiseong County, North Gyeongsang Province, while one patient, a tour guide, came from Seoul. Health authorities have traced multiple contacts by the cases of this cluster, and additional cases were confirmed after that, raising concerns about the potential risk of secondary infections.

Discussion

This is the first study to report estimates of the transmission potential of COVID-19 in Korea based on the trajectory of the epidemic, which was reconstructed by using the dates of onset of the first reported cases in Korea. The estimates of R clearly indicate the sustained transmission of the novel coronavirus in Korea; the case fatality rate appears to be higher among males and older populations (Table 1). Moreover, the imported cases contribute little to secondary disease transmission in Korea, as a majority of these cases occurred in the early phase of the epidemic, with the most recent imported case reported on Feb 9, 2020. These findings support the range of social distancing interventions that the Korean government put in place to bring the outbreak under control as soon as possible.

Our estimates of the reproduction number can be compared with earlier estimates reported for the epidemic in China, where the estimates of R lie in the range 2–7.1 (Lai et al., 2020; Li et al., 2020; Mizumoto et al., 2020; Read et al., 2020; Special Expert Group for Control of the Epidemic of Novel Coronavirus Pneumonia

of the Chinese Preventive Medicine A, 2020; Wu et al., 2020; Zhang et al., 2020; Zhou et al., 2020). Moreover, the mean R reached values as high as ~ 11 for the outbreak that unfolded aboard the Princess Cruises ship during January–February 2020 (Mizumoto and Chowell, 2020). In contrast, a recent study on Singapore's COVID-19 transmission dynamics reported lower estimates for R_t (1.1, 95% CI: 1.1, 1.3) as of Feb 19, 2020, reflecting a significant impact of the control interventions that were implemented in Singapore (Tariq et al., 2020). The estimates of the scaling of growth parameter (p) in our study indicate sub-exponential growth dynamics of COVID-19 in Korea. This aligns well with the sub-exponential growth patterns of COVID-19 in Singapore and all Chinese provinces except Hubei (Roosa et al., 2020; Tariq et al., 2020).

Since the first COVID-19 case was reported on Jan 20, 2020, the epidemic's trajectory showed a rapid upturn until Feb 18, 2020, when a superspreader (Case 31) was identified in the Shincheonji Church of Jesus in Daegu cluster. Since then, Korea's confirmed cases have risen tremendously. In fact, 55% of confirmed cases are linked to one cluster of infections, i.e., the Shincheonji Church of Jesus in Daegu (KCDC, 2020). Such superspreading events have been reported earlier for the 2015 MERS outbreak in South Korea (Cowling et al., 2015). Amplification of MERS in the hospital setting has been associated with diagnostic delays, which increase the window of opportunity for the generation of secondary cases (Chowell et al., 2015). This underscores the need for rapid testing, case detection, and active contact tracing to isolate infectious individuals.

Beyond Korea, substantial COVID-19 transmission has been reported in Italy, Iran, Germany, France, and aboard the Diamond cruise ship (Marcus, 2020; Woods, 2020). While the Chungdo Daenam hospital cluster and the cluster related to the Pilgrimage tour to Israel seem to have stabilized, the other two clusters are still being consolidated. Public health authorities are currently focused on containing the outbreak in the city of Daegu, the epicenter of the outbreak, and North Gyeongsang Province, where active contact tracing is being conducted. Nation-wide preventative measures are expected to reduce community transmission and ultimately bring R_t below one.

This is the first study to estimate the transmission potential and severity of COVID-19 in Korea. Our current findings suggest that there is a sustained disease transmission in the region, underscoring the need to implement a wide array of social distancing measures to rapidly contain the outbreak in Korea, mitigate the morbidity and mortality impact of the disease, and stem the number of case exportations to other nations.

Contributions

ES, AT, and GC analyzed the data. YS and WC retrieved and managed the data. ES, AT, and GC wrote the first draft of the paper. All authors contributed to the writing of this article.

Financial support

For ES and WC, this work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government(MSIT) (No. 2018R1C1B6001723).

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), a novel coronavirus with high nucleotide identity to SARS-CoV and to SARS-related coronaviruses that have been detected in horseshoe bats, has spread across the world and had a global effect on healthcare systems and economies^{1,2}. A suitable small animal model is needed to support the development of vaccines and therapies. Here we report the pathogenesis and transmissibility of SARS-CoV-2 in golden (Syrian) hamsters (*Mesocricetus auratus*). Immunohistochemistry assay demonstrated the presence of viral antigens in nasal mucosa, bronchial epithelial cells and areas of lung consolidation on days 2 and 5 after inoculation with SARS-CoV-2, followed by rapid viral clearance and pneumocyte hyperplasia at 7 days after inoculation. We also found viral antigens in epithelial cells of the duodenum, and detected viral RNA in faeces. Notably, SARS-CoV-2 was transmitted efficiently from inoculated hamsters to naive hamsters by direct contact and via aerosols. Transmission via fomites in soiled cages was not as efficient. Although viral RNA was continuously detected in the nasal washes of inoculated hamsters for 14 days, the communicable period was short and correlated with the detection of infectious virus but not viral RNA. Inoculated and naturally infected hamsters showed apparent weight loss on days 6–7 post-inoculation or post-contact; all hamsters returned to their original weight within 14 days and developed neutralizing antibodies. Our results suggest that features associated with SARS-CoV-2 infection in golden hamsters resemble those found in humans with mild SARS-CoV-2 infections.

SARS-CoV-2 was first detected from a cluster of patients with pneumonia in Wuhan (Hubei province, China) in December 2019. Although 55% of the initial cases were linked to one seafood wholesale market at which wild animals were also sold³, multiple viral (sustained human-to-human transmissibility by symptomatic and pre-symptomatic individuals⁴) and ecological (extensive domestic and international travel during Chinese Lunar New Year) factors have contributed to the rapid global spread of the virus. The clinical spectrum of patients with coronavirus disease 2019 (COVID-19) is wide; 19% of 44,415 confirmed patients in China progressed to severe and critical illness⁵, with an estimated 1.4% case fatality risk in symptomatic cases⁶. There is no approved vaccine or treatment against SARS-CoV-2, and the available interventions—including country lockdowns and social distancing—have severely disrupted the global supply chain and economy.

A suitable animal model is essential for understanding the pathogenesis of this disease and for evaluating vaccine and therapeutic candidates. Previous animal studies on SARS-CoV have suggested the importance of the interaction between the viral spike protein and the host angiotensin-converting enzyme 2 (ACE2) receptor^{7–10}, as well as age and innate immune status of the animals^{11–14} in pathogenesis. As with SARS-CoV, the spike protein of SARS-CoV-2 also uses ACE2 as the entry receptor¹. ACE2 is expressed on the surface

of alveolar epithelial cells and enterocytes of the small intestine and can be detected in endothelial cells and arterial smooth muscle cells¹⁵. SARS-CoV-2 showed good binding to human ACE2 but limited binding to mouse ACE2¹, which has limited the use of inbred mice for research. Macaques and transgenic ICR mice that express the human ACE2 receptor have been shown to be susceptible to infection with SARS-CoV-2^{16–18}; however, there is limited availability of these animal models. Cynomolgus macaques and rhesus macaques challenged with SARS-CoV-2 showed pneumonia with limited¹⁷ and moderate¹⁸ clinical signs, respectively. The transgenic mice challenged with SARS-CoV-2 showed pneumonia, moderate weight loss and no apparent histological changes in nonrespiratory tissues¹⁶. Previously generated transgenic mice that express the human ACE2 receptor have been reported to support the replication of SARS-CoV in the epithelial cells of the airway, but were associated with neurological-related mortality owing to high ACE2 expression in the brain^{7–10}.

The golden hamster is a widely used experimental animal model and has previously been reported to support replication of SARS-CoV^{19,20}—but not Middle Eastern respiratory syndrome coronavirus (MERS-CoV)²¹, which uses the dipeptidyl peptidase 4 (DPP4) protein as the main receptor for viral entry. A previous study of the SARS-CoV Urbani strain in 5-week-old golden hamsters

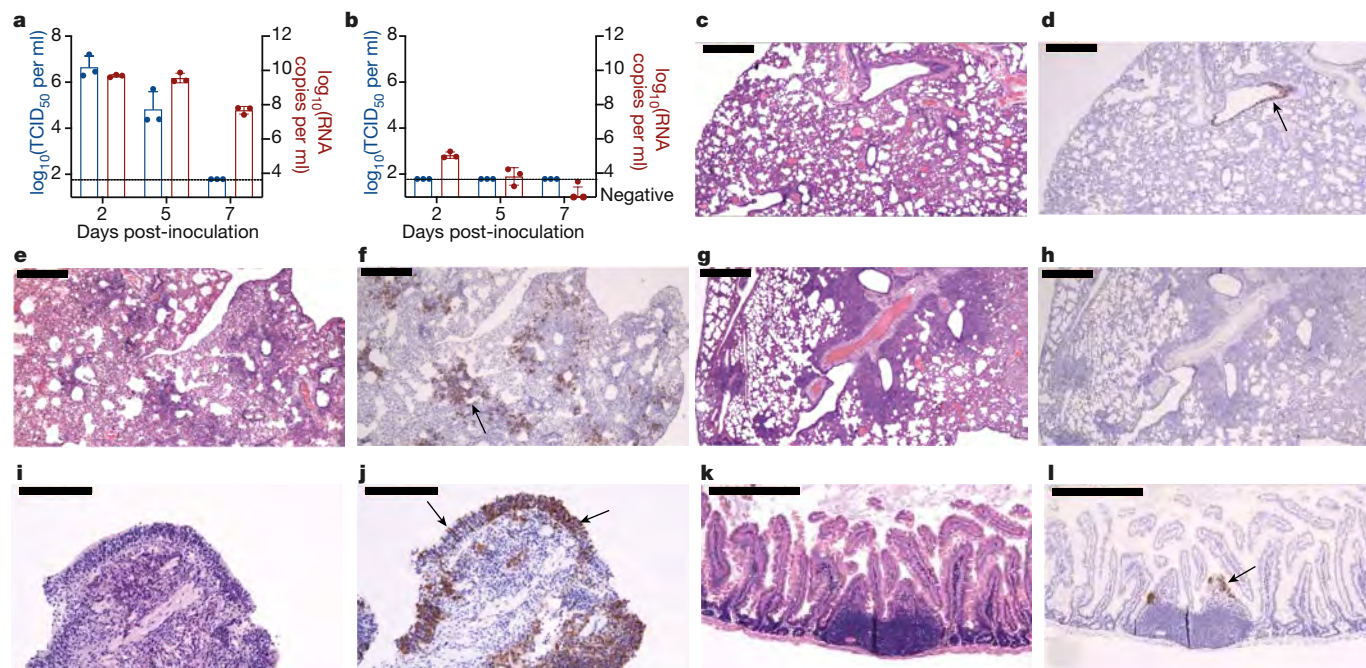

Fig. 1 | Viral load and histopathological changes in golden hamsters intranasally challenged with SARS-CoV-2. **a**, Infectious viral load ($\log_{10}(\text{TCID}_{50} \text{ per ml})$) and viral RNA ($\log_{10}(\text{RNA copies per ml})$) detected in the lungs of hamsters challenged with SARS-CoV-2 ($n=3$) at 2, 5 and 7 dpi. **b**, Infectious viral load and viral RNA detected in the kidney of hamsters challenged with SARS-CoV-2 ($n=3$) at 2, 5 and 7 dpi. Individual data points and mean \pm s.d. are shown; the detection limit ($1.789 \log_{10}(\text{TCID}_{50} \text{ per ml})$) is shown by the dotted line. **c**, Haematoxylin and eosin (H&E) staining of the lungs of hamsters challenged with SARS-CoV-2 at 2 dpi. **d**, Detection of SARS-CoV-2 N protein at bronchial epithelial cells (indicated by an arrow) by immunohistochemistry at 2 dpi. **e**, H&E staining of the lungs at 5 dpi. **f**, Detection of N protein in pneumocytes with lung consolidation (indicated by an arrow) at 5 dpi. **g**, H&E staining of the lungs at 7 dpi. **h**, The lack of detection of N

protein in the lungs at 7 dpi. **i**, H&E staining of nasal turbinate of hamsters challenged with SARS-CoV-2 at 2 dpi. **j**, Detection of N protein in nasal epithelial cells (arrow on the right) and cells morphologically resembling olfactory neurons (arrow on the left) at 2 dpi. **k**, H&E staining of duodenum of hamsters challenged with SARS-CoV-2 at 2 dpi. **l**, Detection of N protein in the duodenum epithelial cells at 2 dpi. The experiment was performed once with 9 hamsters challenged with $8 \times 10^4 \text{ TCID}_{50}$ of SARS-CoV-2, and tissues were collected from 3 hamsters for histopathology examination and immunohistochemistry at each time point. H&E staining and immunohistochemistry performed using tissues from three hamsters showed comparable results; representative images are shown. Scale bars, 200 μm (**i**, **j**), 500 μm (**c**–**h**, **k**, **l**).

showed robust viral replication, with peak viral titres detected in the lungs at 2 days post-inoculation (dpi) followed by rapid viral clearance by 7 dpi, but without weight loss or evidence of disease in the inoculated hamsters²⁰. A follow-up study that reported the testing of different strains of SARS-CoV in golden hamsters found differences in virulence between these strains; lethality was reported in hamsters challenged with the Frk-1 strain, which differs from the nonlethal Urbani strain by an L1148F substitution in the S2 domain¹⁹. Hamsters are permissive for infection by other respiratory viruses—including human metapneumovirus²², human parainfluenza virus 3²³ and influenza A virus—and may support influenza transmission by contact or airborne routes^{24,25}. Alignment of the ACE2 proteins of human, macaque, mouse and hamster suggest that the spike protein of SARS-CoV-2 may interact more efficiently with hamster ACE2 than mouse ACE2 (Extended Data Fig. 1). Here we evaluate the pathogenesis and contact transmissibility of SARS-CoV-2 in 4–5-week-old male golden hamsters.

Hamsters were infected intranasally with 8×10^4 50% tissue culture infective dose (TCID_{50}) of SARS-CoV-2 (BetaCoV/Hong Kong/VM20001061/2020; GISAID identifier EPI_ISL_412028), isolated in Vero E6 cells from the nasopharynx aspirate and throat swab of a patient from Hong Kong with a confirmed case of COVID-19. At 2, 5 and 7 dpi, the nasal turbinate, brain, lungs, heart, duodenum, liver, spleen and kidney were collected to monitor viral replication and histopathological changes. Peak viral load in the lungs was detected at 2 dpi and decreased at 5 dpi; no infectious virus was detected at 7 dpi despite of the continued detection of high copies of viral RNA (Fig. 1a). Infectious

viral load was significantly different between 2 and 7 dpi ($P = 0.019$, Dunn's multiple comparisons test), but the RNA copy number was not ($P = 0.076$). No infectious virus was detected in the kidney, although low copies of viral RNA were detected at 2 and 5 dpi (Fig. 1b).

Histopathological examination detected an increase in inflammatory cells and consolidation in 5–10% of the lungs at 2 dpi (Fig. 1c, d) and 15–35% of the lungs at 5 dpi (Fig. 1e, f). We observed mononuclear cell infiltrate in areas in which viral antigen was detected at 2 and 5 dpi. Immunohistochemistry for the nucleocapsid (N) protein of SARS-CoV-2 demonstrated viral antigen in the bronchial epithelial cells at 2 dpi (Fig. 1d), with progression to pneumocytes at 5 dpi (Fig. 1f). At 7 dpi, there was an increased consolidation in 30–60% of the lungs (Fig. 1g); however, no viral antigen was detected at this time point (Fig. 1h) and type-2 pneumocyte hyperplasia was prominent (Extended Data Fig. 2a). CD3-positive T lymphocytes were detected in the peribronchial region at 5 dpi, which may facilitate the rapid clearance of the infected cells (Extended Data Fig. 2b). There was moderate inflammatory-cell infiltration in the nasal turbinate (Fig. 1i), and viral antigen was detected in the nasal epithelial cells (Fig. 1j) and in olfactory sensory neurons at the nasal mucosa (Fig. 1j). Infection in the olfactory neurons was further confirmed in cells that express both SARS-CoV-2 N protein and neuron-specific tubulin- β III (Extended Data Fig. 2c). Compared to mock infection (Extended Data Fig. 2d, e), infection with SARS-CoV-2 leads to a reduction in the number of olfactory neurons at the nasal mucosal at 2 dpi (Extended Data Fig. 2f), prominent nasal epithelial attenuation at 7 dpi (Extended Data Fig. 2g), followed by tissue repair at 14 dpi (Extended Data Fig. 2h).

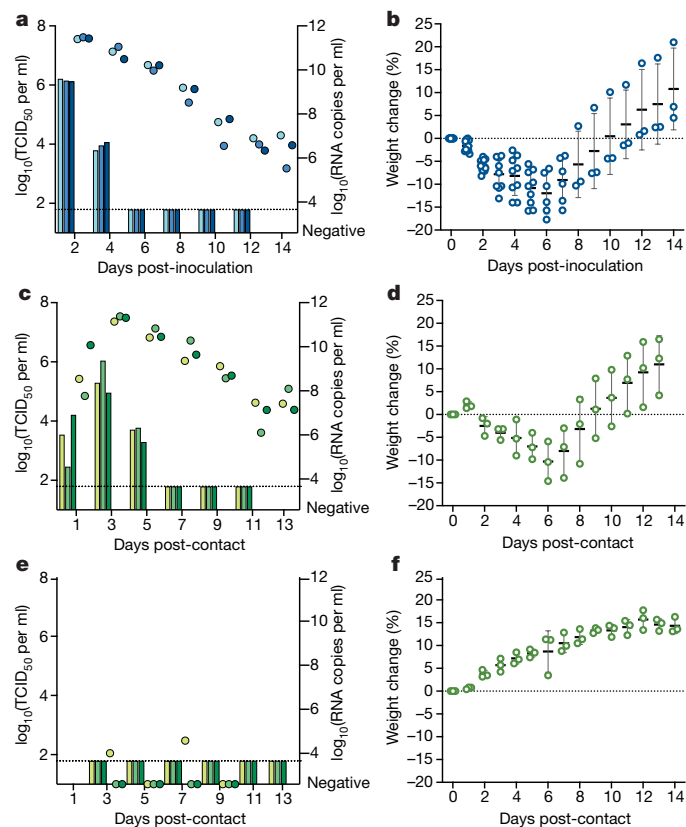

Fig. 2 | Transmission of SARS-CoV-2 in golden hamsters by direct contact.

a, Infectious viral load (\log_{10} (TCID₅₀ per ml), shown as bars) and viral RNA copy numbers (\log_{10} (RNA copies per ml), shown as dots) detected in the nasal washes of donor hamsters ($n=3$) inoculated with 8×10^4 TCID₅₀ of SARS-CoV-2. Colour-matched bars and dots represent results from the same hamster. **b**, Changes in body weight (per cent weight change compared to day 0) of hamsters inoculated with SARS-CoV-2 ($n=9$, including 3 donors and 9 hamsters challenged with SARS-CoV-2, described in Fig. 1); individual data points and mean \pm s.d. are shown. **c**, Transmission of SARS-CoV-2 to naive hamsters ($n=3$), each of which was cohoused with one inoculated donor at 1 dpi; infectious viral load and viral RNA copy numbers detected in the nasal washes of contact hamsters are shown. **d**, Changes in body weight (per cent weight change compared to the day of exposure) of contact hamsters ($n=3$) cohoused with inoculated donor at 1 dpi. **e**, Transmission of SARS-CoV-2 to naive hamsters ($n=3$), each of which was cohoused with one donor at 6 dpi; infectious viral load and viral RNA copy numbers detected in the nasal washes of contact hamsters are shown. **f**, Changes in body weight (per cent weight change compared to the day of exposure) of contact hamsters ($n=3$) cohoused with inoculated donors at 6 dpi. Direct-contact transmission experiments of cohoused donors and naive contacts at 1 dpi and 6 dpi (of the donor), respectively, were each performed once, each with three pairs of donor:direct contact at 1:1 ratio.

Though no inflammation was present (Fig. 1k), viral antigen was detected from the epithelial cells of duodenum at 2 dpi (Fig. 1l). This resembles the detection of replication of SARS-CoV in the epithelial cells of the terminal ileum and colon of patients with SARS-CoV without observing apparent architectural disruption and inflammatory infiltrate²⁶. No apparent histopathological change was observed from the brain, heart, liver and kidney at 5 dpi (Extended Data Fig. 2i–l).

To assess the transmission potential of the SARS-CoV-2 in hamsters, we intranasally inoculated three donor hamsters with 8×10^4 TCID₅₀ of the virus. At 24 hours after inoculation, each donor was transferred to a new cage and cohoused with one naive hamster. Weight changes and clinical signs were monitored daily and nasal washes were collected

every other day from donors and contacts, for 14 days. In donors, the peak infectious viral load in nasal washes was detected soon after inoculation and was followed by a rapid decline, although viral RNA was detected continuously for 14 days (Fig. 2a). Hamsters inoculated with SARS-CoV-2 showed their maximal mean weight loss (mean \pm s.d., $-11.97 \pm 4.51\%$, $n=6$) at 6 dpi (Fig. 2b). Transmission from donor to cohoused contact hamsters was efficient, and SARS-CoV-2 was detected from the cohoused hamsters at 1 day post-contact (dpc), and the peak viral load in nasal washes was detected at 3 dpc (Fig. 2c). The total viral load shed in the nasal washes was approximated by calculating the area under the curve for each hamster. The amount of virus shed in the nasal washes of contact hamsters was comparable to that of the donor hamsters ($P=0.1$, two-tailed Mann–Whitney test). Contact hamsters showed their maximal mean weight loss (mean \pm s.d., $-10.68 \pm 3.42\%$, $n=3$) at 6 dpc; all hamsters had returned to their original weight by 11 dpc (Fig. 2d). Neutralizing antibodies were detected using 90% plaque reduction neutralization (PRNT₉₀) assay from donor hamsters at 14 dpi (titres at 1:640 for all) and from contact hamsters on 13 dpc (titres at 1:160, 1:320 and 1:160). As viral RNA was continuously detected in the nasal washes of the donor for 14 days (whereas infectious virus titres decreased rapidly), we repeated the experiment and cohoused naive contact with donor hamsters at 6 dpi. A low quantity of viral RNA was detected in the nasal washes in one contact hamster at 3 and 7 dpc, without detection of infectious virus in the nasal washes (Fig. 2e); none of the contact hamsters showed weight loss (Fig. 2f). A PRNT₉₀ assay detected no neutralizing antibody ($<1:10$) from the contact hamsters at 12 dpc. The results suggest that the donor hamsters inoculated with SARS-CoV-2 have a short communicable period, of less than six days. Onward transmissibility from donor to cohoused contact hamsters was correlated with the detection of infectious virus, but not viral RNA, in the donor nasal washes.

The transmission from donor to cohoused contact hamster may have been mediated by multiple transmission routes. To investigate the transmissibility of SARS-CoV-2 among hamsters via aerosols (a collection of liquid or solid particles suspended in air and may include large droplets and fine droplet nuclei²⁷), donor hamsters and naive aerosol-contact hamsters were placed in two adjacent wire cages for 8 h at 1 dpi (of the donor) (Extended Data Fig. 3). The experiment was performed in three pairs of donor:aerosol-contact hamsters at a 1:1 ratio. The hamsters were single-housed after exposure, and were monitored daily for 14 days. Donor hamsters shed infectious virus in the nasal washes for 6 days, whereas viral RNA could be continuously detected for 14 days (Fig. 3a). Viral RNA was detected in the faecal samples of the donors at 2, 4 and 6 dpi, without detection of infectious virus (Fig. 3b). All donor hamsters showed comparable weight loss (Fig. 3c), as observed previously (Fig. 2b). Transmission via aerosols was efficient, as shown by the fact that infectious virus was detected in the nasal washes from all exposed contact hamsters at 1 dpc, with peak viral loads detected at 3 dpc (Fig. 3d). Viral RNA was continuously detected from the faecal samples of the infected aerosol-contact hamsters for 14 days, although no infectious virus was isolated (Fig. 3e). The aerosol-contact hamsters showed their maximal weight loss (mean \pm s.d., $-7.72 \pm 5.42\%$, $n=3$) at 7 dpc (Fig. 3f). The amount of virus shed in the nasal washes (approximated by area under the curve) of aerosol-contact hamsters was comparable to that of the donor hamsters ($P=0.4$, two-tailed Mann–Whitney test). Neutralizing antibodies were detected using PRNT₉₀ assay from the donor hamsters at 16 dpi (titres at 1:320, 1:640 and 1:640) and the contact hamsters at 15 dpc (titres at 1:640 for all). To evaluate the transmission potential of SARS-CoV-2 via fomites, three naive fomite-contact hamsters were each introduced to a soiled cage that had housed one donor between 0 and 2 dpi. The fomite-contact hamsters were single-housed in the soiled cages for 48 hours, and each was transferred to a new cage at 2 dpc (equivalent to 4 dpi of the donor hamster). Viral RNA was detected from different surfaces sampled

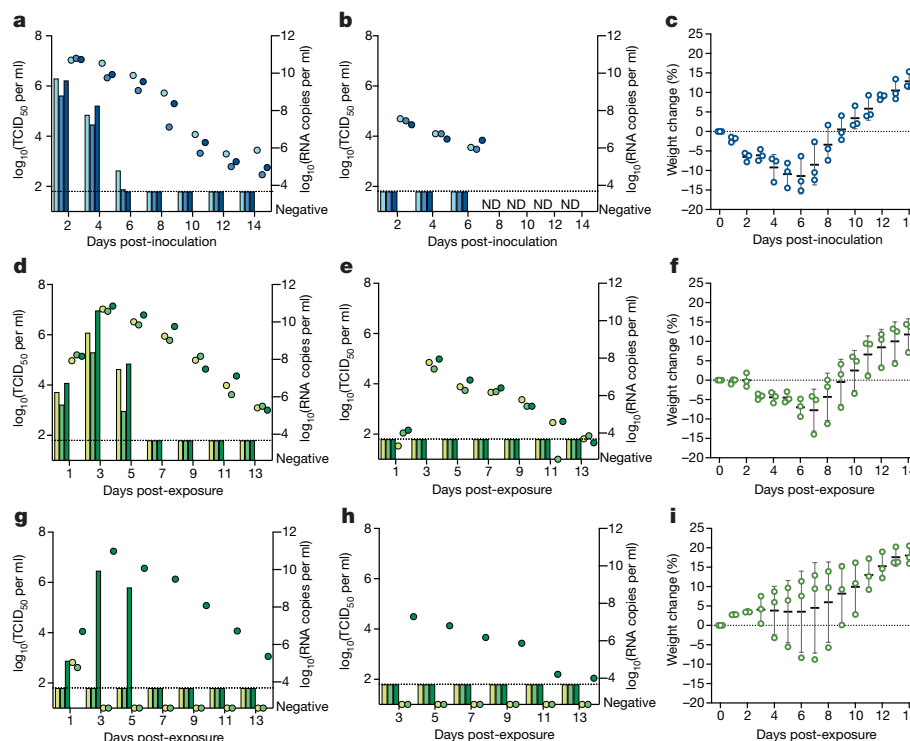

Fig. 3 | Transmission of SARS-CoV-2 in golden hamsters via aerosols and fomites. **a**, Infectious viral load (\log_{10} TCID₅₀ per ml), shown as bars and viral RNA copy numbers (\log_{10} RNA copies per ml), shown as dots detected in the nasal washes of donor hamsters ($n = 3$) inoculated with 8×10^4 TCID₅₀ of SARS-CoV-2. Colour-matched bars and dots represent results from the same hamster. **b**, Infectious virus and viral RNA detected in the faecal samples of donor hamsters ($n = 3$). ND, not determined. **c**, Changes in body weight of donor hamsters ($n = 3$); individual data points and mean \pm s.d. are shown. **d**, Aerosol transmission of SARS-CoV-2 to naive hamsters ($n = 3$) exposed to donors for 8 h at 1 dpi; infectious virus and viral RNA detected in the nasal washes of aerosol-contact hamsters are shown. **e**, Infectious virus and viral RNA detected

in the faecal samples of aerosol-contact hamsters ($n = 3$). **f**, Changes in body weight (per cent weight change compared to the day of exposure) of aerosol-contact hamsters ($n = 3$). **g**, Fomite transmission of SARS-CoV-2 to naive hamsters ($n = 3$) that were single-housed in the soiled cage of a donor for 48 h; infectious virus and viral RNA detected in the nasal washes of fomite-contact hamsters are shown. **h**, Infectious virus and viral RNA detected in the faecal samples of fomite-contact hamsters ($n = 3$). **i**, Changes in body weight (per cent weight change compared to the day of exposure) of fomite-contact hamsters ($n = 3$). Aerosol transmission and fomite transmission experiments were each performed once, with three repeats.

from the soiled cages used for housing the fomite-contact hamsters, with a low titre of infectious virus detected in the bedding (at 2 dpi), cage side surface (at 4 dpi) and water bottle nozzle (at 4 dpi) (Extended Data Table 1). One out of three fomite-contact hamsters shed infectious virus in the nasal washes starting from 1 dpc, with the peak viral load detected at 3 dpc (Fig. 3g). Viral RNA, but not infectious virus, was detected from the faecal samples (Fig. 3h). The maximal weight loss was 8.79% at 7 dpc (Fig. 3i). A PRNT₉₀ assay detected neutralizing antibody from the sera of one out of three fomite-contact hamsters at 16 dpc (titres at 1:320). Taken together, these results suggest that transmission of SARS-CoV-2 among hamsters was mediated mainly by aerosols, rather than by fomites.

Our results indicate that the golden hamster is a suitable experimental animal model for investigating infections with SARS-CoV-2, as there is apparent weight loss in the inoculated and naturally infected hamsters and evidence of efficient viral replication in the nasal mucosa and epithelial cells of the lower respiratory system. The ability of SARS-CoV-2 to infect olfactory sensory neurons at the nasal mucosa may explain the anosmia reported in patients with COVID-19. Hamsters support efficient transmission of SARS-CoV-2 from inoculated donor to naive contact hamsters by direct contact or via aerosols. We also show that transmission from the donor to naive hamsters may occur within a short period soon after inoculation; however, the donors have a short communicable period (of fewer than six days) despite of continuous detection of viral RNA in the nasal washes. Our findings are consistent with a recent report²⁸ that was published while

the current study was under peer review. Hamsters are easy to handle, and there are reagents to support immunological studies for vaccine development^{29–31}. The results also highlighted similarity and differences between the SARS-CoV and SARS-CoV-2 in the hamster model. Both viruses replicated efficiently in respiratory epithelial cells with peak viral load detected soon after inoculation, followed by an infiltration of mononuclear inflammatory cells in the lungs and rapid clearance of infectious virus by 7 dpi. Understanding the host defence mechanism that leads to rapid viral clearance in the respiratory tissues in hamsters may aid the development of effective countermeasures for SARS-CoV-2. The efficient transmission of SARS-CoV-2 to naive hamsters by aerosols also provides an opportunity to understand the transmission dynamics for this coronavirus.

Methods

No statistical methods were used to predetermine sample size. The hamsters were randomized from different litters into experimental groups and investigators were not blinded to allocation during experiments and outcome assessment.

Virus

The BetaCoV/Hong Kong/VM20001061/2020 virus was isolated from the nasopharyngeal aspirate and throat swab of a confirmed patient with COVID-19 in Hong Kong (GISAID identifier EPI_ISL_412028), using Vero E6 cells at the BSL-3 core facility (LKS Faculty of Medicine, University of Hong Kong). Vero E6 cells were purchased from ATCC (CRL-1586) without further authentication, and the cells routinely tested negative for *Mycoplasma* sp. by real-time PCR. Stock virus ($10^{7.25}$ TCID₅₀ per ml) was prepared after three serial passages in Vero E6 cells in Dulbecco's Modified Eagle Medium (DMEM) supplemented with 4.5 g/l D-glucose, 100 mg/l sodium pyruvate, 2% FBS, 100,000 U/l penicillin–streptomycin and 25 mM HEPES. The sequence of the stock virus was identical to the original clinical isolate.

Hamster experiments

Male golden hamsters at 4–5 weeks old were obtained from the Laboratory Animal Services Centre (Chinese University of Hong Kong). The hamsters were originally imported from Harlan (Envigo) in 1998. All experiments were performed at the BSL-3 core facility, (LKS Faculty of Medicine). The hamsters were randomized from different litters into experimental groups, and were acclimatized at the BSL-3 facility for 4–6 d before the experiments. The study protocol was reviewed and approved by the Committee on the Use of Live Animals in Teaching and Research, The University of Hong Kong (CULATR no. 5323-20). Experiments were performed in compliance with all relevant ethical regulations. For challenge studies, hamsters were anaesthetized with ketamine (150 mg/kg) and xylazine (10 mg/kg) via intraperitoneal injection and were intranasally inoculated with 8×10^4 TCID₅₀ of SARS-CoV-2 in 80 µl DMEM. On days 2, 5 and 7, three hamsters were euthanized by intraperitoneal injection of pentobarbital at 200 mg/kg. No blinding was done and a sample size of three hamsters was selected to assess the level of variation between animals. The left lungs and one kidney were collected for viral load determination and were homogenized in 1 ml PBS. Brain, nasal turbinate, right lungs, liver, heart, spleen, duodenum and kidney were fixed in 4% paraformaldehyde for histopathological examination. To collect faecal samples, hamsters were transferred to a new cage one day in advance and fresh faecal samples (10 pieces) were collected for quantitative real-time RT-PCR and TCID₅₀ assay. To evaluate SARS-CoV-2 transmissibility by direct contact, donor hamsters were anaesthetized and inoculated with 8×10^4 TCID₅₀ of SARS-CoV-2. At 1 or 6 dpi, one inoculated donor was transferred to cohousing with one naive hamster in a clean cage; the cohousing of the hamsters continued for at least 13 days. Experiments were repeated with three pairs of donors: direct contact at 1:1 ratio^{32,33}. Body weight and clinical signs of the hamsters were monitored daily. To evaluate SARS-CoV-2 transmissibility via aerosols, one naive hamster was exposed to one inoculated donor hamster in two adjacent stainless steel wired cages at 1 dpi (of the donor) for 8 h (Extended Data Fig. 3). DietGel76A (ClearH₂O) was provided to the hamsters during the 8-h exposure. Exposure was done by holding the hamsters inside individually ventilated cages (IsoCage N, Techniplast) with 70 air changes per h. Experiments were repeated with three pairs of donors: aerosol contact at 1:1 ratio. After exposure, the hamsters were single-housed in separate cages and were monitored daily for 14 d. To evaluate the transmission potential of SARS-CoV-2 virus via fomites, three naive fomite contact hamsters were each introduced to a soiled donor cage at 2 dpi. The fomite contact hamsters were single-housed for 48 h inside the soiled cages and then were each transferred to a new cage at 4 dpi

(of the donor). All hamsters were monitored daily for 14 d. For nasal wash collection, hamsters were anaesthetized using ketamine (100 mg/kg) and xylazine (10 mg/kg) via intraperitoneal injection and 160 µl of PBS containing 0.3% BSA was used to collect nasal washes from both nostrils of each hamster. Collected nasal washes were diluted 1:1 by volume and aliquoted for TCID₅₀ assay in Vero E6 cells and for quantitative real-time RT-PCR. The contact hamsters were handled first, followed by surface decontamination using 1% virkon and handling of the donor hamster.

Environmental sampling

To monitor the level of fomite contamination of SARS-CoV-2 virus in soiled cages, surface samples (5 cm × 5 cm; the whole water bottle nozzle was also swabbed) were collected using flocked polyester swabs (Puritan). Swabs were stored in 0.5 ml of viral transport medium (VTM, containing 0.45% bovine serum albumin, vancomycin, amikacin and nystatin) at −80 °C. In addition, 10 pieces of corn cob bedding were collected from the soiled cage and were soaked in 1 ml VTM for 30 min before titration of infectious virus and viral RNA extraction. Infectious viral loads were determined in Vero E6 cells, and viral RNA copy numbers were determined by quantitative real-time RT-PCR.

Viral load determination by quantitative real-time RT-PCR

RNA was extracted from 140-µl samples using QIAamp viral RNA mini kit (Qiagen) and eluted with 60 µl of water. Two µl RNA was used for quantitative real-time RT-PCR to detect and quantify the *N* gene of SARS-CoV-2 using TaqMan Fast Virus 1-Step Master Mix, as previously described³⁴.

PRNT₉₀ assay

The experiments were carried out in duplicate using Vero E6 cells seeded in 24-well culture plates. Serum samples were heat-inactivated at 56 °C for 30 min and were serially diluted and incubated with 30–40 plaque-forming units of SARS-CoV-2 for 1 h at 37 °C. The virus–serum mixtures were added to the cells and incubated 1 h at 37 °C in 5% CO₂ incubator. The plates were overlaid with 1% agarose in cell culture medium and incubated for 3 d. Thereafter, the plates were fixed and stained with 1% crystal violet. Antibody titres were defined as the highest serum dilution that resulted in >90% reduction in the number of plaques (PRNT₉₀).

Histopathology and immunohistochemistry

Tissue (hearts, livers, spleens, duodenums, brains, right lungs and kidneys) were fixed in 4% paraformaldehyde and were processed for paraffin embedding. The 4-µm sections were stained with haematoxylin and eosin for histopathological examinations. For immunohistochemistry, SARS-CoV-2 N protein was detected using monoclonal antibody (4D11)³⁵; CD3 was detected using polyclonal rabbit anti-human CD3 antibodies (DAKO); and neuron-specific β-III tubulin was detected using monoclonal antibody clone TuJ1 (R&D Systems). Images were captured using a Leica DFC 5400 digital camera and were processed using Leica Application Suite v.4.13.

Statistics and reproducibility

Kruskal–Wallis test and Dunn's multiple comparisons test were used to compare viral loads in the lungs and kidney at 2, 5 and 7 dpi. The area under the curve was calculated from the nasal washes of the donor and contact hamsters followed by Mann–Whitney test. Data were analysed in Microsoft Excel for Mac, version 16.35 and GraphPad Prism version 8.4.1. For the detection of viral replication in hamsters, 9 hamsters were inoculated and tissues were collected from hamsters at 2 ($n=3$), 5 ($n=3$) and 7 ($n=3$) dpi; the results from the three hamsters were similar (Fig. 1a, b). Inoculation of the donor hamsters was independently performed twice and the inoculated hamsters showed comparable weight loss and shed comparable amount of virus in the nasal washes (Figs. 2a, b, 3a, b).

Article

Transmissions by direct contact, aerosols or fomites were performed with three pairs of donor:contacts at 1:1 ratio.

Extended Data Fig. 1 | Sequence alignment of ACE2 proteins (1-420) from human, macaque, hamster and mouse. Asterisks denote amino acid residues of human ACE2 that have been shown by structural analysis to interact with the

receptor-binding domain of SARS-CoV-2³⁶. Amino acid residues that are important for the interaction between human ACE2 and receptor-binding domain of SARS-CoV are highlighted by red boxes³⁷.

Extended Data Fig. 2 | Haematoxylin and eosin staining and immunohistochemistry on hamster tissues challenged with SARS-CoV-2.

a, Hyperplasia of the pneumocytes detected at 7 dpi. **b**, Detection of CD3-positive cells (using rabbit anti-human CD3 polyclonal antibody) in the lungs at 5 dpi. **c**, Detection of SARS-CoV-2 N protein (red staining, using monoclonal antibody 4D11) and olfactory neurons (brown staining, using monoclonal antibody TuJ1) from the nasal turbinate at 5 dpi. **d**, Detection of olfactory neurons (using monoclonal antibody TuJ1) from the nasal turbinate of a mock-infected hamster ($n=1$). **e**, Nasal epithelial cells from the nasal turbinate of a mock-infected hamster ($n=1$) showed negative staining for TuJ1.

f, Detection of olfactory neurons from nasal turbinate at 2 dpi. **g**, Detection of olfactory neurons from nasal turbinate at 7 dpi. **h**, Detection of olfactory neurons from nasal turbinate at 14 dpi. **i**, Haematoxylin and eosin (H&E) staining of the brain tissue at 5 dpi. **j**, H&E staining of the heart at 5 dpi. **k**, H&E staining of the liver at 5 dpi. **l**, H&E staining of the kidney at 5 dpi. Hamsters were intranasally inoculated with PBS (mock infection, $n=1$) or with 8×10^4 TCID₅₀ of SARS-CoV-2 ($n=9$), and the tissues were collected at 2 ($n=3$), 5 ($n=3$) and 7 ($n=3$) dpi. H&E and immunohistochemistry performed on tissues from three hamsters at day 2, 5 and 7 dpi showed similar results; representative results are shown.

Extended Data Fig. 3 | Experimental layout for the aerosol transmission experiment in hamsters. To evaluate SARS-CoV-2 transmissibility via aerosols, one naive hamster was exposed to one inoculated donor hamster in two adjacent stainless steel wired cages at 1 dpi for 8 h. DietGel76A (ClearH₂O) was provided to the hamsters during the 8-h exposure. Exposure was done by

holding the hamsters inside individually ventilated cages (IsoCage N, Techniplast) with 70 air changes per h. Experiments were repeated with three pairs of donors:aerosol contact at 1:1 ratio. After exposure, the hamsters were single-housed in separate cages and were monitored daily for 14 d.

Extended Data Table 1 | Detection of SARS-CoV-2 in the soiled cages

Days post-inoculation	Animal cage info	Sampled area	Material	log ₁₀ TCID ₅₀ / mL	log ₁₀ RNA copies/ mL
Day 2	donor cage A			1.79	6.70
	donor cage B	bedding	corn cobs	<	5.18
	donor cage C			<	5.79
Day 4	fomite contact cage A	cage side (in direct contact with the animals)	plastic	<	6.89
	fomite contact cage B			<	5.21
	fomite contact cage C			1.79	6.33
	fomite contact cage A	cage lid	plastic	<	3.76
	fomite contact cage B			<	4.33
	fomite contact cage C			<	4.10
	fomite contact cage A	pre-filter	paper-based	<	5.26
	fomite contact cage B			<	5.27
	fomite contact cage C			<	5.31
	fomite contact cage A	water bottle nozzle	stainless steel	<	3.64
	fomite contact cage B			<	4.20
	fomite contact cage C			2.21	6.06
	fomite contact cage A	bedding	corn cobs	<	4.84
	fomite contact cage B			<	5.27
	fomite contact cage C			<	6.06
Day 6	fomite contact cage A	cage side (in direct contact with the animals)	plastic	<	5.70
	fomite contact cage B			<	5.61
	fomite contact cage C			<	6.51
	fomite contact cage A	cage lid	plastic	<	4.75
	fomite contact cage B			<	3.46
	fomite contact cage C			<	4.24
	fomite contact cage A	pre-filter	paper-based	<	5.48
	fomite contact cage B			<	5.23
	fomite contact cage C			<	5.36
	fomite contact cage A	bedding	corn cobs	<	5.12
	fomite contact cage B			<	6.24
	fomite contact cage C			<	5.58

To evaluate transmission potential of SARS-CoV-2 virus via fomites, three naive fomite contact hamsters were each introduced to a soiled cage that was housed by a donor from 0 to 2 dpi. The fomite contact hamsters were single-housed for 48 h inside the soiled cages, and each was then transferred to a new cage (equivalent to 4 dpi of the donor). The soiled cages were left empty at room temperature and were sampled again at 6 dpi of the donor. Surface samples and corn cob bedding were collected from the soiled cages at different time points to monitor infectious viral load and viral RNA copy numbers in the samples.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see [Authors & Referees](#) and the [Editorial Policy Checklist](#).

Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.

n/a Confirmed

- ☐ ☒ The exact sample size (n) for each experimental group/condition, given as a discrete number and unit of measurement
- ☐ ☒ A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
- ☐ ☒ The statistical test(s) used AND whether they are one- or two-sided
Only common tests should be described solely by name; describe more complex techniques in the Methods section.
- ☒ ☐ A description of all covariates tested
- ☒ ☐ A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
- ☐ ☒ A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
- ☐ ☒ For null hypothesis testing, the test statistic (e.g. F , t , r) with confidence intervals, effect sizes, degrees of freedom and P value noted
Give P values as exact values whenever suitable.
- ☒ ☐ For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
- ☒ ☐ For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
- ☒ ☐ Estimates of effect sizes (e.g. Cohen's d , Pearson's r), indicating how they were calculated

Our web collection on [statistics for biologists](#) contains articles on many of the points above.

Software and code

Policy information about [availability of computer code](#)

Data collection

Experimental data were recorded in Microsoft Excel for Mac, version 16.35. Images were captured using a Leica DFC 5400 digital camera and were processed using Leica Application Suite v4.13

Data analysis

Data were analyzed in Microsoft Excel for Mac, version 16.35 and GraphPad Prism version 8.4.1.

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors/reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research [guidelines for submitting code & software](#) for further information.

Data

Policy information about [availability of data](#)

All manuscripts must include a [data availability statement](#). This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

The accession number for the SARS-CoV-2 virus used for the study was provided.

There are two figures that have associated raw data. All data will be provided upon request.

Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

☒ Life sciences ☐ Behavioural & social sciences ☐ Ecological, evolutionary & environmental sciences

Life sciences study design

All studies must disclose on these points even when the disclosure is negative.

Sample size	This is an observational study investigates the suitability of using golden Syrian hamsters as an animal model for SARS-CoV-2. There is no comparison to be made with another virus, and a sample size of 3 was selected to evaluate the level of variation between individuals. Transmission studies are generally performed in 3-4 pairs of donor: contact at 1:1 ratio (Nishura et al., PLOS ONE 2013 and Belser et al., Future Microbiol 2013).
Data exclusions	No data was excluded in the analyses.
Replication	The challenge experiment was repeatedly performed three times. Direct contact transmission experiments were independently performed twice and naive animals were co-housed with inoculated donors on day 1 and day 6, respectively. Each experiment was performed with three pairs of donor: contact at 1:1 ratio. Aerosol transmission and fomite transmission experiments were each performed once with three pairs of donor: contact at 1:1 ratio.
Randomization	Randomization was performed while assigning the animals from different litters into experimental groups.
Blinding	Blinding was not possible for the experimental design due to the need to identify each animal (inoculated or contact) accurately.

Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.

Antibodies

Antibodies used	SARS-CoV-2 N protein was detected using monoclonal antibody (4D11). CD3 was detected using polyclonal rabbit anti-human CD3 antibody purchased from DAKO. Neuron-specific beta-III tubulin was detected using monoclonal clone TuJ1 (R&D Systems).
Validation	4D11 monoclonal antibody was reported in Nicholls et al. PLoS Med. 2006 Feb;3(2):e27. PubMed PMID: 16379499 Other antibodies are available commercially.

Eukaryotic cell lines

Policy information about [cell lines](#)

Cell line source(s)	Vero E6 (ATCC CRL-1586)
Authentication	The cell line was purchased from ATCC (ATCC CRL-1586). The cell line has not been authenticated since it was purchased from ATCC.
Mycoplasma contamination	The cell line was tested negative for mycoplasma.
Commonly misidentified lines (See ICLAC register)	No commonly misidentified lines were used.

Animals and other organisms

Policy information about [studies involving animals](#); [ARRIVE guidelines](#) recommended for reporting animal research

Laboratory animals	Male golden Syrian hamsters, at 4-5 weeks old
Wild animals	This study does not involve wild animals.
Field-collected samples	This study does not involve field-collected samples.
Ethics oversight	Animal ethics was approved by the the Committee on the Use of Live Animals in Teaching and Research, The University of Hong Kong (CULATR # 5323-20).

Note that full information on the approval of the study protocol must also be provided in the manuscript.

SARS-CoV-2 Transmission and Infection Among Attendees of an Overnight Camp — Georgia, June 2020

On July 31, 2020, this report was posted as an MMWR Early Release on the MMWR website (<https://www.cdc.gov/mmwr>).

Limited data are available about transmission of SARS-CoV-2, the virus that causes coronavirus disease 2019 (COVID-19), among youths. During June 17–20, an overnight camp in Georgia (camp A) held orientation for 138 trainees and 120 staff members; staff members remained for the first camp session, scheduled during June 21–27, and were joined by 363 campers and three senior staff members on June 21. Camp A adhered to the measures in Georgia's Executive Order* that allowed overnight camps to operate beginning on May 31, including requiring all trainees, staff members, and campers to provide documentation of a negative viral SARS-CoV-2 test ≤12 days before arriving. Camp A adopted most† components of CDC's Suggestions for Youth and Summer Camps§ to minimize the risk for SARS-CoV-2 introduction and transmission. Measures not implemented were cloth masks for campers and opening windows and doors for increased ventilation in buildings. Cloth masks were required for staff members. Camp attendees were cohorted by cabin and engaged in a variety of indoor and outdoor activities, including daily vigorous singing and cheering. On June 23, a teenage staff member left camp A after developing chills the previous evening. The staff member was tested and reported a positive test result for SARS-CoV-2 the following day (June 24). Camp A officials began sending campers home on June 24 and closed the camp on June 27. On June 25, the Georgia Department of Public Health (DPH) was notified and initiated an investigation. DPH recommended that all attendees be tested and self-quarantine, and isolate if they had a positive test result.

A line list of all attendees was obtained and matched to laboratory results from the State Electronic Notifiable Disease Surveillance System¶ and data from DPH case investigations. A COVID-19 case associated with the camp A outbreak was

defined as a positive viral SARS-CoV-2 test** in a camp A attendee from a specimen collected or reported to DPH from the first day at camp A (June 17 for staff members and trainees; June 21 for campers) through 14 days after leaving camp A (trainees left on June 21; staff members and campers left during June 24–June 27). Out-of-state attendees (27) were excluded from this preliminary analysis. Attack rates were calculated by dividing the number of persons with positive test results by the total number of Georgia attendees, including those who did not have testing results, because negative test results are not consistently reported in Georgia.

A total of 597 Georgia residents attended camp A. Median camper age was 12 years (range = 6–19 years), and 53% (182 of 346) were female. The median age of staff members and trainees was 17 years (range = 14–59 years), and 59% (148 of 251) were female. Test results were available for 344 (58%) attendees; among these, 260 (76%) were positive. The overall attack rate was 44% (260 of 597), 51% among those aged 6–10 years, 44% among those aged 11–17 years, and 33% among those aged 18–21 years (Table). Attack rates increased with increasing length of time spent at the camp, with staff members having the highest attack rate (56%). During June 21–27, occupancy of the 31 cabins averaged 15 persons per cabin (range = 1–26); median cabin attack rate was 50% (range = 22%–70%) among 28 cabins that had one or more cases. Among 136 cases with available symptom data, 36 (26%) patients reported no symptoms; among 100 (74%) who reported symptoms, those most commonly reported were subjective or documented fever (65%), headache (61%), and sore throat (46%).

The findings in this report are subject to at least three limitations. First, attack rates presented are likely an underestimate because cases might have been missed among persons not tested or whose test results were not reported. Second, given the increasing incidence of COVID-19 in Georgia in June and July, some cases might have resulted from transmission occurring before or after camp attendance.†† Finally, it was

*<https://gov.georgia.gov/document/2020-executive-order/06112001/download>.

† Notable adopted measures included cohorting of attendees by cabin (≤26 persons), staggering of cohorts for use of communal spaces, physical distancing outside of cabin cohorts, and enhanced cleaning and disinfection, especially of shared equipment and spaces.

§ <https://www.cdc.gov/coronavirus/2019-ncov/community/schools-childcare/summer-camps.html>.

¶ <https://sendss.state.ga.us/>.

** CDC defines a viral test as one that detects SARS-CoV-2 nucleic acids (e.g., polymerase chain reaction) or antigens. <https://www.cdc.gov/coronavirus/2019-ncov/hcp/testing-overview.html>.

†† <https://dph.georgia.gov/covid-19-daily-status-report>.

TABLE. SARS-CoV-2 attack rates^{*,†} among attendees of an overnight camp, by selected characteristics — Georgia, June 2020

Characteristic	No. [§]	No. positive	Attack rate, %
Total	597	260	44
Sex			
Male	267	123	46
Female	330	137	42
Age group, yrs			
6–10	100	51	51
11–17	409	180	44
18–21	81	27	33
22–59	7	2	29
Type of attendee (dates attended camp)			
Trainee (June 17–21)	134	26	19
Staff member (June 17–27 ^{¶, **})	117	66	56
Camper (June 21–27 [¶])	346	168	49
Cabin size during camp^{††} (no. of persons/cabin)^{§§}			
Small (1–3)	13	5	38
Medium (7–13)	75	29	39
Large (16–26)	375	200	53

Abbreviation: COVID-19 = coronavirus disease 2019.

* Although positive and negative test results for Georgia residents are reportable in the state of Georgia, negative results are not consistently reported. Attack rates were calculated by dividing the number of persons with a positive test result reported to the Georgia Department of Public Health (DPH) by the total number of Georgia attendees, including those who did not provide testing results.

† A COVID-19 case associated with the camp outbreak was defined as a positive viral SARS-CoV-2 test in an attendee from a specimen collected or reported to DPH from the first day at camp A (June 17 for staff members, including trainees; June 21 for campers) through 14 days after leaving camp A (trainees left on June 21; staff members and campers left during June 24–June 27).

§ Out-of-state attendees' (n = 27; 4%) test results were not reported to DPH and therefore were not included in this analysis.

¶ Camp departures began June 24 and were completed June 27.

** Three staff members arrived June 21.

†† Among camp attendees during June 21–27 (n = 463).

§§ No cabins included 4–6 or 14–15 persons.

not possible to assess individual adherence to COVID-19 prevention measures at camp A, including physical distancing between, and within, cabin cohorts and use of cloth masks, which were not required for campers.

These findings demonstrate that SARS-CoV-2 spread efficiently in a youth-centric overnight setting, resulting in high attack rates among persons in all age groups, despite efforts by camp officials to implement most recommended strategies to prevent transmission. Asymptomatic infection was common and potentially contributed to undetected transmission, as has been previously reported (1–4). This investigation adds to the body of evidence demonstrating that children of all ages are susceptible to SARS-CoV-2 infection (1–3) and, contrary to early reports (5,6), might play an important role in transmission (7,8). The multiple measures adopted by the camp were not sufficient to prevent an outbreak in the context of substantial community transmission. Relatively large cohorts sleeping in the same cabin and engaging in regular singing and cheering likely contributed to transmission (9). Use of cloth

masks, which has been shown to reduce the risk for infection (10), was not universal. An ongoing investigation will further characterize specific exposures associated with infection, illness course, and any secondary transmission to household members. Physical distancing and consistent and correct use of cloth masks should be emphasized as important strategies for mitigating transmission in congregate settings.

Coronavirus Disease 2019 in Children — United States, February 12–April 2, 2020

CDC COVID-19 Response Team

On April 6, 2020, this report was posted as an MMWR Early Release on the MMWR website (<https://www.cdc.gov/mmwr>).

As of April 2, 2020, the coronavirus disease 2019 (COVID-19) pandemic has resulted in >890,000 cases and >45,000 deaths worldwide, including 239,279 cases and 5,443 deaths in the United States (1,2). In the United States, 22% of the population is made up of infants, children, and adolescents aged <18 years (children) (3). Data from China suggest that pediatric COVID-19 cases might be less severe than cases in adults and that children might experience different symptoms than do adults (4,5); however, disease characteristics among pediatric patients in the United States have not been described. Data from 149,760 laboratory-confirmed COVID-19 cases in the United States occurring during February 12–April 2, 2020 were analyzed. Among 149,082 (99.6%) reported cases for which age was known, 2,572 (1.7%) were among children aged <18 years. Data were available for a small proportion of patients on many important variables, including symptoms (9.4%), underlying conditions (13%), and hospitalization status (33%). Among those with available information, 73% of pediatric patients had symptoms of fever, cough, or shortness of breath compared with 93% of adults aged 18–64 years during the same period; 5.7% of all pediatric patients, or 20% of those for whom hospitalization status was known, were hospitalized, lower than the percentages hospitalized among all adults aged 18–64 years (10%) or those with known hospitalization status (33%). Three deaths were reported among the pediatric cases included in this analysis. These data support previous findings that children with COVID-19 might not have reported fever or cough as often as do adults (4). Whereas most COVID-19 cases in children are not severe, serious COVID-19 illness resulting in hospitalization still occurs in this age group. Social distancing and everyday preventive behaviors remain important for all age groups as patients with less serious illness and those without symptoms likely play an important role in disease transmission (6,7).

Data on COVID-19 cases were reported to CDC from 50 states, the District of Columbia, New York City, and four U.S. territories. Jurisdictions voluntarily report data on laboratory-confirmed cases using a standardized case report form.* Data on cases occurring during February 12–April 2, 2020 and submitted through an electronic case-based COVID-19

surveillance database were reviewed for this report. Data submitted to CDC are preliminary and can be updated by health departments as more data become available. At the time of this analysis, characteristics of interest were available for only a minority of cases, including hospitalization status (33%), presence of preexisting underlying medical conditions (13%), and symptoms (9.4%). Because of the high percentage of cases with missing data and because cases with severe outcomes are more likely to have hospitalization or intensive care unit (ICU) status reported, percentages of patients hospitalized, including those admitted to the ICU, were estimated as a range, for which the denominator for the lower bound included cases with both known and unknown hospitalization or ICU status, and the upper bound included only cases with known hospitalization or ICU status. For other characteristics, percentages were calculated from among the number of cases with known information for that characteristic. Demographics of COVID-19 cases were assessed among cases in children aged <18 years and adults aged ≥18 years. Because clinical severity of COVID-19 is higher among adults aged ≥65 years than in younger age groups (8), clinical features including symptoms and hospitalizations were assessed among adults aged 18–64 years and compared with those among the pediatric cases. Statistical comparisons were not performed because of the high percentage of missing data.

As of April 2, 2020, data on 149,760 laboratory-confirmed U.S. COVID-19 cases were available for analysis. Among 149,082 (99.6%) cases for which patient age was known, 2,572 (1.7%) occurred in children aged <18 years and 146,510 (98%) in adults aged ≥18 years, including 113,985 (76%) aged 18–64 years. Among the 2,572 pediatric cases, 850 (33%) were reported from New York City; 584 (23%) from the rest of New York state; 393 (15%) from New Jersey; and the remaining 745 (29%) from other jurisdictions. The distribution of reporting jurisdictions for pediatric cases was similar to that of reporting jurisdictions for cases among adults aged ≥18 years, except that a lower percentage of adult cases was reported from New York state (14%). The first pediatric U.S. COVID-19 case was reported to CDC on March 2, 2020; since March 5, pediatric cases have been reported daily (Figure 1).

Among all 2,572 COVID-19 cases in children aged <18 years, the median age was 11 years (range 0–17 years). Nearly one third of reported pediatric cases (813; 32%) occurred in children aged 15–17 years, followed by those in children aged 10–14 years (682; 27%). Among younger

FIGURE 1. COVID-19 cases in children* aged <18 years, by date reported to CDC (N = 2,549)[†] — United States, February 24–April 2, 2020[§]

* Includes infants, children, and adolescents.

[†] Excludes 23 cases in children aged <18 years with missing report date.

[§] Date of report available starting February 24, 2020; reported cases include any with onset on or after February 12, 2020.

children, 398 (15%) occurred in children aged <1 year, 291 (11%) in children aged 1–4 years, and 388 (15%) in children aged 5–9 years. Among 2,490 pediatric COVID-19 cases for which sex was known, 1,408 (57%) occurred in males; among cases in adults aged ≥18 years for which sex was known, 53% (75,450 of 143,414) were in males. Among 184 (7.2%) cases in children aged <18 years with known exposure information, 16 (9%) were associated with travel and 168 (91%) had exposure to a COVID-19 patient in the household or community.

Data on signs and symptoms of COVID-19 were available for 291 of 2,572 (11%) pediatric cases and 10,944 of 113,985 (9.6%) cases among adults aged 18–64 years (Table). Whereas fever (subjective or documented), cough, and shortness of breath were commonly reported among adult patients aged 18–64 years (93% reported at least one of these), these signs and symptoms were less frequently reported among pediatric patients (73%). Among those with known information on each symptom, 56% of pediatric patients reported fever, 54% reported cough, and 13% reported shortness of breath, compared with 71%, 80%, and 43%, respectively, reporting these signs and symptoms among patients aged 18–64 years. Myalgia, sore throat, headache, and diarrhea were also less commonly reported by pediatric patients. Fifty-three (68%) of the 78 pediatric cases reported not to have fever, cough, or shortness of breath had no symptoms reported, but could not be classified as asymptomatic because of incomplete symptom information. One (1.3%) additional pediatric patient with a positive test result for SARS-CoV-2 was reported to be asymptomatic.

Information on hospitalization status was available for 745 (29%) cases in children aged <18 years and 35,061 (31%) cases in adults aged 18–64 years. Among children with COVID-19, 147 (estimated range = 5.7%–20%) were reported to be hospitalized, with 15 (0.58%–2.0%) admitted to an ICU (Figure 2). Among adults aged 18–64 years, the percentages of patients who were hospitalized (10%–33%), including those admitted to an ICU (1.4%–4.5%), were higher. Children aged <1 year accounted for the highest percentage (15%–62%) of hospitalization among pediatric patients with COVID-19. Among 95 children aged <1 year with known hospitalization status, 59 (62%) were hospitalized, including five who were admitted to an ICU. The percentage of patients hospitalized among those aged 1–17 years was lower (estimated range = 4.1%–14%), with little variation among age groups (Figure 2).

Among 345 pediatric cases with information on underlying conditions, 80 (23%) had at least one underlying condition. The most common underlying conditions were chronic lung disease (including asthma) (40), cardiovascular disease (25), and immunosuppression (10). Among the 295 pediatric cases for which information on both hospitalization status and underlying medical conditions was available, 28 of 37 (77%) hospitalized patients, including all six patients admitted to an ICU, had one or more underlying medical condition; among 258 patients who were not hospitalized, 30 (12%) patients had underlying conditions. Three deaths were reported among the pediatric cases included in this analysis; however, review of these cases is ongoing to confirm COVID-19 as the likely cause of death.

TABLE. Signs and symptoms among 291 pediatric (age <18 years) and 10,944 adult (age 18–64 years) patients* with laboratory-confirmed COVID-19 — United States, February 12–April 2, 2020

Sign/Symptom	No. (%) with sign/symptom	
	Pediatric	Adult
Fever, cough, or shortness of breath [†]	213 (73)	10,167 (93)
Fever [§]	163 (56)	7,794 (71)
Cough	158 (54)	8,775 (80)
Shortness of breath	39 (13)	4,674 (43)
Myalgia	66 (23)	6,713 (61)
Runny nose [¶]	21 (7.2)	757 (6.9)
Sore throat	71 (24)	3,795 (35)
Headache	81 (28)	6,335 (58)
Nausea/Vomiting	31 (11)	1,746 (16)
Abdominal pain [¶]	17 (5.8)	1,329 (12)
Diarrhea	37 (13)	3,353 (31)

* Cases were included in the denominator if they had a known symptom status for fever, cough, shortness of breath, nausea/vomiting, and diarrhea. Total number of patients by age group: <18 years (N = 2,572), 18–64 years (N = 113,985).

[†] Includes all cases with one or more of these symptoms.

[§] Patients were included if they had information for either measured or subjective fever variables and were considered to have a fever if “yes” was indicated for either variable.

[¶] Runny nose and abdominal pain were less frequently completed than other symptoms; therefore, percentages with these symptoms are likely underestimates.

Discussion

Among 149,082 U.S. cases of COVID-19 reported as of April 2, 2020, for which age was known, 2,572 (1.7%) occurred in patients aged <18 years. In comparison, persons aged <18 years account for 22% of the U.S. population (3). Although infants <1 year accounted for 15% of pediatric COVID-19 cases, they remain underrepresented among COVID-19 cases in patients of all ages (393 of 149,082; 0.27%) compared with the percentage of the U.S. population aged <1 year (1.2%) (3). Relatively few pediatric COVID-19 cases were hospitalized (5.7%–20%; including 0.58%–2.0% admitted to an ICU), consistent with previous reports that COVID-19 illness often might have a mild course among younger patients (4,5). Hospitalization was most common among pediatric patients aged <1 year and those with underlying conditions. In addition, 73% of children for whom symptom information was known reported the characteristic COVID-19 signs and symptoms of fever, cough, or shortness of breath.

These findings are largely consistent with a report on pediatric COVID-19 patients aged <16 years in China, which found that only 41.5% of pediatric patients had fever, 48.5% had cough, and 1.8% were admitted to an ICU (4). A second report suggested that although pediatric COVID-19 patients infrequently have severe outcomes, the infection might be more severe among infants (5). In the current analysis, 59 of 147 pediatric hospitalizations, including five of 15 pediatric ICU admissions, were among children aged <1 year; however, most reported U.S. cases in infants had unknown hospitalization status.

FIGURE 2. COVID-19 cases among children* aged <18 years, among those with known hospitalization status (N = 745),[†] by age group and hospitalization status — United States, February 12–April 2, 2020

Abbreviation: ICU = intensive care unit.

* Includes infants, children, and adolescents.

[†] Number of children missing hospitalization status by age group: <1 year (303 of 398; 76%); 1–4 years (189 of 291; 65%); 5–9 years (275 of 388; 71%); 10–14 years (466 of 682; 68%); 15–17 years (594 of 813; 73%).

Summary

What is already known about this topic?

Data from China suggest that pediatric coronavirus disease 2019 (COVID-19) cases might be less severe than cases in adults and that children (persons aged <18 years) might experience different symptoms than adults.

What is added by this report?

In this preliminary description of pediatric U.S. COVID-19 cases, relatively few children with COVID-19 are hospitalized, and fewer children than adults experience fever, cough, or shortness of breath. Severe outcomes have been reported in children, including three deaths.

What are the implications for public health practice?

Pediatric COVID-19 patients might not have fever or cough. Social distancing and everyday preventive behaviors remain important for all age groups because patients with less serious illness and those without symptoms likely play an important role in disease transmission.

In this preliminary analysis of U.S. pediatric COVID-19 cases, a majority (57%) of patients were males. Several studies have reported a majority of COVID-19 cases among males (4,9), and an analysis of 44,000 COVID-19 cases in patients of all ages in China reported a higher case-fatality rate among men than among women (10). However, the same report, as well as a separate analysis of 2,143 pediatric COVID-19 cases from China, detected no substantial difference in the number of cases among males and females (5,10). Reasons for any potential difference in COVID-19 incidence or severity between males and females are unknown. In the present analysis, the predominance of males in all pediatric age groups, including patients aged <1 year, suggests that biologic factors might play a role in any differences in COVID-19 susceptibility by sex.

The findings in this report are subject to at least four limitations. First, because of the high workload associated with COVID-19 response activities on local, state, and territorial public health personnel, a majority of pediatric cases were missing data on disease symptoms, severity, or underlying conditions. Data for many variables are unlikely to be missing at random, and as such, these results must be interpreted with caution. Because of the high percentage of missing data, statistical comparisons could not be conducted. Second, because many cases occurred only days before publication of this report, the outcome for many patients is unknown, and this analysis might underestimate severity of disease or symptoms that manifested later in the course of illness. Third, COVID-19 testing practices differ across jurisdictions and might also differ across age groups. In many areas, prioritization of testing for severely

ill patients likely occurs, which would result in overestimation of the percentage of patients with COVID-19 infection who are hospitalized (including those treated in an ICU) among all age groups. Finally, this analysis compares clinical characteristics of pediatric cases (persons aged <18 years) with those of cases among adults aged 18–64 years. Severe COVID-19 disease appears to be more common among adults at the high end of this age range (6), and therefore cases in young adults might be more similar to those among children than suggested by the current analysis.

As the number of COVID-19 cases continues to increase in many parts of the United States, it will be important to adapt COVID-19 surveillance strategies to maintain collection of critical case information without overburdening jurisdiction health departments. National surveillance will increasingly be complemented by focused surveillance systems collecting comprehensive case information on a subset of cases across various health care settings. These systems will provide detailed information on the evolving COVID-19 incidence and risk factors for infection and severe disease. More systematic and detailed collection of underlying condition data among pediatric patients would be helpful to understand which children might be at highest risk for severe COVID-19 illness.

This preliminary examination of characteristics of COVID-19 disease among children in the United States suggests that children do not always have fever or cough as reported signs and symptoms. Although most cases reported among children to date have not been severe, clinicians should maintain a high index of suspicion for COVID-19 infection in children and monitor for progression of illness, particularly among infants and children with underlying conditions. However, these findings must be interpreted with caution because of the high percentage of cases missing data on important characteristics. Because persons with asymptomatic and mild disease, including children, are likely playing a role in transmission and spread of COVID-19 in the community, social distancing and everyday preventive behaviors are recommended for persons of all ages to slow the spread of the virus, protect the health care system from being overloaded, and protect older adults and persons of any age with serious underlying medical conditions. Recommendations for reducing the spread of COVID-19 by staying at home and practicing strategies such as respiratory hygiene, wearing cloth face coverings when around others, and others are available on CDC's coronavirus website at <https://www.cdc.gov/coronavirus/2019-ncov/prevent-getting-sick/prevention.html>.

On July 24, 2020, this report was posted as an MMWR Early Release on the MMWR website (<https://www.cdc.gov/mmwr>).

Prolonged symptom duration and disability are common in adults hospitalized with severe coronavirus disease 2019 (COVID-19). Characterizing return to baseline health among outpatients with milder COVID-19 illness is important for understanding the full spectrum of COVID-19–associated illness and tailoring public health messaging, interventions, and policy. During April 15–June 25, 2020, telephone interviews were conducted with a random sample of adults aged ≥18 years who had a first positive reverse transcription–polymerase chain reaction (RT-PCR) test for SARS-CoV-2, the virus that causes COVID-19, at an outpatient visit at one of 14 U.S. academic health care systems in 13 states. Interviews were conducted 14–21 days after the test date. Respondents were asked about demographic characteristics, baseline chronic medical conditions, symptoms present at the time of testing, whether those symptoms had resolved by the interview date, and whether they had returned to their usual state of health at the time of interview. Among 292 respondents, 94% (274) reported experiencing one or more symptoms at the time of testing; 35% of these symptomatic respondents reported not having returned to their usual state of health by the date of the interview (median = 16 days from testing date), including 26% among those aged 18–34 years, 32% among those aged 35–49 years, and 47% among those aged ≥50 years. Among respondents reporting cough, fatigue, or shortness of breath at the time of testing, 43%, 35%, and 29%, respectively, continued to experience these symptoms at the time of the interview. These findings indicate that COVID-19 can result in prolonged illness even among persons with milder outpatient illness, including young adults. Effective public health messaging targeting these groups is warranted. Preventative measures, including social distancing, frequent handwashing, and the consistent and correct use of face coverings in public, should be strongly encouraged to slow the spread of SARS-CoV-2.

Prolonged illness is well described in adults with severe COVID-19 requiring hospitalization, especially among older adults (1,2). Recently, the number of SARS-CoV-2 infections

in persons first evaluated as outpatients have increased, including cases among younger adults (3). A better understanding of convalescence and symptom duration among outpatients with COVID-19 can help direct care, inform interventions to reduce transmission, and tailor public health messaging.

The Influenza Vaccine Effectiveness in the Critically Ill (IVY) Network, a collaboration of U.S. health care systems, is conducting epidemiologic studies on COVID-19 in both inpatient and outpatient settings (4,5). Fourteen predominantly urban academic health systems in 13 states each submitted a list of adults with positive SARS-CoV-2 RT-PCR test results obtained during March 31–June 4, 2020, to Vanderbilt University Medical Center. Site-specific random sampling was then performed on a subset of these patients who were tested as outpatients and included patients tested in the emergency department (ED) who were not admitted to the hospital at the testing encounter and those tested in other outpatient clinics. At 14–21 days from the test date, CDC personnel interviewed the randomly sampled patients or their proxies by telephone to obtain self-reported baseline demographic, socioeconomic, and underlying health information, including the presence of chronic medical conditions. Call attempts were made for up to seven consecutive days, and interviews were conducted in several languages (4). Respondents were asked to report the number of days they felt unwell before the test date, COVID-19–related symptoms experienced at the time of testing (6), whether symptoms had resolved by the date of the interview, and whether the patient had returned to their usual state of health. For this data analysis, respondents were excluded if they did not complete the interview, if a proxy (e.g., family member) completed the interview (because of their incomplete knowledge of symptoms), if they reported a previous positive SARS-CoV-2 test (because the reference date for symptoms questions was unclear), or (because this analysis focused on symptomatic persons) if they did not answer symptoms questions or denied all symptoms at testing.

Descriptive statistics were used to compare characteristics among respondents who reported returning and not returning to their usual state of health by the date of the interview.

Summary**What is already known about this topic?**

Relatively little is known about the clinical course of COVID-19 and return to baseline health for persons with milder, outpatient illness.

What is added by this report?

In a multistate telephone survey of symptomatic adults who had a positive outpatient test result for SARS-CoV-2 infection, 35% had not returned to their usual state of health when interviewed 2–3 weeks after testing. Among persons aged 18–34 years with no chronic medical conditions, one in five had not returned to their usual state of health.

What are the implications for public health practice?

COVID-19 can result in prolonged illness, even among young adults without underlying chronic medical conditions. Effective public health messaging targeting these groups is warranted.

Generalized estimating equation regression models with exchangeable correlation structure accounting for clustering by site were fitted to evaluate the association between baseline characteristics and return to usual health, adjusting for potential a priori-selected confounders. Resolution and duration of individual symptoms were also assessed. Statistical analyses were conducted using Stata software (version 16; StataCorp).

At least one telephone call was attempted for 582 patients (including 175 [30%] who were tested in an ED and 407 [70%] in non-ED settings), with 325 (56%) interviews completed (89 [27%] ED and 236 [73%] non-ED). Among 257 nonrespondents, 178 could not be reached, 37 requested a callback but could not be reached on further call attempts, 28 refused the interview, and 14 had a language barrier. Among the 325 completed interviews, 31 were excluded: nine (3%) because a proxy was interviewed, 17 (5%) because a previous positive SARS-CoV-2 test was reported, and five (2%) who did not answer the symptoms questions. Two additional respondents were called prematurely at 7 days and were also excluded.* Among the 292 remaining patient respondents, 274 (94%) reported one or more symptoms at testing and were included in this data analysis. Following outpatient testing, 7% (19 of 262 with available data) reported later being hospitalized, a median of 3.5 days after the test date. The median age of symptomatic respondents was 42.5 years (interquartile range [IQR] = 31–54 years), 142 (52%) were female, 98 (36%) were Hispanic, 96 (35%) were non-Hispanic white, 48 (18%) were non-Hispanic black, and 32 (12%) were other non-Hispanic

race. Overall, 141 of 264 (53%) with available data reported one or more chronic medical conditions. The median interval from test to interview date was 16 days (IQR = 14–19 days); the median number of days respondents reported feeling unwell before being tested for SARS-CoV-2 was 3 (IQR = 2–7 days).

Return to Usual State of Health

Among the 270 of 274 interviewees with available data on return to usual health,[†] 175 (65%) reported that they had returned to their usual state of health a median of 7 days (IQR = 5–12 days) from the date of testing (Table 1). Ninety-five (35%) reported that they had not returned to their usual state of health at the time of interview. The proportion who had not returned to their usual state of health differed across age groups: 26% of interviewees aged 18–34 years, 32% aged 35–49 years, and 47% aged ≥50 years reported not having returned to their usual state of health ($p = 0.010$) within 14–21 days after receiving a positive test result. Presence of chronic conditions also affected return to health rates; among 180 persons with no or one chronic medical condition, 39 with two chronic medical conditions, and 44 with three or more chronic medical conditions, 28%, 46%, and 57%, respectively, reported not having returned to their usual state of health ($p = 0.003$) within 14–21 days after having a positive test result. Among respondents aged 18–34 years with no chronic medical condition, 19% (nine of 48) reported not having returned to their usual state of health. Adjusting for other factors, age ≥50 versus 18–34 years (adjusted odds ratio [aOR] = 2.29; 95% confidence interval [CI] = 1.14–4.58) and reporting three or more versus no chronic medical conditions (aOR = 2.29; 95% CI = 1.07–4.90) were associated with not having returned to usual health (Table 2). Obesity (body mass index ≥30 kg per m²) (aOR 2.31; 95% CI = 1.21–4.42) and reporting a psychiatric condition[§] (aOR 2.32; 95% CI = 1.17–4.58) also were associated with more than twofold odds of not returning to the patient's usual health after adjusting for age, sex, and race/ethnicity.

Resolution of Symptoms and Duration

Among the 274 symptomatic outpatients, the median number of symptoms was seven of 17 listed in the interview tool (IQR = 5–10), with fatigue (71%), cough (61%), and headache (61%) those most commonly reported (Figure). Among respondents who reported fever and chills on the day of testing, these resolved in 97% and 96% of respondents, respectively.

*Two patients interviewed early at 12 days and three interviewed at 13 days after testing were included. Two patients who requested interview after 21 days because they were unavailable at 14–21 days were included (interviews were conducted at 25 and 26 days). All other included respondents were interviewed 14–21 days after testing.

[†]Patients were asked the question “Would you say that you are feeling back to your usual health?”

[§]Psychiatric conditions included anxiety disorder (38), depression (21), posttraumatic stress disorder (two), paranoia (two), obsessive-compulsive disorder (one), schizophrenia (one); some patients reported more than one condition.

TABLE 1. Characteristics of symptomatic outpatients with SARS-CoV-2 real-time reverse transcription–polymerase chain reaction (RT-PCR)—positive test results (N = 270)* who reported returning to usual state of health or not returning to usual state of health at an interview conducted 14–21 days after testing — 14 academic health care systems,† United States, March–June 2020

Characteristic	Total	Returned to usual health, no. (row %)		P-value [§]

Congestive heart failure	2	2 (100)	0 (0)	0.54

* 294 patients responded to an interview 2–3 weeks after testing, did not report a previous positive SARS-CoV-2 test before the reference test, and answered questions about symptoms. Of these, 276 (94%) reported one or more symptoms at the time of SARS-CoV-2 RT-PCR testing, with 272 (99%) reporting whether they had returned to their usual state of health by the time of the interview. Two additional patients excluded who were called at 7 days, with 270 included here.

† Patients were randomly sampled from fourteen academic healthcare systems in 13 states (University of Washington [Washington], Oregon Health and Sciences University [Oregon], University of California Los Angeles and Stanford University [California], Hennepin County Medical Center [Minnesota], Vanderbilt University [Tennessee], Ohio State University [Ohio], Wake Forest University [North Carolina], Montefiore Medical Center [New York], Beth Israel Deaconess Medical Center and Baystate Medical Center [Massachusetts], Intermountain Healthcare [Utah/Idaho], University of Colorado Hospital [Colorado], and Johns Hopkins University [Maryland]).

§ Respondents who reported returning to usual health and respondents who reported not returning to usual health were compared using the chi-square test or Fisher's exact test.

¶ Excluding seven (3%) patients who did not answer questions about chronic underlying medical conditions; for those who answered questions about underlying conditions, some respondents were missing data on obesity (two), neurologic conditions (one), and psychiatric conditions (one).

Symptoms least likely to have resolved included cough (not resolved in 43% [71 of 166]) and fatigue (not resolved in 35% [68 of 192]); among 90 who reported shortness of breath at the time of testing, this symptom had not resolved in 26 (29%). The median interval to symptom resolution among those who reported individual symptoms at the time of testing but not at the time of the interview ranged from 4 to 8 days from the test date, with the longest intervals reported for loss of smell (median = 8 days; IQR = 5–10.5 days) and loss of taste (median = 8 days; IQR = 4–10 days). Among respondents who

reported returning to their usual state of health, 34% (59 of 175) still reported one or more of the 17 queried COVID-related symptoms at the time of the interview.

Discussion

Most studies to date have focused on symptoms duration and clinical outcomes in adults hospitalized with severe COVID-19 (1,2). This report indicates that even among symptomatic adults tested in outpatient settings, it might take weeks for resolution of symptoms and return to usual health.

TABLE 2. Characteristics associated with not returning to usual health among symptomatic outpatients with SARS-CoV-2 real-time reverse transcription–polymerase chain reaction (RT-PCR)–positive test results (N = 270)* reported at an interview conducted 14–21 days after testing — 14 academic health care systems,† United States, March–June 2020

Abbreviations: BMI = body mass index; CI = confidence interval.

* 294 patients responded to 14–21-day interview, did not report a previous positive SARS-CoV-2 test before the reference test, and answered questions about symptoms; 276 (94%) of these reported one or more symptoms at the time of SARS-CoV-2 RT-PCR testing, with 272 (99%) reporting whether they had returned to their usual state of health by the time of the interview. Two additional patients who were called at 7 days were excluded, with 270 included here.

† Patients were randomly sampled from academic healthcare systems in 13 states (University of Washington [Washington], Oregon Health and Sciences University [Oregon], University of California Los Angeles and Stanford University [California], Hennepin County Medical Center [Minnesota], Vanderbilt University [Tennessee], Ohio State University [Ohio], Wake Forest University [North Carolina], Montefiore Medical Center [New York], Beth Israel Deaconess Medical Center and Baystate Medical Center [Massachusetts], Intermountain Healthcare [Utah/Idaho], University of Colorado Hospital [Colorado], and Johns Hopkins University [Maryland]).

§ For this analysis, generalized estimation equation (GEE) models with exchangeable correlation structure were used to estimate the association between characteristics and the odds of not returning to usual health by the date of the 14–21-day interview. GEE models were used to account for clustering of cases by site. 95% CIs including 1.00 are not considered statistically significant.

¶ In adjusted GEE models for age, sex, race/ethnicity, and number of chronic medical conditions, the other variables were used to adjust for potential confounders. Models for individual conditions (e.g., hypertension) were adjusted for age, sex, and race/ethnicity.

** Medical conditions are not exclusive and individual patients could have more than one chronic medical condition.

Not returning to usual health within 2–3 weeks of testing was reported by approximately one third of respondents. Even among young adults aged 18–34 years with no chronic medical conditions, nearly one in five reported that they had not returned to their usual state of health 14–21 days after testing. In contrast, over 90% of outpatients with influenza recover within approximately 2 weeks of having a positive test result (7). Older age and presence of multiple chronic medical conditions have previously been associated with illness severity among adults hospitalized with COVID-19 (8,9); in this study, both were also associated with prolonged illness in an

outpatient population. Whereas previous studies have found race/ethnicity to be a risk factor for severe COVID-19 illness (10), this study of patients whose illness was diagnosed in an outpatient setting did not find an association between race/ethnicity and return to usual health although the modest number of respondents might have limited our ability to detect associations. The finding of an association between chronic psychiatric conditions and delayed return to usual health requires further evaluation. These findings have important implications for understanding the full effects of COVID-19, even in persons with milder outpatient illness. Notably, convalescence can be

FIGURE. Self-reported symptoms at the time of positive SARS-CoV-2 reverse transcription–polymerase chain reaction (RT-PCR) testing results and unresolved symptoms 14–21 days later among outpatients (N = 274)* — 14 academic health care systems,[†] United States, March–June 2020

* 294 patients responded to 14–21-day interview, did not report a previous positive SARS-CoV-2 test before the reference test, and answered questions about symptoms; 276 (94%) of these reported one or more symptoms at the time of SARS-CoV-2 RT-PCR testing; those who were interviewed at 7 days were excluded, with 274 included here.

[†] Patients were randomly sampled from 14 academic health care systems in 13 states (University of Washington [Washington], Oregon Health and Sciences University [Oregon], University of California Los Angeles and Stanford University [California], Hennepin County Medical Center [Minnesota], Vanderbilt University [Tennessee], Ohio State University [Ohio], Wake Forest University [North Carolina], Montefiore Medical Center [New York], Beth Israel Deaconess Medical Center and Baystate Medical Center [Massachusetts], Intermountain Healthcare [Utah/Idaho], University of Colorado Hospital [Colorado], and Johns Hopkins University [Maryland]).

prolonged even in young adults without chronic medical conditions, potentially leading to prolonged absence from work, studies, or other activities.

The findings in this report are subject to at least three limitations. First, nonrespondents might have differed from survey respondents; for example, those with more severe illness might have been less likely to respond to telephone calls if they were

subsequently hospitalized and unable to answer the telephone. Second, symptoms that resolved before the test date or that commenced after the date of testing were not recorded in this survey. Finally, as a telephone survey, this study relied on patient self-report and might have been subject to incomplete recall or recall bias.

Nonhospitalized COVID-19 illness can result in prolonged illness and persistent symptoms, even in young adults and

persons with no or few chronic underlying medical conditions. Public health messaging should target populations that might not perceive COVID-19 illness as being severe or prolonged, including young adults and those without chronic underlying medical conditions. Preventative measures, including social distancing, frequent handwashing, and the consistent and correct use of face coverings in public, should be strongly encouraged to slow the spread of SARS-CoV-2.

Abstract

Victoria has been Australia's hardest hit state by the COVID-19 pandemic, but was successful in reversing its second wave of infections through aggressive policy interventions. The clear reversal in the epidemic trajectory combined with information on the timing and geographical scope of policy interventions offers the opportunity to estimate the relative contribution of each change. We developed a compartmental model of the COVID-19 epidemic in Victoria that incorporated age and geographical structure, and calibrated it to data on case notifications, deaths and health service needs according to the administrative divisions of Victoria's healthcare, termed clusters. We achieved a good fit to epidemiological indicators, at both the state level and for individual clusters, through a combination of time-varying processes that included changes to case detection rates, population mobility, school closures, seasonal forcing, physical distancing and use of face coverings. Estimates of the risk of hospitalisation and death among persons with disease that were needed to achieve this close fit were markedly higher than international estimates, likely reflecting the concentration of the epidemic in groups at particular risk of adverse outcomes, such as residential facilities. Otherwise, most fitted parameters were consistent with the existing literature on COVID-19 epidemiology and outcomes. We estimated a significant effect for each of the calibrated time-varying processes on reducing the risk of transmission per contact, with broad estimates of the reduction in transmission risk attributable to seasonal forcing (27.8%, 95% credible interval [95%CI] 9.26-44.7% for mid-summer compared to mid-winter), but narrower estimates for the individual-level effect of physical distancing of 12.5% (95%CI 5.69-27.9%) and of face coverings of 39.1% (95%CI 31.3-45.8%). That the multi-factorial public health interventions and mobility restrictions led to the dramatic reversal in the epidemic trajectory is supported by our model results, with the mandatory face coverings likely to have been particularly important.

Introduction

The COVID-19 pandemic has had an unprecedented impact on human health and society,^{1,2} with high-income, urban and temperate areas often the most severely affected.³⁻⁵ The impacts of the virus are felt through the direct effect of the virus, particularly through its considerable risk of mortality following infection^{6,7} and likely substantial post-infection sequelae,⁸ but also through the extreme lockdown measures often needed to achieve control.⁹

Australia has been relatively successful in controlling COVID-19,¹⁰ with all jurisdictions of the country achieving good control of the first wave of imported cases through March and April. However, the southern state of Victoria suffered a substantial second wave of locally-transmitted cases, reaching around 600 notifications per day, predominantly in metropolitan Melbourne in winter.

In response to the pandemic, the Victorian Government implemented a number of recommendations and policy changes with the aim of reversing the escalating case numbers that had a severe impact on social and economic activities. Specific changes included stringent restrictions on movement, increased testing rates, school closures and face covering requirements. In metropolitan Melbourne face coverings were mandated from 23rd July and significantly more stringent movement restrictions were implemented from 9th of July (moving to “stage 3”) and from 2nd August (moving from “stage 3” to “stage 4”). Case numbers peaked in the final days of July and first days of August and declined thereafter. Understanding the relative contribution of each of these interventions is complicated by several interventions being implemented within a few weeks, along with policy differences between metropolitan and regional areas. Nevertheless, the clear reversal in the trajectory of the epidemic following the implementation of these policy changes offers the opportunity to explore the contribution of these factors to the epidemic profile. Indeed, the experience of Victoria’s second wave is virtually unique in that the pattern of substantial and escalating daily community cases was reversed following these policy changes, with elimination

subsequently achieved in November. We adapted our computational model to create a unified transmission model for the state and infer the contribution of the policy interventions implemented to changing the direction of the epidemic trajectory.

Methods

We adapted the transmission dynamic model that we had used to produce forecasts of new cases, health system capacity requirements and deaths for the Victorian Department of Health and Human Services (DHHS) at the health service cluster level (henceforward “cluster”). By incorporating geographical structure to represent clusters, we built a unified model of the COVID-19 epidemic in Victoria, and fitted the model to multiple indicators of epidemic burden in order to infer the effectiveness of each component of the response to the epidemic. Full methods are provided in the Supplementary Methods, key features of the model are illustrated in Figure 1 and all code is available at <https://github.com/monash-emu/AuTuMN>.

Base model

Our model of COVID-19 epidemiology is a stratified, deterministic SEIR framework, with sequential compartments representing non-infectious and infectious incubation periods and early and late active disease (Figure 1A). The late incubation compartment and the two active compartments are stratified to simulate epidemiological considerations including asymptomatic cases,¹¹ incomplete detection of symptomatic cases, hospitalisation and ICU admission (Figure 1B). All model compartments were then stratified by age, with susceptibility, the clinical fraction, hospitalisation risk and infection fatality rate modified by age group.⁶ We introduced heterogeneous mixing by age using the synthetic mixing matrix for Australia developed by Prem *et al.* 2017 (Figure 1D).¹²

Simulation of public health interventions

We simulated movement restrictions (including school closures, business closures and working from home) by varying the relative contribution of three of four locations to the overall mixing matrix (Figure 1E) continuously over time. Using Google mobility data (<https://www.google.com/covid19/mobility/>) weighted to cluster, we scaled the work contribution with workplace mobility and the contribution from other locations (contacts outside of schools, homes, and work) with an average of mobility from the remaining Google mobility locations other than residential (Figure 1E). We simulated school closures by scaling the school contribution according to the proportion of children attending schools on site. We assumed that schools began transitioning to onsite learning from the 26th of May, at which time 400,000 of 1,018,000 students returned to onsite education. The remaining students were considered to return onsite from the 9th of June, before 90% of students moved to remote learning from the 9th of July, which continued until October.

The term “micro-distancing” is used to refer to behavioural changes that reduce the risk of transmission given an interpersonal contact and so are not captured through data on population mobility (e.g. maintaining physical distance and use of face coverings). Micro-distancing was assumed to reduce the risk of both transmission from index cases and the risk of infection of susceptible persons, with the effect of both physical distancing and face coverings applied to all three non-residential locations. Both the coverage and the effectiveness of each intervention were incorporated, with time-varying functions representing the proportion of the population complying with recommendations over time and constant calibration parameters scaling these functions to represent the effectiveness of the intervention. The profiles of compliance with these two recommendations was estimated by fitting to YouGov data, available at <https://github.com/YouGov-Data/covid-19-tracker>, with hyperbolic tan functions providing a good fit to data (Supplemental Figures 5 and 6).

Because face coverings were mandated ten days later in regional Victoria than metropolitan Melbourne, the face coverings compliance function was delayed by this period for regional clusters, while the physical distancing function was identical for all clusters.

We defined the modelled case detection rate as the proportion of all symptomatic cases that were detected (Figure 1B). We related the case detection rate (CDR, Equation 1) to the number of tests performed using an exponential function, under the assumption that a certain per capita daily testing rate is associated with a specific case detection rate, with this relationship varied during calibration (Supplemental Figure 4):

$$\text{Equation 1: } CDR(\text{time}) = 1 - e^{-\text{shape} \times \text{tests}(\text{time})}$$

Seasonal forcing was incorporated using a transposed sine function, with maximum value at the winter solstice.

Incorporation of health service clusters

We further stratified the above model to Victoria's nine health service clusters, including four clusters which together constitute metropolitan Melbourne (North, West, South, South East Metro) and five regional clusters which together constitute the rest of Victoria (Barwon South West, Gippsland, Grampians, Hume, Loddon-Mallee). We split the estimated age-specific population for Victoria (Figure 1C) according to historical patterns of accessing health service clusters provided by DHHS. The infectious seed was split across the compartments representing current infection and assigned evenly across the metropolitan clusters, with the remainder of the population assigned to the susceptible compartments. The force of infection in each cluster was calculated as a weighted average of the age-specific force of infection for each cluster, with the index cluster having the greatest weight and all non-index clusters having equal weight. The final model included 2,592 compartments interacting through a dynamic mixing matrix of dimensions 144 x 144 (16 age groups and nine geographical patches), with each matrix element scaling over time to reflect changes to population mixing in response to changes in mobility and pandemic-related policy decisions as introduced above.

Calibration

Because of the high-dimensional parameter space, we calibrated the model to reproduce local COVID-19 dynamics during Victoria's second wave using an adaptive Metropolis algorithm, which is non-Markovian but retains ergodic properties (Table 1; Supplement).¹³ For the prior distributions of epidemiological calibration parameters, we used uniform priors for highly uncertain quantities and truncated normal distributions for quantities informed by epidemiological evidence. We included adjusters in our calibration parameters to modify the proportion of symptomatic individuals, proportion of symptomatic individuals hospitalised, and the infection fatality rate. The parameters are multiplicative factors that are applied to the odds ratio equivalent to the proportion parameter, rather than directly to the parameter value itself; thus ensuring that the adjusted value lies between zero and one.

The likelihood function was constructed by first incorporating Poisson distributions with rate parameters equal to each of the state-wide daily time-series for notifications, hospitalisations, ICU admissions and deaths. This was then multiplied by terms for the daily time-series of notifications for each cluster, smoothed with a four-day moving average, using normal distributions. As there is no requirement for individuals living in a cluster catchment to attend that health service, we allocated each cluster a proportion of each notification according to the historical tendency of persons from each Local Government Area (LGA) to attend a hospital from that cluster (such that daily cluster-specific notification and death counts are not integer-valued).

Results

Calibration fit

We achieved good calibration fits to all calibration targets (Figures 2-4), along with close matches to cluster-specific indicators not used for calibration (Supplemental Figures 7-10) under the framework of a single state-wide model. The epidemic peaks in the regional clusters occurred somewhat later than in the metropolitan clusters, which is attributable to the modelled infection first being seeded in the metropolitan regions before triggering epidemics outside of Greater Melbourne and is consistent with historical reality. These fits were associated with a post-wave proportion of the population recovered of around 1-2%, with higher proportions in metropolitan regions and young adults (Figure 9).

Parameter estimation

The posterior estimates of model calibration parameters are presented in Table 1. Several epidemiological parameters with good evidence from international studies showed posteriors that were consistent with prior beliefs. This prevented overfitting, reduced the degree of freedom and provided better estimates of key free parameters including the effect of time-varying processes, allowing insights into the dynamics of the epidemic. The unadjusted risk of transmission per contact (specifically the risk of transmission per contact between a susceptible person aged 15-64 years and a symptomatic infectious person not in isolation) was estimated at 2-5%. This needed to be adjusted for each cluster modelled, with the modifiers applied to the metropolitan clusters reaching values up to double that for the regional clusters (other than Barwon South West). The extent of mixing between geographical patches was low, with around 1-2% of the total force of infection contributed by regions other than the index patch.

Estimates of the incubation period, the infectious period, the period prior to ICU admission and the duration in ICU were similar to our prior estimates derived from the literature.

Likewise, the estimated proportion of incident cases resulting in symptomatic disease was

similar to our prior estimate. However, the risk of hospitalisation (and hence ICU admission) and of death given infection were considerably greater than our age-specific prior estimates obtained from the literature. This likely reflects higher rates of exposure and infection in population groups at particularly high risk of adverse outcomes, including residents of aged care facilities.

The case detection rate associated with a testing rate of one test per 1,000 population per day was estimated at 33.0% (95%CI, 22.4-45.3), such that peak rates of detection of symptomatic infections were estimated at greater than 60%.

To understand the reasons behind the epidemic curve plateauing at the start of August and beginning to decline thereafter, we were particularly interested in parameters governing the effect of time-varying processes. We estimated that physical distancing behaviours and face coverings were both important in achieving control of Victoria's second wave, with face coverings estimated to have reduced transmission and infection risk by around 31 to 46%, while fitting to data provided little information on the effect of seasonal forcing (around 9 to 45%). Physical distancing behaviour was estimated to have reduced risk of transmission/infection by around 6 to 28%, although the smaller changes in reported adherence to this intervention (Supplemental Figure 5) meant that this had a lesser impact on the epidemic profile. For the behavioural changes in particular, the posterior probability density was substantially more informative than the prior and had negligible density around the value of zero, consistent with an effect of each of these interventions in reversing the epidemic trajectory. Additionally, the posterior probabilities of the parameters were only moderately collinear (Figure 8), supporting independent effects for each process.

Counterfactual scenarios

Figure 10 presents four counterfactual scenarios in addition to the baseline scenario. The effect of re-opening schools from 9th July (the date that stage 3 restrictions were imposed) was projected to be modest, with daily case rates peaking around 200 higher than under baseline conditions, but with the epidemic profile otherwise broadly similar. The effect of not

mandating face coverings was projected to be dramatic, with case numbers in the thousands for several months under the counterfactual of face coverings usage remaining at the baseline level of 13.0%. Returning to full mobility from 9th July resulted in a similarly poorly controlled epidemic, under the assumption that face coverings usage could not then have reached the baseline estimate of >90% compliance in all workplaces and other locations if industries such as hospitality were fully re-opened. An epidemic unmitigated by any movement and behavioural restrictions was projected to substantially overwhelm expanded ICU capacity.

Discussion

We found that the improvement in Victoria's second wave of COVID-19 cases could be well captured in our transmission model through a combination of time-variant processes that included: testing rates, population mobility, use of face coverings, physical distancing and seasonal forcing. The lower rates of COVID-19 observed in regional clusters were captured with the introduction of the infectious seed through the metropolitan clusters only, without needing to unrealistically manipulate the risk of transmission by cluster. Risk of infection in metropolitan areas was estimated to be up to double that of regional areas, consistent with international findings of a moderate correlation between population density and epidemic severity.⁵ Although Barwon South West showed transmission rates that were more comparable to metropolitan Melbourne, this region includes Victoria's second largest city of Geelong. Interaction between populations of different clusters was low in the context of significant restrictions on movement between regions. Each of the time-varying processes modelled appeared to be important to the observed dynamics, with both face coverings and behavioural changes associated with a significant reduction in transmission risk per contact. However, face coverings had a considerably greater effect on reversing the epidemic, which was observable due to the sharp transition in the extent of their use when they were mandated.

Victoria's second wave of cases was dramatically different from its first autumn wave, which was driven by importations and during which time the effective reproduction number was consistently estimated to be below one.^{14,15} Victoria's second wave was initiated by quarantine escape, from which widespread community transmission soon followed. Progressively more extensive lockdown measures were then implemented, with local targeting of specific residential blocks and then postcodes, which were insufficient to reverse the epidemic trajectory.

As noted previously, stage 3 restrictions were associated with a reduction in the effective reproduction number,¹⁶ although significant case rates persisted throughout July, and further reductions in mobility were observed with stage 4. An agent-based model with detailed social networks consideration of multiple intervention types and without geographical structure was calibrated to the Victorian epidemic.¹⁷ This model emphasised the importance of associations between individuals who would not otherwise be in regular contact to the epidemic. By contrast to previous work, our model captures the temporal and spatial implementation of the policy changes in Victoria to allow inference of the effect of each intervention. As concern increased that epidemic control had not been achieved over the course of July, policy changed rapidly in an attempt to bring the epidemic under control. Testing numbers increased following a nadir in early June and lockdown measures were implemented differently in twelve Melbourne postcodes, the remaining postcodes of Greater Melbourne, Mitchell Shire (immediately north of Greater Melbourne) and the remainder of regional Victoria. We captured these complicated geographical patterns of restriction by scaling our mixing matrices using Google mobility data, which are available at the LGA level for Victoria. School closure and face covering policy changes were captured according to the dates of policy changes.

Most of the inferred parameters were consistent with previous evidence, including a potentially important effect of seasonal forcing in terms of the absolute reduction in virus transmissibility.¹⁸ The minimal information provided on seasonal forcing is likely attributable to our simulation period spanning less than four months and so covering a small proportion

of the cycling period, such that the effect could represent other secular changes during the period modelled. Sensitivity analysis (not presented) with seasonal forcing set to zero throughout the simulations made a negligible difference to the estimates for the other parameters of interest. The effect of face coverings was greater than is typically estimated at the individual level,¹⁹ but is consistent with the dominant importance of the respiratory route to transmission.²⁰ The finding was also not unexpected given the marked shift in population use of face coverings at this time and the timing of the policy change in late July relative to the dramatic reversal in case numbers occurring around one week later. The significant estimated effect of behavioural changes suggests that reductions in interpersonal associations (macro-distancing) alone were insufficient to achieve the dramatic reversal in the epidemic trajectory observed. However, the Google mobility functions used to capture macro-distancing simulated falls in attendance at workplaces and other non-household locations to considerably below baseline values in several clusters (Figure 1), emphasising their importance. The dramatic effect of each of these interventions on the epidemic trajectory is partly attributable to our implementation of these processes as applying to both the infectious cases and the exposed individual. This approach is analogous to simulating the use of bed-nets for malaria control, where the overall effect of the intervention is quadratic, as it affects both the disease vector and the infection reservoir.²¹

Despite the complexity of our model, it is inevitably a simplification of reality. Although we assumed that asymptomatic cases were undetectable, this was addressed by varying two epidemiological parameters pertaining to these patients, and the posterior estimate of the infectiousness of asymptomatic cases suggested around threefold lower infectiousness per unit time. Our findings relating to the impact of time-varying interventions could be proxies for other effects. For example, although we considered that the effectiveness of case detection scaled with the number of tests performed, changes in the effectiveness of tracing, testing and isolation activities during the course of the epidemic wave may also have been important.

Victoria's second wave is known to have had particularly dramatic effects on residents of aged care facilities and health care workers, which we did not explicitly capture except by varying parameters relating to disease severity. Because of this, it was necessary to scale international estimates of the age-specific infection fatality rate around two- to three-fold. Although this factor seems extreme, age-specific infection fatality rate estimates increase dramatically with age,⁷ and it should be noted that the age-specific infection fatality rate parameters we used increase up to three-fold with each successive decade of age.⁶ Therefore, an age distribution of the infected population that is one decade higher than that simulated would be expected to have a comparable effect. Our age-specific estimates of the risk of hospitalisation given symptomatic COVID-19 do not fully capture the consideration that hospital admission is driven by factors other than disease severity, including infection control and workforce capacity and staff isolation requirements in residential aged care facilities, which were particularly important to this epidemic wave.

With the state's explicit objective of achieving no community transmission in Victoria (and therefore across Australia) within a few months,^{22,23} our findings emphasise that multiple interacting components of the public health interventions were required to achieve this within the modelled period.^{24,25} Consistent with findings from elsewhere,^{26–28} without reductions in contacts outside the home and mandating the use of masks, there would have been no reasonable prospect of driving transmission to zero within a time period tolerable to the community, given the starting point of the epidemiological situation in late July. The small effect of school closures was also consistent with findings from overseas,^{25,29} although if schools had remained open throughout the epidemic wave, some additional weeks would likely have been required for transmission to decline to the point that elimination was an immediate prospect. Nonetheless, it is encouraging that in a low transmission scenario, school closures are likely not necessary to gain control in the presence of other effective population-level restrictions, including masks.

In conclusion, we found that Victoria's major second wave of COVID-19 was brought under control through a combination of policy interventions that were synergistic and together

contributed substantially to the dramatic reversal in the observed epidemic trajectory. In particular the considerable individual-level effect of face coverings was critical to achieving epidemic control, and so should be a cornerstone of any public health response given the much lesser inconvenience associated with their use compared to restrictions on mobility. Rates of hospitalisation and death were higher than anticipated given international estimates of parameters pertaining to these quantities, likely reflecting the concentration of the epidemic in high-risk groups, particularly residents of aged care facilities. As vaccination is rolled out as a more targeted intervention, protection of high-risk settings, including aged care will be critical, particularly in regions with low or negligible population immunity that remain at risk of explosive epidemics.

Author declarations

BS and ACC wish to emphasise their important statutory roles during Victoria's pandemic response in 2020, as Chief Health Officer and acting Chief Health Officer respectively. MJL and GWD were also employed by DHHS during 2020. JMT provided regular advice to DHHS during this time as an independent advisor.

Funding statement

The Epidemiological Modelling Unit of Monash University provided the health system cluster-level projections for notifications, admissions and deaths under contract to the Victorian Department of Health and Human Services in 2020. JMT is a recipient of an Early Career Fellowship from the Australian National Health and Medical Research Council (APP1142638).

Acknowledgements

We gratefully acknowledge the support and advice of staff of the Victorian Department of Health and Human Services (now the Victorian Department of Health) for provision of data and assistance with its interpretation. We thank A/Prof Nicholas Golding for providing the micro-distancing compliance factors.

Contributor statement

JMT and RR constructed the model. GD, MJL and JN assisted with provision of data. JMT wrote the first draft of the manuscript, which was then revised with input from all authors.

Abstract

To study bacterial coinfection following 1918 H1N1 influenza virus infection, mice were inoculated with the 1918 influenza virus followed by *Streptococcus pneumoniae* 72 h later. Coinfected mice exhibited markedly more severe disease, shortened survival time and more severe lung pathology, including widespread thrombi. Transcriptional profiling revealed activation of coagulation only in coinfecting mice, consistent with the extensive thrombogenesis observed. Immunohistochemistry showed extensive expression of tissue factor (F3) and prominent deposition of neutrophil elastase on endothelial and epithelial cells in coinfecting mice. Lung sections of SP-positive 1918 autopsy cases showed extensive thrombi and prominent staining for F3 in alveolar macrophages, monocytes, neutrophils, endothelial and epithelial cells, in contrast to coinfection-positive 2009 pandemic H1N1 autopsy cases. This study reveals that a distinctive feature of 1918 influenza virus and SP coinfection in mice and humans is extensive expression of tissue factor and activation of the extrinsic coagulation pathway leading to widespread pulmonary thrombosis.

1918 influenza; *Streptococcus pneumoniae*; coinfection; inflammation; extrinsic pathway of coagulation; pulmonary thrombosis

Introduction

The 1918 influenza pandemic was responsible for the deaths of ~50 million people [1]. There is abundant evidence for secondary bacterial pneumonia being the predominant cause of death. A review of detailed epidemiology, pathology and microbiology findings in >8 000 post-mortem examinations consistently implicated secondary bacterial pneumonia, caused by common upper respiratory-tract bacteria, in most fatal influenza cases [2,3].

Enhanced pathology associated with viral-bacterial coinfection is well documented and several possible mechanisms have been proposed (reviewed in [4,5]). Specifically, viral-mediated changes in the respiratory tract, including epithelial damage, alterations in airway function and exposure of receptors, are thought to prime the upper airway for secondary bacterial infection [4]. Both enhanced and dysfunctional innate immune responses have also been implicated in the increased severity of coinfection [5]. Finally, bacteria-mediated cleavage of the viral haemagglutinin (HA) antigen has been suggested as a mechanism for increased viral replication following bacterial challenge, potentially leading to more severe lung damage and poor outcome in coinfecting mice [6,7]. Interestingly, synergism during coinfection appears to be influenced by both viral and bacterial strain-specific factors [8]. Differences in the abilities of *Streptococcus pneumoniae* (SP) strains to replicate in lungs of mice following infection with influenza was associated with differential mortality, suggesting strain specificity in the ability of SP to cause pneumonia during influenza infection [9]. Secondary infection with SP resulted in a lethal coinfection in mice inoculated with 2009 pandemic H1N1, but not seasonal H1N1, and was associated with loss of airway basal epithelial cells and lung repair responses [10]. Similar studies suggest bacterial strain-related differences also influence the synergy between *Staphylococcus aureus* and influenza virus [11].

Infection with 1918 influenza has been shown to result in severe lung pathology typified by necrotizing bronchitis, bronchiolitis, neutrophil-predominant alveolitis, and acute oedema associated with significant activation of antiviral, pro-inflammatory and cell death response genes in lung tissue in animals and humans [12-15]. The inflammatory response induced by 1918 infection has been shown to be immunopathogenic in mice and results in significant activation of reactive oxygen species (ROS) with marked oxidative damage to respiratory epithelial cells [16].

While secondary bacterial infections caused the majority of deaths during the 1918-1919 influenza pandemic, little is known about the underlying mechanisms responsible for the synergy between 1918 influenza and bacteria. In the current study, effects of secondary SP infection in mice that were infected with the 1918 influenza virus were investigated. SP was chosen because it was the most commonly identified bacteria in fatal 1918 influenza cases [2,3]. The results show that SP secondary infection greatly enhanced lung pathology in

mice; it shortened survival, increased early bacterial replication, and altered the host response to infection, with evidence including increased neutrophil activation and activation and aggregation of platelets and clotting. (AQ: please check this sentence retains your intended meaning). Histological and immunohistochemical analyses validated this thrombogenic response and showed abundant thrombi and extensive staining for F3. Importantly, staining of two SP-positive 1918 autopsy cases showed similar extensive F3 staining along with abundant thrombi. In contrast, minimal F3 staining and no thrombi was observed in SP- or *Streptococcus pyogenes*-positive 2009 pandemic H1N1 fatalities. These data support and expand observations of pulmonary thrombi observed in post mortem examinations of 1918 virus autopsies [17,18] and demonstrate that widespread pulmonary vascular thrombogenesis was a feature of 1918 pandemic H1N1 and SP coinfection, which may help explain the high death toll of the 1918 pandemic.

Materials and Methods

Viruses and bacteria

The reconstructed 1918 influenza virus, A/Brevig Mission/1/1918 (H1N1), was rescued and titred using published protocols [16,19]. SP strain A66.1 (serotype 3; x0en10; Perkin Elmer) and grown as described in [10]. All work with the reconstructed 1918 influenza virus was performed in enhanced BSL-3 and enhanced ABSL-3 laboratories at the NIH in accordance with the Biosafety in Microbiological and Biomedical Laboratories (BMBL), 5th Edition, and the Division of Select Agents and Toxins at the Centers for Disease Control and Prevention (DSAT/CDC) and the NIH and under supervision of the Biosurety Program of the NIH Department of Health and Safety.

Mouse infection studies

Groups of five 8-9 week old female BALB/c mice (Jackson Labs, Bar Harbor, ME) were placed under light anaesthesia as described in [10] and inoculated with 5×10^2 PFU of the reconstructed 1918 H1N1 influenza virus; sham inoculated with PBS at this time (day 0); or inoculated intra nasally (AQ: please check this substitution) with 10^5 colony-forming units (CFU) of SP at 3 days post-virus. Virus-alone groups were sham inoculated with PBS at day 3. Body weights were measured daily for 7-10 d post-infection and mice were humanely euthanized if they lost more than 25% of starting body weight. Lungs from three animals were collected for RNA isolation and from two animals for pathology at day 3 to 6 post-1918 (day 0 to +3 post-SP, respectively). Lungs collected for pathology were inflated with 10% neutral buffered formalin at the time of isolation. All experimental animal work was performed in accordance with United States Public Health Service (PHS) Policy on Humane Care and Use of Laboratory Mice in an enhanced ABSL-3 laboratory at NIH following approval of animal safety protocols by the NIAID Animal Care and Use Committee and in accordance with DSAT/CDC.

RNA isolation and expression microarray analysis

Total RNA was isolated from lungs and used for gene expression profiling using Agilent Mouse Whole Genome 44K microarrays as described in [10,16] and Supporting Information online. In brief, RNA from three biological replicates per condition was labelled and

hybridized to individual arrays and processed as described in [10,16]. Data normalization was performed in Analyst using central tendency followed by relative normalization using pooled RNA from mock infected mouse lung (n=4) as a reference. Transcripts showing differential expression (2-fold, $p < 0.01$) between infected and control mice were identified by standard t test. The Benjamini-Hochberg procedure was used to correct for false positive rate in multiple comparisons. Ingenuity Pathway Analysis was used for gene ontology and pathway analysis. The complete microarray dataset has been deposited in NCBI Gene Expression Omnibus [20] and is accessible through GEO Series accession number GSE70445.

Reverse Transcription Quantitative-PCR

RT-qPCR was used to estimate bacterial and viral loads in lung tissue. Reverse transcription of total lung RNA was performed with primers specific for influenza M gene, mouse *Gapdh*, SP 16S rRNA, *endA*, *nanA*, *nanB*, or *ply* using standard protocols. Primers are listed in Table S1. Quantification of each gene's C_T was graphed relative to that of the calibrator as described in [10].

Histopathology and immunohistochemistry

Mouse tissue samples were processed for histopathological examination using standard protocols. Gram staining was performed using the method of Brown and Hopps, and Movat's pentachrome staining was performed using standard protocols. Mouse immunohistochemical studies were performed using standard protocols [19] following heat-mediated antigen retrieval using antibodies specific to CD11b, ELANE, F3, MPO, thrombin, Ly6g (clone 1A8) or TPA as described in Supporting Information. Immunohistochemical studies on human 1918 and 2009 pandemic H1N1 autopsy cases used 5 μ m thick sections cut from the FFPE lung tissue blocks from cases described previously [3,21] and stained for F3 as described in Supporting Information. These samples were considered exempt for human subjects review under US Government guidelines (<http://www.hhs.gov/ohrp/policy/checklists/decisioncharts.html#c5>).

Results

Bacterial coinfection accelerated mortality of 1918 pandemic influenza virus infection

To study effects of secondary bacterial infection following primary influenza virus infection, mice were inoculated intra nasally with 5×10^2 PFU of the 1918 virus followed by inoculation with 10^5 CFU SP 72 h later. Mice inoculated with 1918- alone exhibited significant weight loss with 100% mortality by day 11 post-inoculation (Fig. 1A-B). Mice inoculated with SP-alone displayed weight loss with 100% mortality by day 7 post-SP (day 10 post-1918). Mice coinfectd with 1918 virus followed by SP 72 h later (1918+SP), showed more severe illness than mice inoculated with virus- or SP-alone, with 100% mortality by day 6 post-1918 (day +3 post-SP). Significantly, the majority of deaths in 1918+SP groups occurred in moribund mice prior to reaching 25% weight loss euthanasia criteria. The results shown are typical of three independent experiments.

Increased bacterial load and SP virulence factor expression during coinfection

Expression of influenza virus M gene RNA and bacterial 16S rRNA in lungs of infected mice was measured by RT-qPCR. The lungs of 1918 virus alone infected mice had consistent viral loads throughout the time-course (Fig. 1C). Mice exposed to 1918 virus followed by SP had similar viral levels at 4 days post-1918 (day +1 post-SP), but significantly lower levels at days five and six post-1918 inoculation compared to mice exposed to virus alone ($p < 0.05$). Bacterial levels were significantly higher in 1918+SP compared to SP-alone infected mice at days 4 and 5 post-1918 (days +1 and +2 post-SP), but equivalent at 6 d post-1918 (day +3 post-SP) (Fig. 1D). Detection of 16S rRNA in spleen tissue by RT-qPCR from both SP and 1918+SP mice provided evidence of bacteraemia on days 5 and 6 post-1918 (days +2 and +3 post-SP, respectively) (Fig. S1). The expression of several important SP virulence factor genes [22] were also measured by RT-qPCR and normalized to bacterial 16S rRNA (Fig. 1E), including pneumolysin (*ply*), endonuclease A (*endA*); and neuraminidases *nanA* and *nanB*. At day 4 to 6 post-1918 (day +1 to +3 post-SP), *ply*, *endA*, *nanA* and *nanB* RNA were detected in 1918+SP mice. In contrast, very low or undetectable levels of *endA*, *nanA* and *nanB* RNA were observed in SP-alone infected mice.

Bacterial coinfection significantly enhances lung pathology

Lungs from mice were collected at days 3-6 post-1918 (days 0 to +3 post-SP) for histopathology. A unique gross pathological feature of the 1918+SP infected mice on days 4-5 (days +2 and +3 post-SP) was the presence of extensive fibrinous pleuritis with instances of fusion of the lungs to the chest wall and diaphragm. Lung pathology was evaluated in mice at days 4 to 6 following viral infection. In infected animals, histopathological changes increased from days 4 to 6, and day 6 pathology is described in here (Fig. 2). Mock-infected mice showed no histopathological changes in their lungs (Fig. 2A-C). SP-infected mice showed mild, focal changes (Fig. 2D-F), including focal acute bronchiolitis and rare microscopic foci of acute pleuritis. Gram-positive bacteria morphologically consistent with SP were occasionally observed within the focal lesions (not shown). 1918 virus-infected mice showed a more severe pathology, affecting >25% of the lung parenchyma (Fig. 2G-I), with widespread acute bronchiolitis and multifocal areas of acute alveolitis characterized by a mixed inflammatory cell infiltrate with prominent neutrophils in both alveolar airspaces and interstitium (Fig. 2I). Coinfected mice showed very severe histopathological changes affecting >50% of lung parenchyma (Fig. 2J-L) with consolidation consisting of an acute pneumonia, featuring alveolar airspaces packed with neutrophil- and macrophage-predominant inflammatory infiltrates, extensive acute suppurative pleuritis, widespread necrotizing bronchiolitis, and abundant fibrin thrombi in veins, venules, and capillaries (Fig. 2J, arrow).

Bacterial coinfection causes perturbations in inflammation-related coagulation homeostasis

Global transcriptional profiling was performed on lung tissue mRNA at days 3-6 post-1918 (day 0 to +3 post-SP). For each experiment, mRNA from an individual infected animal was compared to mRNA from a pool of mock-infected mice ($n = 4$). Approximately 14 800

sequences showed a 2-fold change in expression ($p < 0.01$) in at least one experimental group (Fig. S2). The expression levels of 457, 1412, and 1 487 transcripts differed significantly (2-fold, $p < 0.01$) between mice infected with 1918-alone and 1918+SP at days 4, 5, and 6, respectively, correlating with increased differences in disease pathology throughout the time-course. At day 4 post-1918 (day +1 post-SP), the direction of gene expression changes were similar between 1918 alone and 1918+SP, with enhanced magnitude of change generally observed in coinfecting mice (Fig. 3A). Expression during SP-alone infection is shown for comparison. However, by days 5 and 6 post-1918 (day +2 and +3 post-SP) there were also increasingly larger groups of sequences that showed increased expression only in 1918+SP-infected mice.

Functional annotation of differentially expressed genes between 1918 and 1918+SP infected mice revealed enrichment of genes related to inflammatory response, immune cell trafficking, haematological system, and genes related to tissue injury (Fig. 3B). The distribution of enriched functional groups was generally consistent across all time points, with the exception of day 4 which showed higher enrichment of ROS scavenging and lower involvement of immune cell trafficking and inflammation, coinciding with a significantly higher bacterial burden (Fig. 1D). Examination of expression of an additional ~700 inflammatory mediators revealed that while 1918+SP coinfection was associated with increased expression of genes relative to 1918-alone, differences were modest (Fig. S3). Furthermore, many inflammation-related genes that showed higher expression levels or were specifically increased in 1918+SP mice relative to 1918-alone infected mice were not increased in SP-alone mice (Fig. S3).

Many immune response-related genes that were either more highly expressed or uniquely expressed in 1918+SP mice at day 5 are involved in neutrophil recruitment/activation, platelet aggregation/activation and coagulation (Fig. 3C-E). Levels of the mRNA for certain chemokines and adhesion molecules mediating neutrophil infiltration (e.g., *Ccl2*, *Ccl7*, *Cd177*, and *Itgam*) were significantly higher in 1918+SP-infected mice relative to 1918-alone. In contrast, those for other chemokines and adhesion molecules (e.g., *IL15*, *Ccl11*, *Ccl24*, *Itgb2*, *Ccr12*) were increased only in 1918+SP mice. Notably, many key neutrophil activation marker mRNAs were also either uniquely increased (including granule components *Mpo*, cathepsin G (*Ctsg*), *Dao*, *Mmp9*, *Fcgr3* and *Fpr2*) or more highly increased (*Mmp8*, *Fcgr1*) in 1918+SP infected mice. Certain neutrophil-related genes (including *Cleblb*, cathepsin G (*Ctsg*), *F3*, *Pf4* and *Itgb2*) also function to promote platelet aggregation/activation. Levels for Proteinase 3 (*Prtn3*), encoding a serine protease that contributes to the proteolytic generation of antimicrobial peptides and also inhibits clearance of apoptotic neutrophils, promoting inflammation, were also increased (Fig. 3C).

Expression of genes associated with platelet aggregation included those from Gp1b-IX-V/GpVI-dependent platelet activation pathway (collagen 1, *Itgb2*, and glycoproteins *Gp-1B alpha*, *Gp-1B beta*, Gp-V, Gp-VI, and Gp-IX) (**AQ: not all of these are approved mouse gene names**), which plays a critical role in collagen-induced platelet aggregation and thrombus formation at sites of vascular injury, were also significantly higher in 1918+SP infected mice (Fig. 3D). Similarly, increased mRNA levels for other genes involved in platelet aggregation were observed in 1918+SP mice including platelet-activating factor

receptor (*Ptafr*), thrombospondin s1 (*Thbs1*), platelet factor 4 (*Pf4*), a chemokine released from alpha granules of activated platelets, and purinergic receptor P2Y, G-protein coupled, 12 (*P2ry12*), a neutrophil-specific receptor. Pro-platelet basic protein (*Pbbp*), which protein activates neutrophils and stimulates the secretion of plasminogen activator, was increased only in 1918+SP mice.

Consistent with gene expression data supportive of enhanced platelet activity, increased expression of numerous coagulation cascade genes, including those for factors III, V, X, and XIII (Fig. 3E) was observed in coinfecting mice. Levels for Tissue plasminogen activator (*Plat*), encoding the key enzyme responsible for converting plasminogen to plasmin and urokinase plasminogen activator receptor (*Plaur*) were also significantly induced only in coinfecting mice. Concordantly, increased *Plat* expression was observed in 1918+SP mice by immunohistochemistry (Fig. S4). Increased expression of genes that inhibit platelets and coagulation was also observed, including tissue factor pathway inhibitor 2 (*F3pi2*), *Serpine1*, *Serpine3*, annexin A3 (*Anxa3*) and phospholipase A2 group VII (*Pla2g7*). Similar to the observations for neutrophil-related genes, expression of the majority of genes involved in platelet function and coagulation were not increased in SP-alone mice.

Neutrophil activation and deposition of elastase onto vascular endothelial cells during coinfection

To further examine the neutrophil infiltration and activation, mouse lung sections were immunostained for Ly6G, myeloperoxidase (MPO), and neutrophil elastase (ELANE), key enzyme constituents of azurophilic granules in neutrophils. 1918-SP-coinfection produced extensive and progressive infiltration of LY6G-positive neutrophils with particularly high expression in lung regions with the greatest histopathological changes, in contrast to the lower, but clearly detectable, accumulation of LY6G-positive neutrophils in mice infected with 1918- or SP-alone (Fig. 4). In coinfecting mice, cellular infiltrates expressed high levels of MPO and ELANE compared to lower expression in mice infected with 1918- or SP-alone. The 1918+SP infected mice also showed increased extracellular ELANE deposition along the endothelium of many blood vessels consistent with an enhanced degranulation response. Similarly, ELANE was also prominently expressed on alveolar and bronchiolar epithelium and neutrophils in 1918+SP infected mice (Fig. 4H). Immunohistochemical time courses for Ly6G, MPO, ELANE and the monocyte/neutrophil marker CD11b are shown in Figs. S5-S8.

Activation of coagulation and vascular thrombogenesis in lungs of coinfecting mice

Immunohistochemical staining of day 6 mouse lung sections with F3 revealed differential staining between groups (Fig. 5). SP-infected mice showed only minimal F3 staining (Fig. 5 A), especially around regions of bronchiolitis, both in respiratory epithelial cells and inflammatory cells. No evidence of vascular pathology was noted (Fig. 5 B-C). 1918-infected mice showed widespread F3 staining in areas of bronchiolitis and alveolitis (Fig. 5 D). Vessels showed prominent perivascular inflammatory cell infiltrates (Fig. 5 E-F) without evidence of thrombus formation. In marked contrast, coinfecting mice showed extensive and very prominent F3 staining throughout the lungs, especially in areas of acute pneumonia, bronchiolitis, and pleuritis (Fig. 5G & J). Unlike the other groups, there were also abundant

thrombotic lesions in small veins, venules and capillaries (Fig. 5H, I, K, L), consisting of fibrinous thrombi, sometimes with recanalization (Fig. 5 K, L). Examination of F3 expression over the infection time course revealed marked accumulation of F3 staining in the lungs of coinfecting mice, and to a lesser extent in the 1918- and SP-infected mice (Fig. S9). Similarly, 1918+SP-coinfection also resulted in prominent thrombin staining (Fig. S10).

Extensive expression of F3 and occurrence of vascular thrombi in 1918 pandemic autopsy samples with bacterial coinfection

Postmortem lung tissue sections from victims of the 1918 [3] and 2009 [21] H1N1 influenza pandemics were subsequently examined for correlative changes. F3 showed little to no immunostaining in normal lung (Fig. 6A), and only minimal levels in two 2009 pandemic autopsy cases (Fig. 6B-C). Interestingly, two 1918 pandemic autopsy cases showed marked F3 expression (Fig. 6D-F), very similar to F3 in mouse lung sections from the coinfecting group (Fig. 5G & J). As in coinfecting mouse lungs, F3 staining was observed in monocytes, macrophages, neutrophils, and also epithelial cells (Fig. 6F). Examination of ten 1918 autopsy cases showed abundant small vessel thrombosis in most cases, as previously described in 1918 [17,18]. Fibrinous thrombi were commonly observed in small veins, venules, and capillaries on examination of H&E stained lung sections (Fig. 6G-L). Some thrombi showed evidence of organization with ingrowth of fibroblasts, collagen deposition (Fig. 6J), or recanalization (Fig. 6K & L).

Discussion

In this study, SP secondary infection following 1918 pandemic virus was shown to enhance lung pathology, damage endothelial cells and activate coagulation in mice. These attributes of 1918+SP coinfection fulfil the requirements for thrombosis in Virchow's triad of reduced flow, hypercoagulability, and endothelial damage (Fig. S11). Significantly, findings from the mouse model were validated in 1918 human lung autopsy samples from two SP-positive cases. These cases showed intense and widespread F3 staining in neutrophils, monocytes, alveolar macrophages, as well as epithelial and endothelial cells accompanied by numerous small vessel thrombi. In contrast, minimal F3 staining was observed in SP- or *Streptococcus pyogenes*-positive 2009 pandemic H1N1 autopsy samples. Retrospective analysis of a previously published study from SP coinfecting 1918 and 2009 pandemic H1N1 autopsy samples [15] revealed that of 292 coagulation-related genes identified, 47% were more abundant in the 1918 samples, including, factor VIII (*F8*), von Willebrand factor (*VWF*), *PLAUR* and *PLAT*; while only 6% of these gene transcripts were more abundant in the 2009 autopsy samples. The findings of widespread thrombi and extensive expression of clotting factors strongly support activation of coagulation during 1918+SP coinfection and may explain increased fatalities associated with secondary bacterial infections during the 1918 influenza pandemic.

Increased bacterial and/or viral loads during coinfection have previously been associated with enhanced severity of influenza virus and SP coinfection [4,5,10]. Early increases in bacterial burden in 1918+SP infected mice suggests that virus-mediated damage to the respiratory epithelium increased the initial bacterial colonization, possibly by exposing

receptors for bacterial attachment [23]. Indeed, higher levels of *Ptafr*, the product of which plays a role in adhesion and invasion of *S. pneumonia*, were observed in coinfecting animals [24]. Lower levels of 1918 virus during SP coinfection are likely related to loss in tissue viability. Despite similar bacterial loads in the lungs of SP and 1918+SP infected mice at day 3 post-SP infection, there was significantly higher expression of SP virulence factors in 1918+SP mice, including *endA*, *nanA* and *nanB*, and *ply*. EndA degrades the DNA scaffold of neutrophil extracellular traps (NETs) and allow bacteria to spread from the upper airways to the lungs and into the blood-stream during pneumonia [25]; *nanA* and *nanB* play important roles in colonization [26] and *ply* has been reported to activate macrophages and neutrophils and has haemolytic and cytotoxic activities [27,28]. Differential expression of bacterial virulence factors during viral coinfection is intriguing and future studies will characterize SP virulence factor expression and roles in pathology during coinfection, which may provide insight into how viral infection-mediated immune responses modulate bacterial survival responses.

Pathology, transcript profiling, and immunohistochemical analysis of lung tissue all support perturbation of immune-related coagulation homeostasis and thrombogenesis during 1918+SP coinfection. Importantly, acute haemorrhage and thrombus formation were common findings in fatal 1918 influenza cases [3,18], suggesting the mouse model accurately reflects the underlying pathology observed in human disease. Furthermore, neutrophil transepithelial migration contributes to pulmonary oedema [29], another common finding associated with fatal 1918 infections [3]. Following 1918 influenza virus infection, the lung may be primed for perturbation of immune-related thrombosis following secondary bacterial infection. First, 1918 influenza virus is associated with enhanced damage to the respiratory epithelium relative to other influenza viruses [18]. Second, 1918 viral infection results in extensive lung infiltration of neutrophils in animals [19,30] and 1918 influenza autopsy cases [3]. It is possible that the combination of viral and bacterial stimuli result in a unique functional neutrophil phenotype, which is supported by gene expression and immunohistochemistry data of enhanced activation of neutrophils during coinfection. Increasingly, neutrophils are thought to play a key role in the interaction between inflammatory and thrombotic pathways [31-34]. The neutrophil serine proteases ELANE and cathepsin G, both of which had increased mRNA expression in 1918+SP-infected mice, are known to promote coagulation and intravascular thrombus growth through proteolysis of the coagulation suppressor tissue factor pathway inhibitor (TFPI) [34]. While infiltration of neutrophils and F3 expression is observed in mice infected with 1918 alone, there appears to be less activation of neutrophils as evidenced by less intense staining of MPO and ELANE and lower expression of numerous genes associated with neutrophil activation compared to coinfection. Exposure to SP may subsequently cause activation of extensive population of neutrophils already present in the lung, initiating the coagulation cascade, possibly through elastase/cathepsin G-mediated cleavage of TFPI. This process may further be amplified by bacteria-induced NETs, which are thought contribute to thrombosis by providing the scaffold for fibrin deposition and platelet aggregation/activation [35,36]. Therefore, while 1918-infection alone may prime the lung for thrombogenesis, in the absence of SP-induced activation of neutrophils and possibly NETs, expression of F3 and presence of neutrophils may not be sufficient for initiation of the coagulation cascade and thrombus formation. The

absence of thrombus in SP-alone infected mice can be attributed to lack of significant F3 expression and extensive infiltration of neutrophils. While SP infection alone could be associated with mortality, this may be due to different pathological mechanisms such as bacteraemia as 16S rRNA was detected in spleens of some mice as early as 2 days post-SP inoculation in both SP-alone and 1918+SP infected groups.

Secondary bacterial infections played a major role in the high mortality of the 1918 influenza pandemic, but the underlying pathophysiology responsible has not been previously investigated. While much has been learned about the genetic determinants responsible for the extreme virulence of 1918 influenza viral infection in animal models, particularly the role of the 1918 HA gene in neutrophil activation and recruitment [19,37] and the role of the viral protein PB1-F2 in susceptibility to secondary bacterial infection [38], this study represents the first investigation of the reconstructed 1918 virus and bacterial coinfection. Coinfection-induced pulmonary thrombosis would exacerbate vascular leak and alveolar oedema due to passive congestion limiting compensatory ventilation responses contributing to severe hypoxia and death (and possibly to the unusual frequency of rapid-onset cyanosis reported in 1918). Experiments evaluating efficacy of targeting neutrophil activation and/or components of the coagulation pathway to reduce severity of pneumonia during influenza viral and bacterial coinfection could open new treatment modalities.

Abbreviations

SP	<i>Streptococcus pneumoniae</i>
F3	tissue factor
ELANE	elastase, neutrophil expressed
HA	Hemagglutinin
IFN	Interferon
1918 virus	1918 H1N1 influenza virus
ROS	Reactive oxygen species
CFU	Colony forming units
PFU	Plaque forming units
qRT-PCR	Quantitative reverse-transcriptase polymerase chain reaction
MPO	myeloperoxidase
NETs	neutrophil extracellular traps
Ptafr	platelet-activating factor receptor

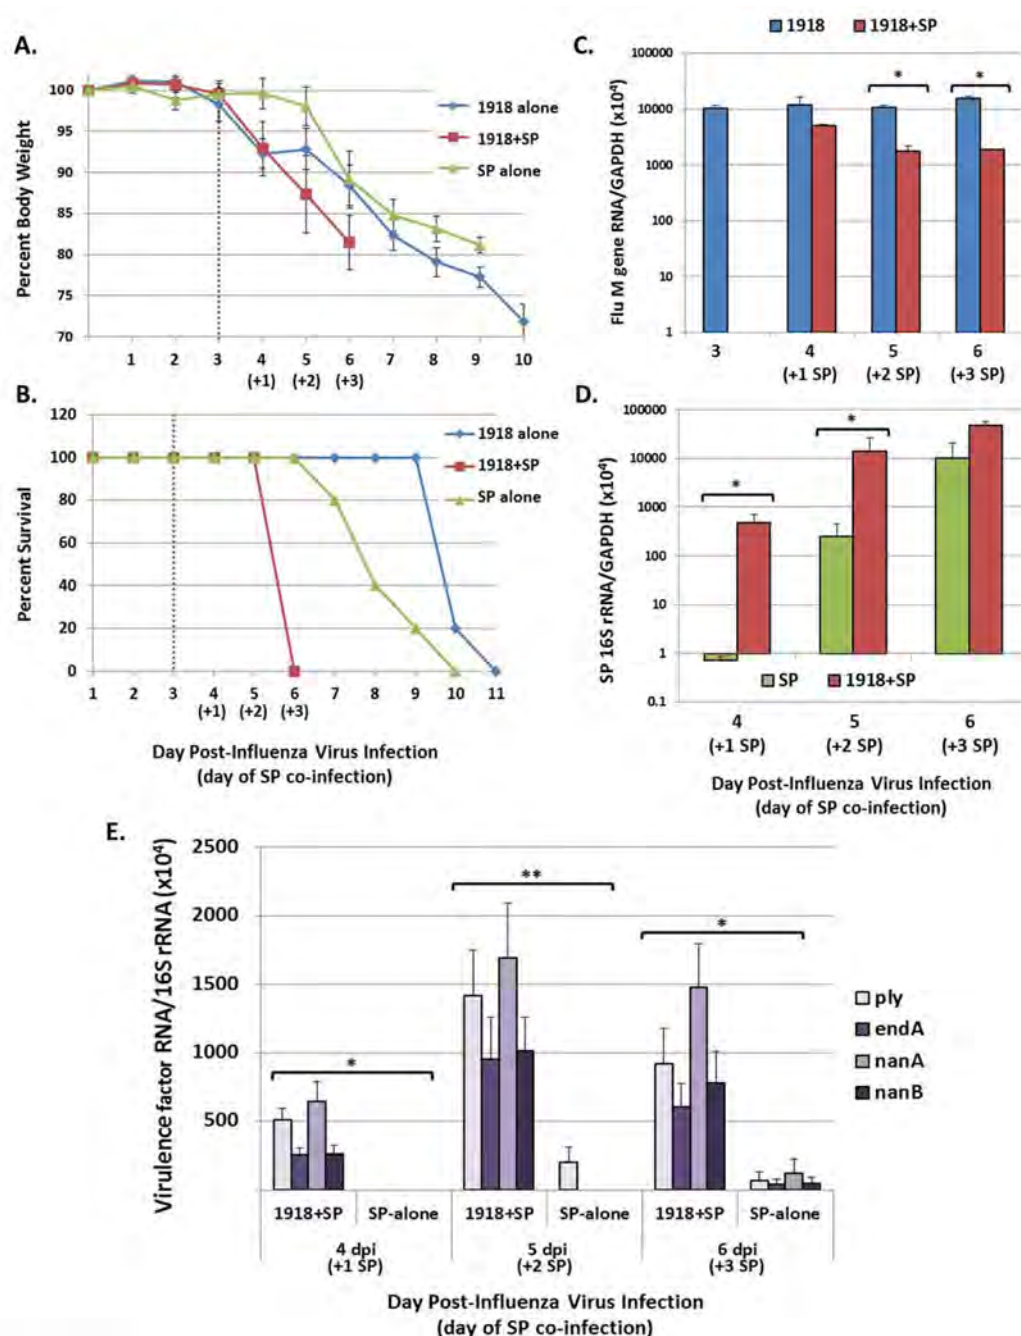

Fig. 1. Coinfection of 1918 pandemic H1N1 influenza virus and SP shortens survival and increases bacterial growth and virulence factor expression

Groups of mice were inoculated as described in Materials and methods. (A) Change in body weight following initial infection in 1918 virus-alone, SP-alone and 1918+SP infected groups. Inoculation with SP is indicated at 3 dpi following influenza virus by the dashed line. (B) Survival of 1918 virus-alone, SP-alone and 1918+SP infected mice. These data are representative of three independent experiments. (C) Quantification of influenza virus M gene mRNA expression and (D) quantification of bacterial 16S rRNA present in lung tissue using RT-qPCR. Data are presented as mean \pm standard error of the mean (SEM) of 2^{-Ct}

values relative to *Gapdh* present in RNA isolated from the lungs of three mice per group. (E) Quantification of mRNA levels of SP pneumolysin (*Ply*), endonuclease *EndA*, and neuraminidases *NanA* and *NanB* in 1918+SP and SP-alone infected lung tissue using RT-qPCR analysis. Data are presented as mean \pm SEM of 2^{-C_t} values of each virulence factor relative to 16S rRNA present in RNA isolated from the lungs of three mice per group. * $p < 0.05$ or ** $p = 0.05$ by two-tailed Mann-Whitney U-test.

Fig. 2. 1918 and SP coinfection greatly increases severity of lung pathology

Lungs from mock and infected mice were harvested at 6 days post-1918 (3 d post-SP) and were stained with H&E. (A-C) Representative photomicrographs of mock-infected mice showing (A) no lung pathology, (B) normal bronchioles (Br), and alveoli without pathology. (D-F) Representative photomicrographs of SP-infected mice showing (D) focal, mild pathological changes, including (E) focal acute bronchiolitis (Br), and (F) rare foci of pleuritis (star). (G-I) Representative photomicrographs of 1918-infected mice showing (G) multifocal pathological changes including alveolitis (arrow) affecting >25% of lung

parenchyma, (H) multifocal acute bronchiolitis (Br), and (I) an acute alveolitis with numerous mixed inflammatory cells in the airspaces and interstitium, including abundant neutrophils. (J-K) Representative photomicrographs of 1918-SP infected mice showing (J) widespread acute pneumonia with consolidation and abundant thrombi (arrow) affecting >50% of the lung parenchyma, (K) multifocal acute bronchiolitis (Br), and (L) an acute pneumonia pattern with alveolitis with numerous mixed inflammatory cells in the airspaces and interstitium, including abundant neutrophils, and extending into an acute pleuritis (star). (A, D, G, J original magnification $\times 20$; B, C, E, F, H, I, K, L original magnification $\times 200$).

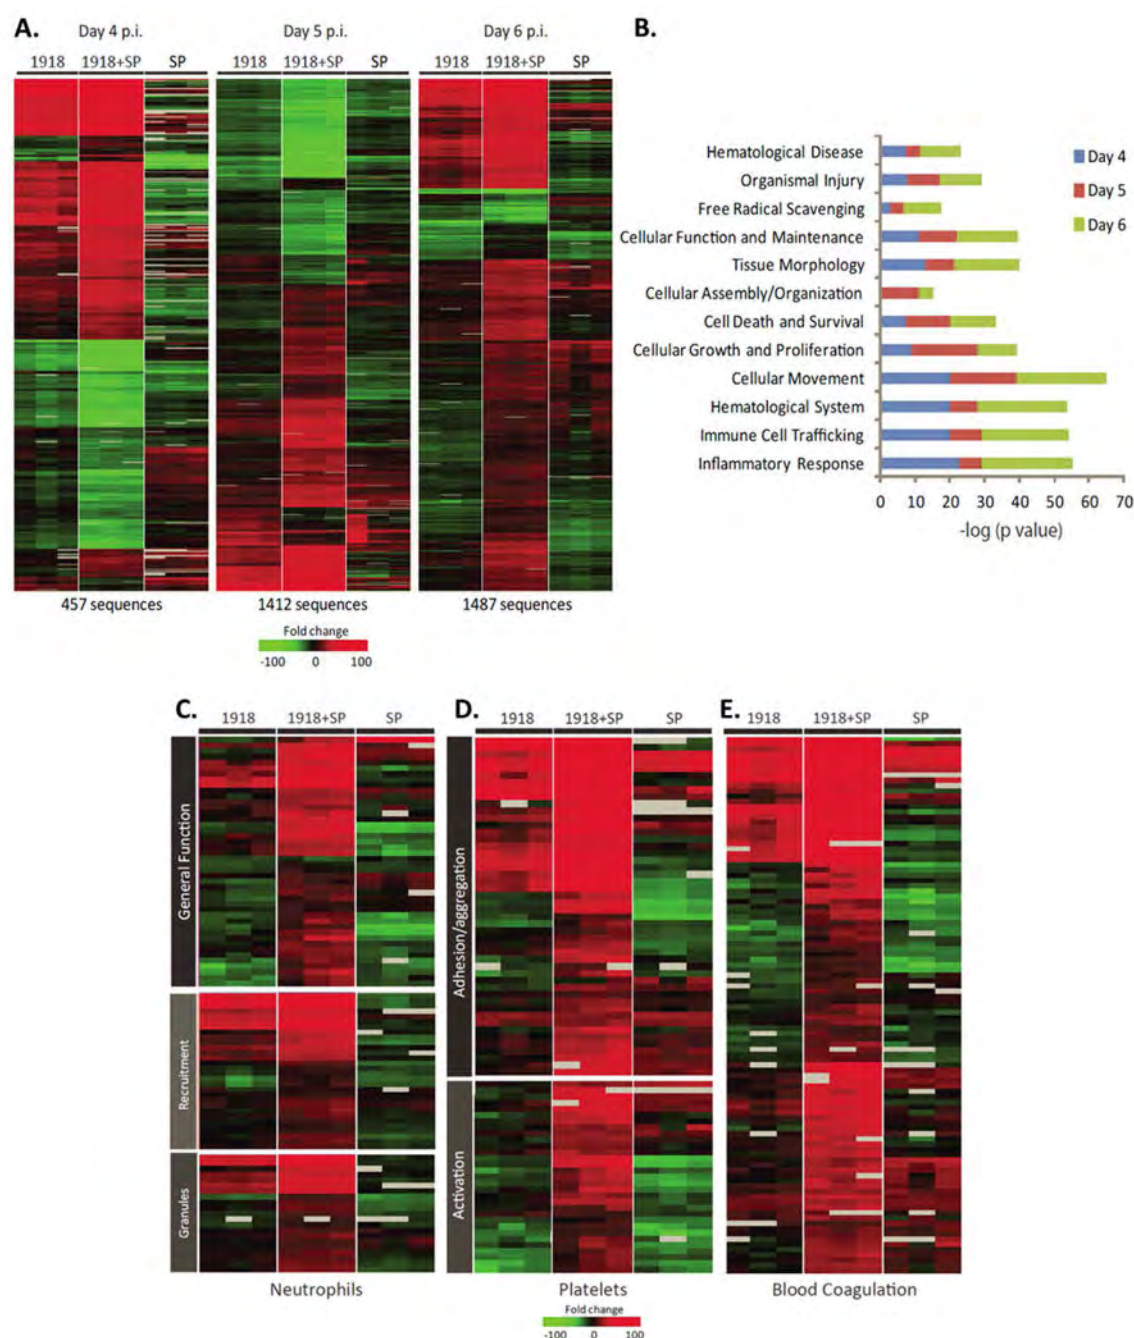

Fig. 3. Coinfection of 1918 influenza virus and SP induces a unique host response compared to either pathogen alone

(A) A standard t-test comparison was used to identify genes whose mRNA levels differed significantly (at least 2-fold difference in median expression level, $p < 0.01$) in lung tissue from 1918+SP versus 1918-infected mice. Each column represents gene expression data from an individual experiment comparing lung tissue from an infected animal relative to pooled tissue from mock infected mice ($n=9$). Red shows increased, green decreased, and black no change in mRNA levels in infected relative to uninfected mice. (B) Functional annotation analysis of genes differentially expressed between 1918+SP and 1918-infected

mice at day 4 to 6 post-1918. (C-E) Differences in host response to 1918 and SP coinfection suggest perturbations in inflammation-related coagulation homeostasis. Expression profiles of transcripts involved in (C) neutrophil infiltration and activity, (D) platelet aggregation and (E) blood coagulation that are differentially expressed in 1918, SP, and 1918+SP infected mice at day 6 post viral infection. Each column represents gene expression data from an individual experiment comparing lung tissue from an infected animal relative to pooled tissue from mock mice (n=9). Red shows increased, green decreased, and black no change in mRNA levels in infected relative to uninfected mice.

Fig. 4. 1918 and SP coinfection induces extensive neutrophil infiltration and activation

Mouse lung sections harvested at 6 d post-infection with influenza virus (3 d post-infection with SP in coinfection groups) were stained for Ly6G, a specific neutrophil marker, MPO, and neutrophil elastase (ELANE). (A-D) 1918 alone and (I-L) SP alone induced detectable increases in Ly6G-positive neutrophils with low level expression of MPO and ELANE localized primarily around large airways and blood vessels. (E-H) 1918-SP infected mice showed extensive infiltration of Ly6G-positive neutrophils with high expression levels of MPO and ELANE. Extracellular ELANE deposition was also noted on the inner lining of

many large and medium-sized blood vessels (asterisk). (H) ELANE-positive intra-alveolar neutrophils and alveolar walls (black arrows) were observed in 1918-SP infected mice whereas with (D) 1918 and (L) SP infection ELANE-positive neutrophils remained within the interstitium. (A-C, E-G, I-K original magnification $\times 100$; D, H, L original magnification $\times 600$).

Fig. 5. 1918 and SP coinfection causes significant and widespread expression of F3 and pulmonary thrombosis in mice

Lung sections from SP-infected, 1918-infected, and coinfecting mice were immunostained for F3 and pulmonary vessels were examined for pathological changes. (A-C)

Representative photomicrographs of SP-infected mice showing (A) focal F3 staining predominantly around bronchioli, and no vascular pathology. (B-C) serial sections show (B) a normal venule without perivascular inflammation or thrombosis stained with H&E and (C) stained with Movat's stain to highlight elastin. (D-F) Representative photomicrographs of 1918-infected mice showing (D) multifocal prominent F3 staining around bronchioli and

areas of alveolitis. Vessels show perivascular inflammation but no thrombi, (E) H&E and (F) Movat's stain. (G-L) Representative photomicrographs of coinfecting mice showing (G) very prominent and diffuse F3 staining around bronchioli and (J) areas of acute pneumonia. (H, I, K, L) Abundant fibrin thrombi are seen in venules (V). Perivascular inflammation was prominent in (H) H&E stain and the thrombus was highlighted with (I) Movat's stain. Another thrombus (K, L) showed recanalization (stars) seen in both (K) H&E and (L) Movat's stain. (A, D, G original magnification $\times 20$; B, C, E, F, H, I, J, K, L original magnification $\times 200$).

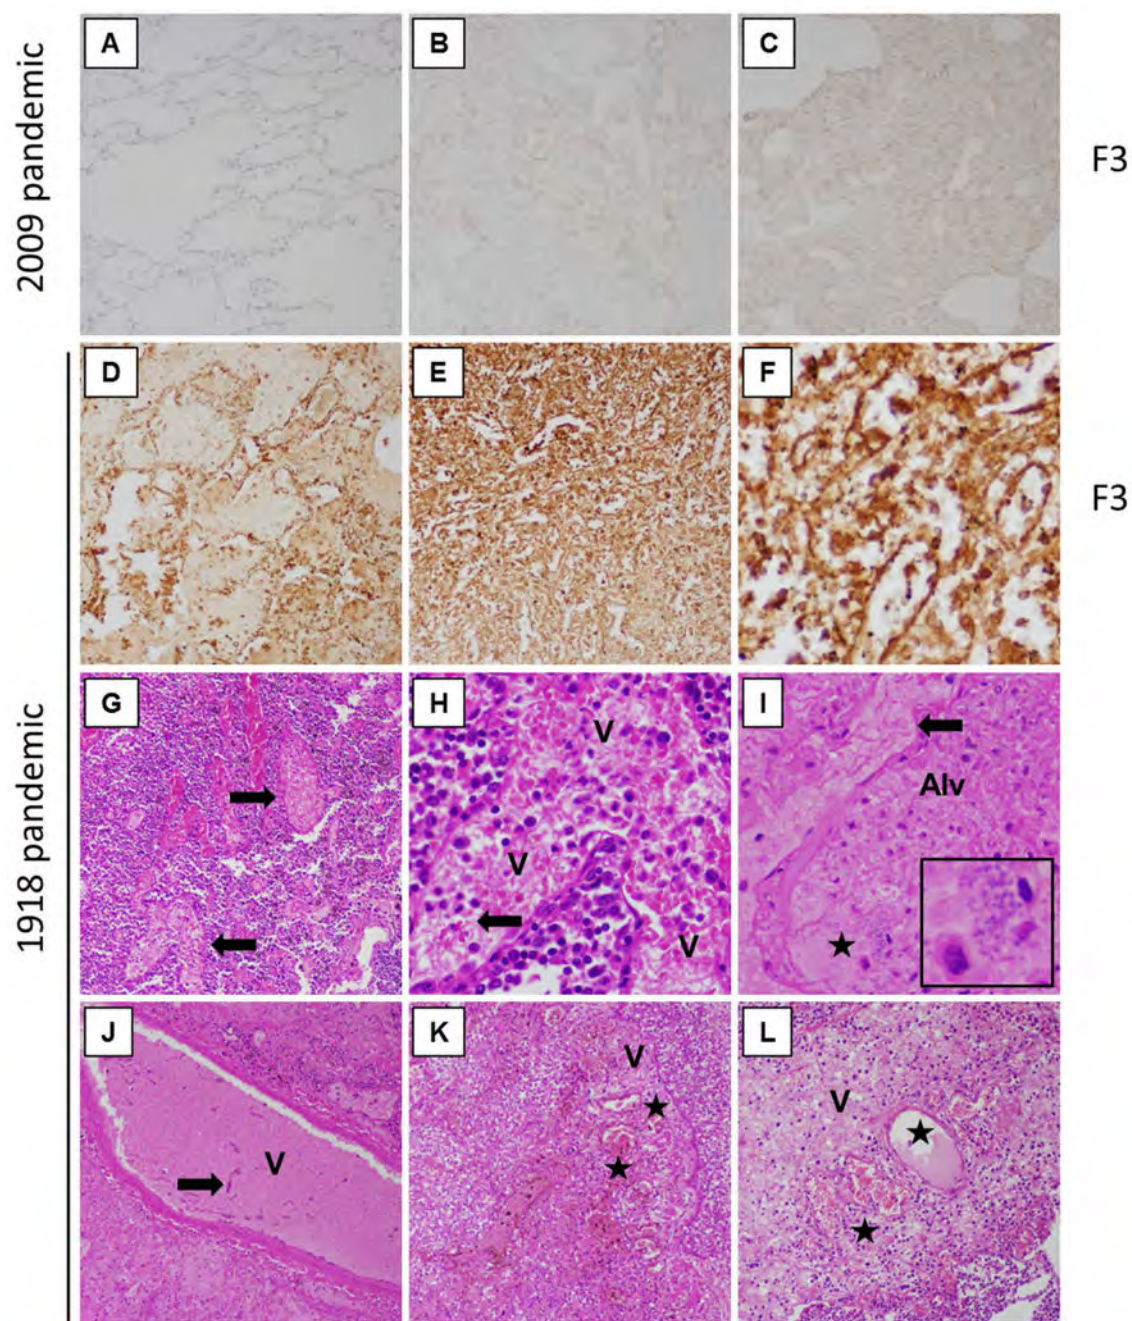

Fig. 6. Abundant and extensive expression of F3 and widespread pulmonary thrombosis in coinfecting 1918 human autopsy case material

(A-F) Post mortem lung sections were stained for F3. (A) Normal control lung showed little-to-no F3 staining. (B-C) Mild-to-moderate F3 staining was observed in two 2009 pandemic influenza post mortem cases, with staining observed in both inflammatory and epithelial cells. (B) 2009 pandemic case 14, and (C) 2009 pandemic case 1, as previously described in Gill et al. 2010 Table 2 [21]. (D-F) F3 staining of 1918 pandemic post mortem cases showing very prominent F3 staining observed in both inflammatory and epithelial cells. (D) 1918 pandemic case 19180925b, and (E-F) 1918 pandemic case 19180924d, as previously

described in Sheng et al. 2011 Supplementary Table 1 [3]. (G-L) Abundant small venule thrombi are observed 1918 pandemic post mortem cases. (G) 1918 case 19180926b showing several venules with fibrin thrombi, arrows. (H) Same case as (G) showing a venule, V, filled with thrombus consisting of erythrocytes admixed with fibrin strands, arrow). (I) 1918 case 19181017 showing an organizing thrombus with prominent fibrin in an interstitial capillary (arrow) next to an alveolus, alveoli filled with oedema, inflammatory cells, and bacteria morphologically consistent with SP (star) and inset. (J) Same case showing a venule, V, with a thrombus with early organization with fibroblasts, arrow, within the thrombus. (K) 1918 case 19180924d (same as in F) showing an organizing thrombus in a venule, denoted by V, with recanalized lumina (denoted by stars). (L) 1918 case 19181008d showing an organizing thrombus in a small vein, V, with recanalized lumina, stars. (A-E original magnification $\times 20$; G, I, J, K, L original magnification $\times 200$; F, H original magnification $\times 400$).

Reduction of secondary transmission of SARS-CoV-2 in households by face mask use, disinfection and social distancing: a cohort study in Beijing, China

ABSTRACT

Introduction Transmission of COVID-19 within families and close contacts accounts for the majority of epidemic growth. Community mask wearing, hand washing and social distancing are thought to be effective but there is little evidence to inform or support community members on COVID-19 risk reduction within families.

Methods A retrospective cohort study of 335 people in 124 families and with at least one laboratory confirmed COVID-19 case was conducted from 28 February to 27 March 2020, in Beijing, China. The outcome of interest was secondary transmission of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) within the family. Characteristics and practices of primary cases, of well family contacts and household hygiene practices were analysed as predictors of secondary transmission.

Results The secondary attack rate in families was 23.0% (77/335). Face mask use by the primary case and family contacts before the primary case developed symptoms was 79% effective in reducing transmission (OR=0.21, 95% CI 0.06 to 0.79). Daily use of chlorine or ethanol based disinfectant in households was 77% effective (OR=0.23, 95% CI 0.07 to 0.84). Wearing a mask after illness onset of the primary case was not significantly protective. The risk of household transmission was 18 times higher with frequent daily close contact with the primary case (OR=18.26, 95% CI 3.93 to 84.79), and four times higher if the primary case had diarrhoea (OR=4.10, 95% CI 1.08 to 15.60). Household crowding was not significant.

Conclusion The study confirms the highest risk of transmission prior to symptom onset, and provides the first evidence of the effectiveness of mask use, disinfection and social distancing in preventing COVID-19. We also found evidence of faecal transmission. This can inform guidelines for community prevention in settings of intense COVID-19 epidemics.

Summary box

What is already known?

- ▶ Mitigation of the COVID-19 pandemic depends solely on non-pharmaceutical interventions until drugs or vaccines are available. Transmission of COVID-19 within families and close contacts accounts for the majority of epidemic growth. Community mask wearing, hand washing and social distancing are thought to be effective but the evidence is not clear.

What are the new findings?

- ▶ The overall secondary attack rate in households was 23.0%. Face masks were 79% effective and disinfection was 77% effective in preventing transmission, while close frequent contact in the household increased the risk of transmission 18 times, and diarrhoea in the index patient increased the risk by four times. The results demonstrate the importance of the pre-symptomatic infectiousness of COVID-19 patients and shows that wearing masks after illness onset does not protect.

What do the new findings imply?

- ▶ The findings inform universal face mask use and social distancing, not just in public spaces, but inside the household with members at risk of getting infected. This further supports universal face mask use, and also provides guidance on risk reduction for families living with someone in quarantine or isolation, and families of health workers, who may face ongoing risk.

INTRODUCTION

In the absence of a vaccine for COVID-19, non-pharmaceutical interventions (NPIs) are the only available disease control measures. We have shown that population level NPIs, including travel bans and the national emergency response, were effective in flattening

the COVID-19 epidemic curve in China.¹ However, the effect of other NPIs, such as mask use and hygiene practices, have not been well studied in the COVID-19 pandemic.

In the USA, the use of face masks in the community has been recommended.² It is thought that universal face mask use (UFMU) may reduce outward transmission from asymptotically infected people and protect well people from becoming infected. However, the World Health Organization and Public Health England recommend against UFMU on the grounds that there is little evidence from randomised controlled trials to support this. Some experts suggest that in a pandemic, the precautionary principle should be used and UFMU encouraged as it is unlikely to cause harm and may result in public health gain.^{3 4} In countries where personal protective equipment is scarce, people are making their own masks.

In China, over 70% of human-to-human transmission of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) occurred in families.^{5 6} However, data to inform COVID-19 risk reduction in households are unavailable. Given epidemic growth is dominated by household transmission,^{5 6} studying the use of NPIs, such as face masks, social distancing and disinfection in the household setting, may inform community epidemic control and prevent transmission of COVID-19 in households.

METHODS

Study population and design

We conducted a retrospective cohort study involving families of laboratory confirmed COVID-19 cases in Beijing, China. We defined family members as those who had lived with primary cases in a house for 4 days before and for more than 24 hours after the primary cases developed illness related to COVID-19. As of 21 February 2020, all laboratory confirmed COVID-19 cases reported in Beijing were enrolled in our study and followed-up. The outcome of interest was secondary transmission in the household. Families with secondary transmission were defined as those where some or all of the family members become infected within one incubation period (2 weeks) of symptom onset of the primary case.

To analyse the predictors of household transmission, we compared families with and without secondary transmission for various measured risk factors, preventive interventions and exposures.

Definition of confirmed case

According to national prevention and control guideline (fifth edition),⁷ confirmed cases were those who met the clinical, epidemiological and laboratory testing criteria for COVID-19 simultaneously.

1. Clinical criteria included: (a) fever and/or one or more respiratory symptoms; (b) radiological evidence of pneumonia; (c) white blood cell count normal or

decreased, and lymphocyte count decreased at the early stage of illness.

2. Epidemiological criteria included: (a) visits to/living in Wuhan or cities around Wuhan or other communities which had already reported COVID-19 cases in the 14 days prior to the onset of symptoms; (b) having contact with a person known to have infection with SARS-CoV-2 in the 14 days prior to onset of symptoms; (c) having contact with a person who had fever or respiratory symptoms and came from Wuhan or adjacent cities or other communities which had already reported COVID-19 cases in the 14 days prior to onset of symptoms; (d) being one of the cluster cases.

Suspected cases met one of the epidemiological criteria and any two of the clinical criteria, or met all of the clinical criteria. Confirmed cases were those suspected cases who met one of the following criteria: (a) respiratory or blood specimen tested positive for SARS-CoV-2 by real time reverse transcriptase-polymerase chain reaction; (b) virus in respiratory or blood specimen was highly homologous with known SARS-CoV-2 through gene sequencing.

Data collection

A three part structured questionnaire was developed. The first part included demographic and clinical information of the primary case. The second part was mainly focused on the primary case's knowledge about and attitudes toward COVID-19, and their self-reported practices (mask wearing, social distancing, living arrangements) and activities in the home. The third part was about self-reported behaviours of all family members, as well as the family's accommodation and household hygiene practices from 4 days before the illness onset to the day the primary case was isolated, including room ventilation, room cleaning and disinfection. Close contact was defined as being within 1 m or 3 feet of the primary case, such as eating around a table or sitting together watching TV. The frequency of contact, disinfection and ventilation was measured.

After diagnosis, the primary case was hospitalised as per standard practice in Beijing. Eligible primary cases and their family members were interviewed between 28 February and 8 March. Data on the primary case were extracted from epidemiological investigating reports from Beijing Centre for Disease Prevention and Control and supplemented by interview.

The clinical severity of the COVID-19 case was categorised as mild, severe or critical. Mild disease included non-pneumonia and mild pneumonia cases. Severe disease was characterised by dyspnoea, respiratory frequency ≥ 30 /min, blood oxygen saturation $\leq 93\%$, PaO₂/FiO₂ ratio < 300 and/or lung infiltrates $> 50\%$ within 24–48 hours. Critical cases were those who exhibited respiratory failure, septic shock and/or multiple organ dysfunction/failure.⁸

Statistical analysis

Risk factors for secondary transmission were analysed by characteristics of the primary case, characteristics of well family members and household hygiene practices. Categorical variables are presented as counts and percentages, and continuous variables as medians (IQR). The χ^2 test and Fisher exact test were applied to compare difference between groups when necessary. A composite COVID-19 knowledge score and hand hygiene score were created with multiple sub-questions. A multivariable logistic regression model was used to identify risk factors associated with SARS-CoV-2 household transmission. Univariable analysis was first performed with all measures and only those variables significant at $p < 0.1$ could be selected in the following multivariable logistic regression analysis. Backward elimination was performed to establish a final model retaining those with $p < 0.05$ in the model. Statistical analyses were performed using SAS software (V.9.4).

Ethics statement

As our study was embedded within the COVID-19 prevention and control practice within public health units, and the telephone interview was a supplementary survey of the epidemiological field investigation, ethics approval was not required. We obtained subjects' verbal informed consent before the start of the interviews.

Patient and public involvement

No patients or the public were involved in the study design, setting the research questions, interpretation or writing up of results, or reporting of the research.

RESULTS

As of 21 February 2020, 399 confirmed COVID-19 cases in 181 families were reported in Beijing. Four family clusters were excluded because we were unable to determine whether there was secondary transmission or co-exposure, leaving 177 families. After reviewing information in the epidemiological investigation reports and survey calls, 40 families were excluded as they did not meet the study inclusion criteria. A further 13 families declined to be interviewed and were also excluded, leaving 124 families for study (figure 1).

Over the 2 weeks of follow-up from onset of the primary case, secondary transmission occurred in 41/124 families (77 secondary cases), and 83/124 families had no secondary transmission. The overall secondary attack rate in families was 23.0% (77/335). In the secondary transmission group, 41 primary cases caused 77 secondary cases, with a median secondary case number in families of 2 (IQR 1–2). In the secondary transmission group, the secondary attack rate in children <18 years of age was 36.1% (13/36), compared with 69.6% (64/92) in adults, and the difference between these two age groups was significant ($\chi^2=12.08$, $p < 0.001$). The median age of the 13 secondary child cases was 3 years (IQR 2–6), 12/13 were

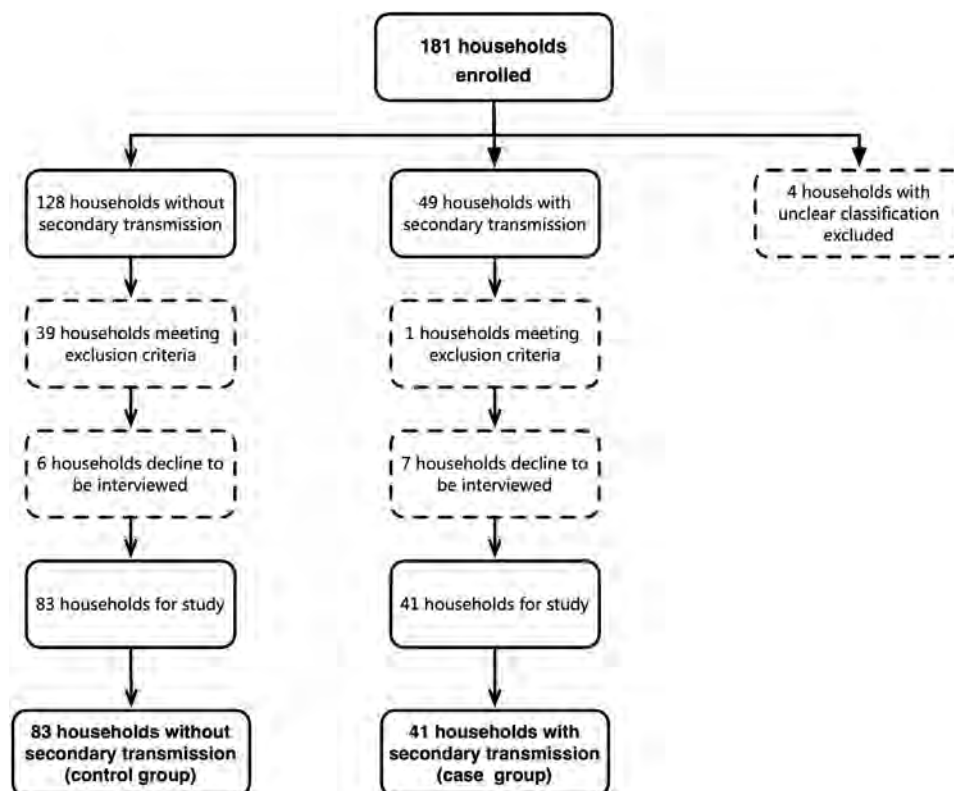

Figure 1 Selection and inclusion of interviewing subjects. Summary of household enrolment, and inclusion and interview response in the analysis of SARS-CoV-2 household transmission in Beijing, China.

*Primary case ever had the symptom of cough when living with others at home.

†Primary case ever had the symptom of diarrhoea (change of character of stool) when living with others at home.

‡Date on which cases self-reported the appearance of either fever ($\geq 37.3^{\circ}\text{C}$) or any respiratory symptom during epidemiological investigation. Date of hospital visit was the earliest date that cases sought medical service for COVID-19 related illness.

§A composite variable involving the primary case's knowledge on the infectivity of SARS-CoV-2, contagious population, transmission route, susceptible population, incubation period, common symptoms and preventive measures.

¶Refers to the primary case or family members wearing a face mask at home, regardless of whether it was a N95 mask, disposable surgical mask or a common mask, including cloth mask. Wearing masks all the time means the primary case wears a mask all the time except when having dinner or sleeping at home.

**A composite variable involving the primary case's hand washing practice, including using running water, washing frequency, using sanitiser and under what conditions.

mild and 1/13 was asymptomatic. Of 64 secondary adult cases, 82.8% (53/64) were mild, 10.9% (7/64) were severe, 1.6% (1/64) was critical and 4.7% (3/64) were asymptomatic. No statistically significant difference was observed in clinical severity between 41 index adult cases (table 1) and 64 secondary adult cases for the secondary transmission group ($p=0.18$).

The univariable analysis for association with secondary transmission of SARS-CoV-2 within families is shown in tables 1–3. Significant associations were:

1. Characteristics, behaviours and knowledge of the primary case: having diarrhoea, interval from illness onset to medical isolation >2 days, self-awareness of being infected with SARS-CoV-2 when the primary case developed the illness, lack of knowledge of their own infectiousness, mask wearing in the home after illness

onset, failing to self-isolate and not eating separately were associated with transmission (table 1).

2. Behaviours of family members: having daily close contact with the primary case at home, and number of family members wearing a mask in the home before and after the primary case's illness onset date were associated with transmission (table 2).
3. Household practices: frequency of using chlorine or ethanol based disinfectant for household cleaning and household ventilation duration were protective (table 3).

In multivariable logistic regression model, four factors remained significantly associated with secondary transmission. The primary case having diarrhoea in the home and daily close contact with the primary case in the home increased the risk. Transmission was significantly reduced

*Family members stay with the primary case at a short distance (within 1 m or 3 feet) for more than 10 min at a time. For example, they have dinner with the primary case around a table or watch TV sitting near.

†Before the primary case developed the illness, the primary case or his/her family contacts wear masks all the time at home.

‡When the primary case developed the illness, the primary case's family contacts wear masks all the time living with the primary case at home.

by frequent use of chlorine or ethanol based disinfectant in households and family members (including the primary case) wearing a mask at home before the primary case developed the illness (table 4).

DISCUSSION

This study confirms that the highest risk of household transmission is prior to symptom onset, but that precautionary NPIs, such as mask use, disinfection and social distancing in households can prevent COVID-19 transmission during the pandemic. This study is the first to confirm the effectiveness of mask use prior to symptom onset by family members, daily household disinfection and social distancing in the home. This could inform precautionary guidelines for families to reduce intrafamilial transmission in areas where there is high community transmission or other risk factors for COVID-19. Household transmission is a major driver of epidemic growth.^{5 6} Further, in countries where health system capacity is exhausted, many people with infection are required to self-isolate at home, where their household contacts will be at risk of infection. In our study, the median family size of the 124 families was 4 (range 2–9), usually with children, parents and grandparents, which is similar to the social structure of most Chinese families.⁹ Therefore, the risk of SARS-CoV-2 household transmission is high if a primary case was introduced and no measure was adopted. We showed that NPIs are effective at preventing transmission, even in homes that are

crowded and small. UFMU is a low risk intervention with potential public health benefits.^{3 4} The results suggest that community face mask use is likely to be the most effective inside the household during severe epidemics.

Almost a quarter of family members became infected, and the findings suggest that the risk was highest either before symptom onset or early in the clinical illness, as most primary cases were hospitalised after diagnosis, and interventions were not effective if applied after symptom onset. In the univariate analysis, wearing a mask after illness onset was significant, but in multivariate analysis, only wearing it before symptom onset was effective. Viral load is highest in the 2 days before symptom onset and on the first day of symptoms, and up to 44% of transmission is during the pre-symptomatic period in settings with substantial household clustering.^{10 11} This supports UFMU, probably by reducing onward transmission from people in the pre-symptomatic phase of the illness^{12 13} as well as protecting well mask users. Randomised clinical trials of face masks in the household have confirmed protection against other respiratory viruses if compliant, if used within 36 hours of the primary case symptom onset, and alone or in combination with hand hygiene.^{14 15} This study now provides specific evidence for UFMU in settings of high epidemic growth to protect against COVID-19. In our study, 91.2% (103/113) of primary cases had a high score on hand hygiene, but it was not effective, confirming the results of previous randomised clinical trials which showed hand

Table 3 Characteristics of the residence and household practices: univariable analysis between two family groups

hygiene alone did not protect against respiratory transmissible viruses, but masks combined with hand hygiene did have effect.¹⁶

As the compliance of UFMU would be poor in the home, there was difficulty and also no necessity for everyone to wear masks at home. We recommended that those families with members who were at risk of getting infected with SARS-CoV-2 (such as ever having contact with a COVID-19 patient, medical workers caring for a COVID-19 patient or having a history of travelling to high risk areas) should apply UFMU to reduce the risk of household transmission.

This study showed that social distancing within the home is effective and having close contact (within 1 m or 3 feet, such as eating around a table or sitting together watching TV) is a risk factor for transmission. The study also provides evidence of effectiveness of chlorine or ethanol based household disinfection in areas with high community transmission, or where one family member is a health worker, or where there is a risk of COVID-19, such as during home quarantine, consistent with advice provided by local health authorities or organisations.¹⁷ Diarrhoea as a symptom in the primary case is also a risk factor for SARS-CoV-2 transmission within families, which highlights the importance of disinfection of the bathroom and toilet, as well as closing the toilet lid when flushing to prevent aerosolisation of the virus.

Our study has limitations. Telephone interview has inherent limitations, including recall bias. It would take about 20 min to complete an interview, and 95% (118/124) of interviews were rated as informative by the interviewers. The evaluation results of mask wearing were reliable, but we did not collect data on the concentration of disinfectant used by families. The strengths of the study were that we had complete follow-up data and were able to accurately ascertain the incidence of secondary transmission in the cohort.

CONCLUSIONS

Household transmission in the pre-symptomatic or early symptomatic period of COVID-19 is a driver of epidemic growth and any measure aimed at reducing this can flatten the curve. This study reinforces the high risk of transmission in households but importantly shows that UFMU and hygiene measures can significantly reduce the risk of household transmission of COVID-19, independent of household size or crowding. This is the first study to show the effectiveness of precautionary mask use, social distancing and regular disinfection in the household, and can inform guidelines for prevention of household transmission. The results may also be informative for families of high risk groups, such as health workers, quarantined individuals or situations where cases of COVID-19 have to be managed at home.

Presymptomatic Transmission of SARS-CoV-2 — Singapore, January 23–March 16, 2020

Wycliffe E. Wei, MPH^{1,2}; Zongbin Li, MBBS¹; Calvin J. Chiew, MPH¹; Sarah E. Yong, MMed¹; Matthias P. Toh, MMed^{2,3}; Vernon J. Lee, PhD^{1,3}

On April 1, 2020, this report was posted as an MMWR Early Release on the MMWR website (<https://www.cdc.gov/mmwr>).

Presymptomatic transmission of SARS-CoV-2, the virus that causes coronavirus disease 2019 (COVID-19), might pose challenges for disease control. The first case of COVID-19 in Singapore was detected on January 23, 2020, and by March 16, a total of 243 cases had been confirmed, including 157 locally acquired cases. Clinical and epidemiologic findings of all COVID-19 cases in Singapore through March 16 were reviewed to determine whether presymptomatic transmission might have occurred. Presymptomatic transmission was defined as the transmission of SARS-CoV-2 from an infected person (source patient) to a secondary patient before the source patient developed symptoms, as ascertained by exposure and symptom onset dates, with no evidence that the secondary patient had been exposed to anyone else with COVID-19. Seven COVID-19 epidemiologic clusters in which presymptomatic transmission likely occurred were identified, and 10 such cases within these clusters accounted for 6.4% of the 157 locally acquired cases. In the four clusters for which the date of exposure could be determined, presymptomatic transmission occurred 1–3 days before symptom onset in the presymptomatic source patient. To account for the possibility of presymptomatic transmission, officials developing contact tracing protocols should strongly consider including a period before symptom onset. Evidence of presymptomatic transmission of SARS-CoV-2 underscores the critical role social distancing, including avoidance of congregate settings, plays in controlling the COVID-19 pandemic.

Early detection and isolation of symptomatic COVID-19 patients and tracing of close contacts is an important disease containment strategy; however, the existence of presymptomatic or asymptomatic transmission would present difficult challenges to contact tracing. Such transmission modes have not been definitively documented for COVID-19, although cases of presymptomatic and asymptomatic transmissions have been reported in China (1,2) and possibly occurred in a nursing facility in King County, Washington (3). Examination of serial intervals (i.e., the number of days between symptom onsets in a primary case and a secondary case) in China suggested that 12.6% of transmission was presymptomatic (2). COVID-19 cases in Singapore were reviewed to determine whether presymptomatic transmission occurred among COVID-19 clusters.

The surveillance and case detection methods employed in Singapore have been described (4). Briefly, all medical practitioners were required by law to notify Singapore's Ministry of Health of suspected and confirmed cases of COVID-19. The definition of a suspected case was based on the presence of respiratory symptoms and an exposure history. Suspected cases were tested, and a confirmed case was defined as a positive test for SARS-CoV-2, using laboratory-based polymerase chain reaction or serologic assays (5). All cases in this report were confirmed by polymerase chain reaction only. Asymptomatic persons were not routinely tested, but such testing was performed for persons in groups considered to be at especially high risk for infection, such as evacuees on flights from Wuhan, China (6), or families that experienced high attack rates.

Patients with confirmed COVID-19 were interviewed to obtain information about their clinical symptoms and activity history during the 2 weeks preceding symptom onset to ascertain possible sources of infection. Contact tracing examined the time from symptom onset until the time the patient was successfully isolated to identify contacts who had interactions with the patient. All contacts were monitored daily for their health status, and those who developed symptoms were tested as part of active case finding.

Clinical and epidemiologic data for all 243 reported COVID-19 cases in Singapore during January 23–March 16 were reviewed. Clinical histories were examined to identify symptoms before, during, and after the first positive SARS-CoV-2 test.

Records of cases that were epidemiologically linked (clusters) were reviewed to identify instances of likely presymptomatic transmission. Such clusters had clear contact between a source patient and a patient infected by the source (a secondary patient), had no other likely explanations for infection, and had the source patient's date of symptom onset occurring after the date of exposure to the secondary patient who was subsequently infected. Symptoms considered in the review included respiratory, gastrointestinal (e.g., diarrhea), and constitutional symptoms. In addition, the source patient's exposure had to be strongly attributed epidemiologically to transmission from another source. This reduced the likelihood that an unknown source was involved in the cases in the cluster.

Summary**What is already known about this topic?**

Preliminary evidence indicates the occurrence of presymptomatic transmission of SARS-CoV-2, based on reports of individual cases in China.

What is added by this report?

Investigation of all 243 cases of COVID-19 reported in Singapore during January 23–March 16 identified seven clusters of cases in which presymptomatic transmission is the most likely explanation for the occurrence of secondary cases.

What are the implications for public health practice?

The possibility of presymptomatic transmission increases the challenges of containment measures. Public health officials conducting contact tracing should strongly consider including a period before symptom onset to account for the possibility of presymptomatic transmission. The potential for presymptomatic transmission underscores the importance of social distancing, including the avoidance of congregate settings, to reduce COVID-19 spread.

Seven Clusters of COVID-19 Cases Suggesting Presymptomatic Transmission

Investigation of COVID-19 cases in Singapore identified seven clusters (clusters A–G) in which presymptomatic transmission likely occurred. These clusters occurred during January 19–March 12, and involved from two to five patients each (Figure). Ten of the cases within these clusters were attributed to presymptomatic transmission and accounted for 6.4% of the 157 locally acquired cases reported as of March 16.

Cluster A. A woman aged 55 years (patient A1) and a man aged 56 years (patient A2) were tourists from Wuhan, China, who arrived in Singapore on January 19. They visited a local church the same day and had symptom onset on January 22 (patient A1) and January 24 (patient A2). Three other persons, a man aged 53 years (patient A3), a woman aged 39 years (patient A4), and a woman aged 52 years (patient A5) attended the same church that day and subsequently developed symptoms on January 23, January 30, and February 3, respectively. Patient A5 occupied the same seat in the church that patients A1 and A2 had occupied earlier that day (captured by closed-circuit camera) (5). Investigations of other attendees did not reveal any other symptomatic persons who attended the church that day.

Cluster B. A woman aged 54 years (patient B1) attended a dinner event on February 15 where she was exposed to a patient with confirmed COVID-19. On February 24, patient B1 and a woman aged 63 years (patient B2) attended the same singing class. Two days later (February 26), patient B1 developed symptoms; patient B2 developed symptoms on February 29.

Cluster C. A woman aged 53 years (patient C1) was exposed to a patient with confirmed COVID-19 on February 26 and likely passed the infection to her husband, aged 59 years (patient C2) during her presymptomatic period; both patients developed symptoms on March 5.

Cluster D. A man aged 37 years (patient D1) traveled to the Philippines during February 23–March 2, where he was in contact with a patient with pneumonia who later died. Patient D1 likely transmitted the infection to his wife (patient D2), aged 35 years, during his presymptomatic period. Both patients developed symptoms on March 8.

Cluster E. A man aged 32 years (patient E1) traveled to Japan during February 29–March 8, where he was likely infected, and subsequently transmitted the infection to his housemate, a woman aged 27 years (patient E2), before he developed symptoms. Both developed symptoms on March 11.

Cluster F. A woman aged 58 years (patient F1) attended a singing class on February 27, where she was exposed to a patient with confirmed COVID-19. She attended a church service on March 1, where she likely infected a woman aged 26 years (patient F2) and a man aged 29 years (patient F3), both of whom sat one row behind her. Patient F1 developed symptoms on March 3, and patients F2 and F3 developed symptoms on March 3 and March 5, respectively.

Cluster G. A man aged 63 years (patient G1) traveled to Indonesia during March 3–7. He met a woman aged 36 years (patient G2) on March 8 and likely transmitted SARS-CoV-2 to her; he developed symptoms on March 9, and patient G2 developed symptoms on March 12.

Investigation of these clusters did not identify other patients who could have transmitted COVID-19 to the persons infected. In four clusters (A, B, F, and G), presymptomatic transmission exposure occurred 1–3 days before the source patient developed symptoms. For the remaining three clusters (C, D, and E), the exact timing of transmission exposure could not be ascertained because the persons lived together, and exposure was continual.

Discussion

This investigation identified seven clusters of COVID-19 in Singapore in which presymptomatic transmission likely occurred. Among the 243 cases of COVID-19 reported in Singapore as of March 16, 157 were locally acquired; 10 of the 157 (6.4%) locally acquired cases are included in these clusters and were attributed to presymptomatic transmission. These findings are supported by other studies that suggest that presymptomatic transmission of COVID-19 can occur (1–3). An examination of transmission events among cases in Chinese patients outside of Hubei province, China, suggested that

Likely period of transmission from source patient to secondary patients

Symptom onset date

12.6% of transmissions could have occurred before symptom onset in the source patient (3).

Presymptomatic transmission might occur through generation of respiratory droplets or possibly through indirect transmission. Speech and other vocal activities such as singing have been shown to generate air particles, with the rate of emission corresponding to voice loudness (7). News outlets have reported that during a choir practice in Washington on March 10, presymptomatic transmission likely played a role in SARS-CoV-2 transmission to approximately 40 of 60 choir members.*

*<https://www.latimes.com/world-nation/story/2020-03-29/coronavirus-choir-outbreak>.

Environmental contamination with SARS-CoV-2 has been documented (8), and the possibility of indirect transmission through fomites by presymptomatic persons is also a concern. Objects might be contaminated directly by droplets or through contact with an infected person's contaminated hands and transmitted through nonrigorous hygiene practices.

The possibility of presymptomatic transmission of SARS-CoV-2 increases the challenges of COVID-19 containment measures, which are predicated on early detection and isolation of symptomatic persons. The magnitude of this impact is dependent upon the extent and duration of transmissibility while a patient is presymptomatic, which, to date, have

not been clearly established. In four clusters (A, B, F, and G), it was possible to determine that presymptomatic transmission exposure occurred 1–3 days before the source patient developed symptoms. Such transmission has also been observed in other respiratory viruses such as influenza. However, transmissibility by presymptomatic persons requires further study.

The findings in this report are subject to at least three limitations. First, although these cases were carefully investigated, the possibility exists that an unknown source might have initiated the clusters described. Given that there was not widespread community transmission of COVID-19 in Singapore during the period of evaluation and while strong surveillance systems were in place to detect cases, presymptomatic transmission was estimated to be more likely than the occurrence of unidentified sources. Further, contact tracing undertaken during this period was extensive and would likely have detected other symptomatic cases. Second, recall bias could affect the accuracy of symptom onset dates reported by cases, especially if symptoms were mild, resulting in uncertainty about the duration of the presymptomatic period. Finally, because of the nature of detection and surveillance activities that focus on testing symptomatic persons, underdetection of asymptomatic illness is expected. Recall bias and interviewer bias (i.e., the expectation that some symptoms were present, no matter how mild), could have contributed to this.

The evidence of presymptomatic transmission in Singapore, in combination with evidence from other studies (9,10) supports the likelihood that viral shedding can occur in the absence of symptoms and before symptom onset. This study identified seven clusters of cases in which presymptomatic transmission of COVID-19 likely occurred; 10 (6.4%) of such cases included in these clusters were among the 157 locally acquired cases reported in Singapore as of March 16. Containment measures should account for the possibility of presymptomatic transmission by including the period before symptom onset when conducting contact tracing. These findings also suggest that to control the pandemic it might not be enough for only persons with symptoms to limit their contact with others because persons without symptoms might transmit infection. Finally, these findings underscore the importance of social distancing

in the public health response to the COVID-19 pandemic, including the avoidance of congregate settings.

Abstract: In 2012, an emerging viral infection was identified in Saudi Arabia that subsequently spread to 27 additional countries globally, though cases may have occurred elsewhere. The virus was ultimately named Middle Eastern Respiratory Syndrome Coronavirus (MERS-CoV), and has been endemic in Saudi Arabia since 2012. As of September 2019, 2468 laboratory-confirmed cases with 851 associated deaths have occurred with a case fatality rate of 34.4%, according to the World Health Organization. An imported case of MERS occurred in South Korea in 2015, stimulating a multi-month outbreak. Several distinguishing factors emerge upon epidemiological and sociological analysis of the two outbreaks including public awareness of the MERS outbreak, and transmission and synchronization of governing healthcare bodies. South Korea implemented a stringent healthcare model that protected patients and healthcare workers alike through prevention and high levels of public information. In addition, many details about MERS-CoV virology, transmission, pathological progression, and even the reservoir, remain unknown. This paper aims to delineate the key differences between the two regional outbreaks from both a healthcare and personal perspective including differing hospital practices, information and public knowledge, cultural practices, and reservoirs, among others. Further details about differing emergency outbreak responses, public information, and guidelines put in place to protect hospitals and citizens could improve the outcome of future MERS outbreaks.

1. Introduction

Infectious diseases pose a significant risk to the global population. The reasons behind their appearance, and how outbreaks differ are of notable interest to epidemiologists and public health professionals. Coronaviruses in particular have become a global health threat following the emergence of severe acute respiratory syndrome coronavirus (SARS-CoV) and Middle East respiratory syndrome coronavirus (MERS-CoV). While human CoVs do circulate causing mild disease year-to-year, SARS-CoV differed in its rapidity and zoonotic origin, in addition to its ability to cause severe disease [1]. SARS-CoV was the first epidemic coronavirus in decades, as well as the first highly pathogenic CoV discovered, when it appeared in Asia in 2002 [2]. This outbreak was swiftly controlled and came to an end within 8 months, in part because of excellent containment policies, limited contact between humans and the putative reservoir host, and efficient use of social media to educate affected populations on containment and protection procedures [3]. However, ten years later, a new related coronavirus emerged in Saudi Arabia in 2012, and despite the success in controlling the SARS epidemic, the new respiratory virus

Viruses 2019, 11, 1119 FOR PEER REVIEW 2 of 13
 has become an endemic problem in the Middle East. MERS-CoV has since spread to over 27 countries in Europe, North Africa, and the Middle East [4]. The global transmission of MERS-CoV is outlined in Figure 1. MERS-CoV has since spread to over 27 countries in Europe, North Africa, and the Middle East [4]. The global transmission of MERS-CoV is outlined in Figure 1.

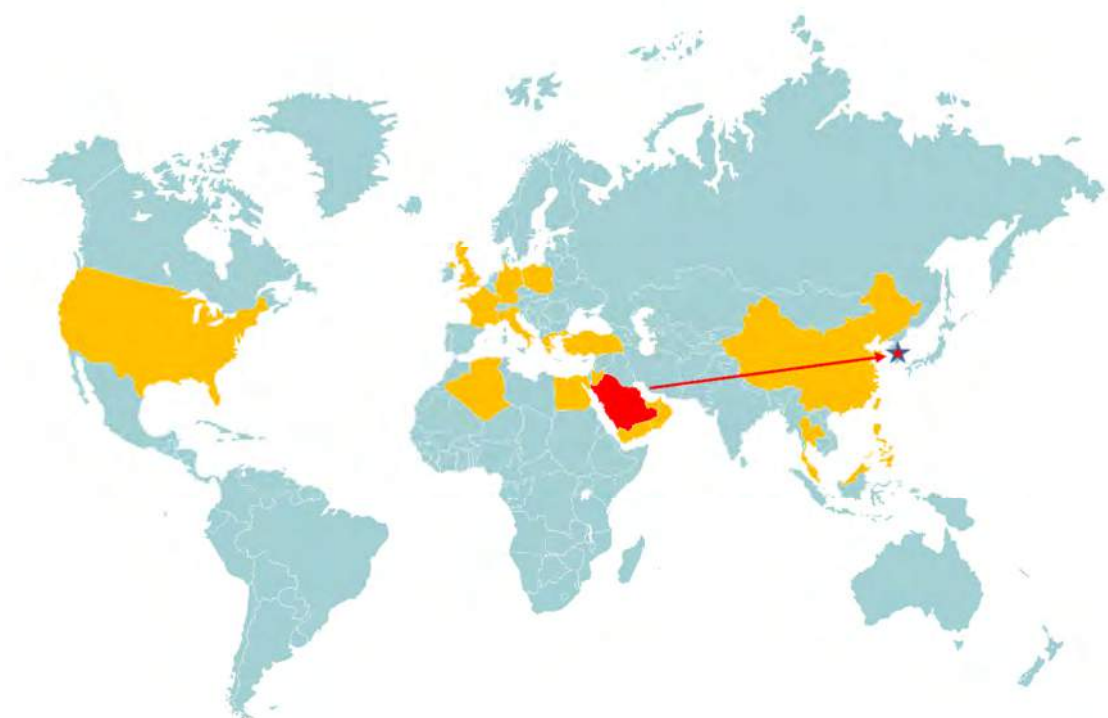

Figure 1. Global distribution of MERS-CoV outbreaks from 2012–2019. Data includes all documented occurrences of disease, including imported, nosocomial, and community cases. Highlighted in orange are countries with past or present MERS-CoV cases, while the countries of interest for the purposes of this paper, Saudi Arabia and South Korea, are shown in red. The direct importation of MERS-CoV from Saudi Arabia to South Korea is shown in red, stimulating the 2015 outbreak. In contrast to the short-lived SARS outbreak, MERS has become an endemic disease in many countries around the Middle East sustained by direct reservoir transmission leading to nosocomial infections and eventual transmission back to surrounding communities [3]. Given that MERS-CoV-like viruses have been isolated from masked palm civets, bats, and camels, these are considered some of the many reservoirs of the virus, which sustain transmission in humans and animals [2]. In fact, MERS-CoV has been detected in camels dating back several decades, and likely was endemic before it was detected by epidemiologists in 2012, as the majority of infected animals show mild or no symptoms [5]. Infection in dromedaries can result in either asymptomatic or symptomatic disease, while bats carrying SARS-like coronavirus have historically been asymptomatic [4]. Asymptomatic hosts and reservoirs can spread disease, and SARS-like coronavirus may be asymptomatic [4]. As of September 2019, 2468 laboratory-confirmed cases with 851 associated deaths have occurred with a case fatality rate of 34.4%. According to the World Health Organization (WHO) [6], here, we review differences between two geographically distinct MERS-CoV outbreaks, one short lived outbreak occurring in South Korea in 2015, and the other, an endemic MERS-CoV outbreak that has persisted in Saudi Arabia since 2013 [7,8]. We will discuss the contributions of transmission differences, potential reservoirs, containment practices, isolation procedures, levels of public education, and clinical detection and monitoring to the outcome of the outbreaks in this review.

2. MERS-CoV Virology

2. MERS-CoV Virology

MERS-CoV is a betacoronavirus with a positive, single stranded RNA genome of 27.9kb [9]. The viral structure consists of a small enveloped spherical virion, measuring approximately 90–120nm [10,11]. The MERS-CoV genome encodes two polyproteins (pp1ab and pp1b) and nested subgenomic mRNAs [2,9]. The genome of the virion is contained within the nucleocapsid, and which is responsible for RNA binding, synthesis, and translation [9]. This is surrounded by the host-derived envelope, containing the four structural proteins, spike (S), nucleocapsid (N), membrane (M), and envelope (E) [12]. The genome also encodes four nonstructural proteins (ns) in ORFs 3, 4a, 4b, and 5, which have vital functions to the virus life cycle [9,12]. The S protein is of particular interest, as it mediates virus attachment to the host cell through interaction with the dipeptidyl peptidase-4 (DPP4) receptor resulting in viral uptake [8]. In most cases, CoV S proteins are cleaved by furin-like proteases of the host into active subunits [10]. Thus, the MERS-CoV S protein is being investigated for the development of antivirals and therapeutics because of its vital role in infection and pathogenesis [13,14].

Attachment of the MERS-CoV virion to the target cell is initiated by the binding of the S1 subunit of the S protein to DPP4, which triggers conformational changes in the S2 subunit, beginning the process of fusion to the target cell [10,15]. MERS CoV was the only CoV shown to use DPP4 to gain entry to host cells [15]. Like many viruses, CoVs utilize proteases such as transmembrane protease, serine 2 (TMPRSS2) and cathepsin to activate the S protein following fusion of the viral envelope and host cell membrane [16]. This multi-step process of the S protein at multiple cleavage sites exposes the fusion peptide, stimulating the fusion process inside acidified endosomes [10]. Within the endosome, MERS-CoV disassembles, releasing the inner genomic material into the cytoplasm [15]. Once inside the cell, transcription in the cytoplasm and RNA replication in the cytoplasm proceed. During this time, coronaviruses in general, including MERS-CoV, are readily able to undergo homologous and non-homologous recombination, leading to higher rates of viral evolution and new subtypes [16]. The replication-transcription complex is formed by further protease cleavage of polyproteins pp1a and pp1ab producing nsp1 and nsp16 template genomic RNA, generating the replication complexes required for transcription and translation [17]. Viral structural and accessory proteins are translated from subgenomic co-terminal mRNAs by replication-transcription complex-mediated transcription of a full-length positive genomic RNA [15,17]. The viral envelope is added to the virion during assembly at the endoplasmic reticulum and Golgi apparatus. During assembly at the Golgi apparatus of the host cell, the S, E, and M proteins are brought together at a “budding compartment”, where the M protein likely forms the basic structure and final viral complex [10]. The fully assembled, active virion is then exocytosed to the extracellular compartment and budded from the host cell.

3. Clinical Manifestations and Diagnosis of MERS-CoV

Following exposure, the incubation period for MERS-CoV is 4–8 days [18,19]. MERS has been shown to display clusters of human-to-human direct transmission, but the R_0 , also known as the basic reproduction number, or number of people a single infected individual can in turn infect, of these events is low, typically less than 1 [20]. This makes the target of prevention a combination of reducing transmission by reservoir hosts, as well as controlling spread within a hospital or community environment. Transmission occurs primarily via dromedary camels, a large source of interaction for Middle Eastern populations [21–23].

In addition to infection of immunocompetent people, immunocompromised populations have increased susceptibility to MERS-CoV. Infection begins with symptoms that are remarkably similar to a cold, but may progress to gastrointestinal symptoms, myalgia, shortness of breath, general malaise, abdominal pain, wheezing, palpitations, and confusion [20,22–24]. Severe disease can result in hospitalization and is associated with acute respiratory distress syndrome (ARDS, a severe respiratory disease resulting from widespread sepsis), lung injury, and requirement of mechanical ventilation due to respiratory failure. Abnormal chest examination results are also commonly noted such as inflammatory lung infiltrates, alveolar collapse, or interstitial thickening of the lung lining [25].

Follow-up chest radiographs of laboratory-confirmed positive individuals have shown lung fibrosis, and pleural thickening [26]. Blood tests of these patients also showed elevated lactate dehydrogenase levels after recovery.

Once the patient has begun showing symptoms, diagnosis presents several distinct challenges. The gold standard for diagnosis of an active MERS-CoV infection is by Real Time Polymerase Chain Reactions (RT-PCR), confirming viral identity by using a well-annotated gene such as the nucleocapsid [27]. While whole blood and plasma can also show active infection of MERS-CoV, respiratory samples are typically used for nucleic acid-based tests and utilize RNA extracted from nasopharyngeal swabs, bronchoalveolar lavage, and tracheal aspirates, among others [27]. After active infection, individuals may be examined for seroconversion suggestive of MERS-CoV infection or exposure. Serology tests include Enzyme-Linked Immunosorbant Assay (i.e., ELISA), and whole virus indirect fluorescent antibody (IFA) testing [27]. Many of these isolation and identification methods begin with a viral culture grown from a clinical isolate (i.e., sputum or respiratory samples isolated from the patient), elongating the wait time for results. This long wait period makes these current diagnostics laborious and time-consuming, precluding rapid turnaround of results, which is more problematic for severely ill patients and poses further problems for nosocomial transmission. Serology tests can detect antibodies present due to previous infections, but this is less useful to identify an active infection [27,28]. Patients who have been actively infected with MERS-CoV could be tested again post-infection and documented for seroconversion, which would be helpful for contact tracing as well as future epidemiological tracking and surveillance. PCR detection and serology testing are vital components to outbreak management and epidemiological tracking, by showing infection patterns and identifying potential risk factors, which can be used by health policy makers or for disease tracking during future outbreaks. However, concerns have been raised regarding the lack of standardization of sample collection, analysis, and data availability post-outbreak, which contribute to the previously discussed information gap in MERS epidemiological analyses [29].

In the midst of an outbreak, diagnostic assay results can be back within hours, however typically, it can take significantly longer for the result to reach the attending physician during an outbreak. This means positive individuals can be left unchecked for hours to days, continuing to transmit the virus before steps are taken to quarantine and isolate them. Close contact with saliva, mucus, respiratory droplets released by coughing and sneezing, and other infected bodily fluids can transmit MERS-CoV [6].

4. MERS-CoV Ecology and Transmission

MERS-CoV was first identified in 2012 following the death of a 60-year old male from a novel respiratory virus in Saudi Arabia [30]. While MERS initially seemed to be extremely similar to its relative, SARS, the condition showed a number of differences from the start of the outbreak. Two immediately noted differences were the incubation period and reservoir transmission. The median incubation period of MERS-CoV infection is 5 days, with the average time from onset of symptoms to hospitalization of approximately 4 days [18]. However, this number varies within the literature, depending on the model utilized. Small samples size can also be a problem in this instance, from lack of documentation or records available. In contrast, SARS exhibited an incubation time of at most 10 days, with symptom onset occurring during this time, averaging 2–7 days post-exposure [28].

In addition to the length of the incubation period, another difference between MERS-CoV and SARS-CoV lies in the animal reservoir. The animal reservoir for SARS-CoV was suspected to be bats, living in large numbers in the forested area behind rural communities in SARS affected areas [8,31,32]. After the initial introduction in Hong Kong, the SARS-CoV outbreak was sustained by human-to-human transmission [28]. While MERS-like viruses have been isolated from bats, MERS-CoV is primarily transmitted by dromedary camels, a commonly farmed and heavily used animal in the Saudi Arabian region, have been suggested to be a reservoir of the virus [3,9]. However, the primary reservoir remains officially unknown. While dromedary camels can transmit the virus and be asymptomatic carriers,

many suggest that it originated in a similar manner to SARS-CoV in the bat population, and has spilled over to many animals, including camels, which are far more difficult to remove from human populations and contact [20,33]. In fact, less commonly cited animals such as llamas, pigs, horses, and sheep have been found to carry the virus in their nasal passages, and have been suggested to also be capable of being potential reservoirs [33]. This presents further problems for transmission, as many potential reservoirs are in daily contact with Middle Eastern populations.

In addition to animal-origin transmission, there are also many documented cases of nosocomial MERS-CoV infection and transmission, occasionally as a result of overcrowding and inadequate infection control measures [21]. Given that this virus is most commonly spread by respiratory droplets from infected individuals, this is not a surprising finding. While the majority of participants in a recent Saudi Arabian study among medical students were aware that infection prevention was ideally through wearing face masks and public information, 53% of participants were unaware of infection control isolation policies in their hospitals, if an outbreak arose [34]. Furthermore, nosocomial transmission is made worse by the presence of MERS-CoV “superspreaders”, who transmit the disease at a significantly higher rate than the average host [35]. There are a number of factors that can affect the interpretation of a “superspreader”, such as nearby immunodeficient patients, sharing of healthcare tools and staff, and poor hygiene in the environment. In a recent study, approximately 33.3% of laboratory-confirmed positive hospital patients were found to be superspreaders [35]. Household transmission occurred in 13–21% of cases, making nosocomial transmission and community/reservoir infections the primary targets for prevention [2].

5. MERS-CoV Pathogenesis and Clinical Manifestations

While the studies of infection control and superspreaders are all relevant to the investigation of MERS-CoV outbreaks and how they occur, there is little information available regarding pathogenesis and previous patient test results, ranging from blood tests and cytokine studies to disease progression. Many of these barriers are linked to two problems, the first being limited post-mortem findings due to religious and cultural beliefs held in the Middle Eastern regions where the outbreaks began [15]. The second is lack of publication of data and results from sample analysis of specimens from laboratory-confirmed positive patients on a global scale. The primary source of information regarding pathologies associated with MERS-CoV and disease progression come from medical imaging, which are few and open to interpretation. This gap in information makes current diagnostic trends, infection patterns, and transmission maps only partially complete, making full interpretation difficult for future infectious disease outbreaks.

The S protein of MERS-CoV targets DPP4 to access human cells [10]. DPP4 is plentiful in the respiratory tract of humans including the bronchial mucosa, but is also expressed in a variety of tissues such as bronchial epithelial cells and kidney cells [36]. This is why renal impairment is a common physiological symptom of infection in addition to lung pathologies [6,37]. However, comorbidities are extremely common in severe cases of MERS-CoV, and documentation of timing of occurrences in the literature is unclear. Therefore, more work in this area is needed before extra-pulmonary symptoms are definitively linked to severe MERS-CoV. Several studies have also shown downregulation causes severe lung pathologies in CoV models of infection, and impairment in cardiovascular health in general [38,39]. Further, progression to ARDS and subsequent cytokine expansion, including IL-8 and 6, CXCL10, and CCL2, and complications such as pulmonary fibrosis, neovascularization, and congestive heart failure due to bilateral pulmonary infiltrates have been noted for infections [2,40]. Lack of availability of samples and tests as previously described has led to a serious lack of information surrounding MERS-CoV pathogenesis, which is crucial to improving healthcare practices during an outbreak. This gap in information due to differences in testing, sample collection, and lack of standardization of collection between countries further contributes to the problem [29].

6. Introduction to the 2013 Saudi Arabian and 2015 South Korean MERS Outbreaks

Containment and clinical management of MERS presents a complicated challenge due to multiple aspects including cultural, social and healthcare practice issues. During the SARS epidemic, the quick end of the outbreak was partially attributed to efficient quarantine and isolation methods, in addition to public awareness and information distribution to affected areas [41]. This included where to seek medical attention and protective measures individuals could take to protect themselves from infection, such as face masks. In the case of MERS, there is a belief that lack of knowledge among medical staff and affected communities could be a risk factor for disease containment [34]. With a combination of hospital and community outbreaks, many have suggested that stronger implementation of proper decontamination procedures could reduce outbreak severity and length [8,42]. It has been suggested that overcrowding, and slow isolation of patients in addition to these factors may have played a role in healthcare-associated outbreaks of MERS [29].

Since 2013, MERS-CoV infections have continued to be a long-term problem for healthcare professionals across Saudi Arabia. However, the same cannot be said for a relatively short outbreak that occurred in South Korea in 2015. The South Korean outbreak was imported by a 68-year old man who had recently travelled to Saudi Arabia, where he contracted MERS, and subsequently transmitted the virus throughout a South Korean hospital following admission [43–45]. In addition, the infected patient did travel through a number of hospitals throughout his travels, likely transmitting the virus to several institutions along the way [46]. What led to the differences in handling, information availability, and ultimately severity of the outbreak in South Korea compared to the ongoing efforts in Saudi Arabia are still a topic of debate. Previous findings have suggested transmission of MERS-CoV in this case was largely determined by the number of personal contacts with the patient, and patient infectivity [47].

The case fatality rate varied significantly during the South Korean outbreak, seeing the highest spike during October 2015, with an overall case fatality rate of 21% with 39 deaths [35,45]. This was slightly lower than the mean case fatality rate of the Saudi Arabian outbreak, which has been estimated to range from 36–46% between 2012 and 2014 [48,49]. The South Korean outbreak began with a single infected individual, and lasted only 2 months, with the government declaring the epidemic over on July 6 2015 [50]. In contrast, the Saudi Arabian outbreak was maintained by a zoonotic source, which sustained the outbreak for over 6 years [51]. Comparisons are highlighted in Table 1.

6.1. Aspect 1 – Public Information and Quarantine/Isolation Practices

One major difference between the Saudi Arabian and South Korean outbreaks is the initial response by the population to declaration of the outbreak, on behalf of their government body. In Saudi Arabia, poor access to healthcare professionals at a hospital and General Practitioner level can result in delays between disease development and progression, and diagnosis or quarantine in a hospital facility [52,53]. As the Saudi Arabian outbreak continued, many individuals who relied on camels for daily living or livelihood denied the correlation between camels and MERS-CoV infections, kicking off the Kiss Your Camel campaign, which became increasingly popular in Social Media in 2015 [54]. The contribution of this to the outbreak remains unclear, but it is a prime example of the negative general reaction to the outbreak. Because of the structure of the Saudi Arabian healthcare system and lack of preparedness for an infectious disease outbreak, panic quickly followed the announcement of the outbreak, leading to the dismissal of the Saudi Arabian Health Minister, Abdullah al-Rabeeah [55]. Confusion about the outbreak and lack of coordination and organization by hospitals and healthcare centers led to loss of control and lack of public information, which further exacerbated the outbreak.

The South Korean outbreak was met with a very different mindset, with the SARS outbreak still fresh in the minds of many older adults. While the index patient denied he had travelled to Saudi Arabia, many citizens of South Korea were more open about their condition and travel during subsequent contact tracing and had a good relationship with the health care professionals in their community [56]. This is due to better universal health coverage, and flexibility to choose health care professionals compared to Saudi Arabia, where the government has more restrictions and involvement

in healthcare decisions [56,57]. From the beginning of the outbreak, South Korean patients who were MERS-positive sought and embraced medical attention much faster than did Saudi Arabian patients [58]. However, this brings about the previously discussed problem of visiting a variety of healthcare environments prior to diagnosis, exacerbating spread.

Table 1. Highlighting key social and public health differences between the 2012 Saudi Arabian and 2015 South Korean MERS outbreaks. Differences in lifestyle of citizens, personal belief systems, and healthcare response to the outbreak are all suspected to have influenced the duration of the outbreak, and the final death toll.

	Saudi Arabia	South Korea
Outbreak Timeline	2013-present	May-July 2015
Type of Outbreak	Endemic	Imported
Patient 0	60-year old resident	68-year old traveller
Case Fatality Rate	36–46%	21%
Estimated Death Toll	>400	39
Primary Source of Infection	Dromedary camels and livestock	Nosocomial
Common Nutrition Source	Dromedary camel milk and meat [59–61]	Rice, pork, and beef
Public Education During Outbreak	Poor	Good
Regulatory Boards in Place	RRT (rapid response team)	MERS-CoV Infection Prevention and Control Guideline Development Committee
Implementation of Education and Regulatory Measures	Poor, conflicted among boards	Good, standardized
Isolation/Sanitation Techniques Employed in Hospitals	Information Unavailable	Mandatory masks, gloves, gowns for visitors and staff
Government Involvement in Healthcare	High	Low
Media Coverage, Globally	High	Low

Whether due to the prior experiences of the SARS epidemic or different healthcare standards, the other unpublicized but important difference between these outbreaks was the access to information for those who may have contracted, or been in direct contact with, MERS-CoV. The South Korean outbreak had stringent decontamination and isolation practices instilled in hospitals very soon after the onset of the outbreak, such as intra-hospital isolation, mandatory masks, gloves, and gowns for workers and visitors, and rapid laboratory assessments to confirm cases [43]. By July 2015, the MERS-CoV Infection Prevention and Control Guideline Development Committee was assembled and gathered in South Korea, joined by the Korean Society of Infectious Diseases, the Korean Society of Healthcare-associated Infection, and the Korean Association of Infection Control Nurses, in a serious effort to stop nosocomial and community transmission through public information and proper isolation and decontamination procedures in hospitals [43–45]. This helped to regulate, monitor, and standardize the effort to reduce and eventually stop cases within hospitals and the surrounding community.

6.2. Aspect 2 – Personal and Cultural Belief Systems

While Saudi Arabian officials did put in place a Rapid Response Team (RRT) to combat the outbreak, a 2017 study found that, even several years after implementation, many interviewed Health Care Workers, nurses, and other hospital support staff were not fully compliant with these guidelines, putting themselves and patients at risk for MERS-CoV infections [58]. The general feeling of Saudi Arabian workers and citizens was largely that MERS was not a substantial problem, and holes in

primary care practices in addition to spread by dromedaries and humans alike in the population contributed to the continuing epidemic in the Saudi Arabian region.

In addition, a 2018 Saudi Arabian study found that many medical professionals working in hospitals with MERS-CoV infected patients were unaware of how the disease spreads, with only 25% of respondents realizing that close contact with an infected patient effectively transmits disease [36]. South Korea on the other hand, quickly implemented strict quarantine countermeasures for patients entering the hospital system [19]. This made a substantial difference in being able to counteract and reduce the number of hospital-acquired infections, sequestering outbreaks before they reached an unmanageable level.

A problem noted previously among South Korean hospital and clinic settings is visiting multiple doctors before being admitted to hospital [50]. By requiring multiple visits to multiple healthcare locations, the patient exposes many other patients who are also compromised by other ailments to the virus. For example, in the index South Korean patient's case, symptom presentation was 11 May, but it wasn't until 20 May that a diagnosis was confirmed [50]. During this time, the patient visited several outpatient clinics and healthcare environments, further contributing to viral spread.

Another contributing factor falls into the category of cultural belief systems. In a 6-country iPhone survey done in the Middle East (including hotspots of MERS-CoV outbreaks), investigators found that two-thirds of the nearly 2000 participants responded as "not concerned" or "slightly concerned" about contracting MERS [58]. Approximately 40% of those participants cited religious convictions as their reason for lack of concern. As previously discussed, cultural beliefs and practices in the Saudi Arabian region have likely contributed to incomplete containment of the outbreak, including attitudes toward personal protection and limited autopsy and post-mortem test results from Middle Eastern fatalities.

6.3. Aspect 3 – Sustained Transmission of MERS-CoV

Another major difference between South Korea and Saudi Arabia remains usage and presence of dromedary camels. A large proportion of Saudi Arabian citizens utilize on dromedary camels for entertainment (the greatest example being races, held often in the region), meat, and milk, though this may vary depending on whether the location is rural or urban [59–61]. While other livestock have been found to transmit MERS-CoV or have the potential to, camels are the only currently cited animal source of transmission to humans [33]. Thus, a primary reason for sustained transmission of MERS-CoV, in addition to previously described healthcare measures, is the constant presence and interaction with dromedary camels in Saudi Arabia. In contrast, South Korea does not utilize dromedary camels in their daily lives, limiting exposure to MERS-CoV by this route.

Another interesting finding by Park et al. is that incubation periods in South Korea were reported as being slightly longer, averaging 6 days, compared to 4.5–5 days in the Middle East [62]. This delay also contributes to sustained transmission of MERS-CoV, as continued exposure to infectious persons can contribute to sustained person-to-person transmission. Higher mortality rates in Saudi Arabia compared to South Korea are likely in part due to these differences, among others described in this review [62].

7. Conclusions and Future Directions

While there have been many treatment and prevention strategies including neutralizing monoclonal antibodies [63], antivirals [64], and orthopoxvirus-based vaccines [65], there remains no medical interventions for prevention or successful treatment of MERS. However, it is promising that an imported outbreak in South Korea was managed so effectively that it was declared over only two months after the index case. There are many lessons to be learned from the South Korean handling of the nosocomial outbreak, but one problem that remains is the cultural barrier faced in Saudi Arabia. Whether cultural, personal, or livelihood based, there are many opposing opinions that hinder the outbreak resolution effort.

Following South Korea's example, there were three major differences between the outbreaks. The first was the open relationship between healthcare professionals and patients seen in South Korea. Patients felt more comfortable with their healthcare workers, and were more willing to go to the

hospital or clinic if they felt unwell. In addition, unlike the South Korean index patient, the majority of infected individuals were truthful about their travel, and if they had been to a MERS-affected area. This allowed professionals to be involved in the isolation and treatment process much sooner than in the Saudi Arabian outbreak.

In addition, there was more stringent training for healthcare professionals in South Korea, particularly in teaching members of medical staff how to manage incoming MERS cases, whether confirmed or not. These individuals were better equipped to deal with potential cases of MERS entering the hospital environment, thus avoiding potential nosocomial spread. In the case of the start of the Saudi Arabian outbreak, some medical professionals were unaware of how to isolate and manage patients, lacking basic knowledge of transmission and viral spread, enabling the virus to travel further and faster than if the patient was isolated and protective equipment were worn by staff and visitors from the onset of treatment.

And finally, there was a notable difference in the daily interactions with camels in the two regions. Use of on dromedaries in the Saudi Arabian region is significantly higher than in South Korea, where a variety of other animals such as horses and cattle are used as well. Continual interaction with these reservoirs of MERS-CoV is the primary cited reason for the frequency and duration of the Saudi Arabian outbreak, in comparison to the South Korean outbreak.

In order to proceed forward, regulatory boards such as the grouping of the MERS-CoV Infection Prevention and Control Guideline Development Committee, among others, during the time of an outbreak is essential to swift declaration and prevention of spread. In performing this step as a unified group, standardization of knowledge, training, and practices to be upheld during an outbreak are more effectively communicated, and nosocomial transmission and infections of hospital staff can be reduced.

While the ultimate research goal remains finding a vaccine and antivirals or other therapies that improve MERS outcome, in the interim, better infection control practices, improved communication of protection knowledge to the general public, and an open, understanding relationship between healthcare providers and their patients are the primary ways to improve outbreak outcomes. MERS remains a complex virus, and has proved difficult to sequester. The future of MERS outbreak prevention is in the hands of government policy makers, hospital workers, and a well-informed general population.

Coronavirus disease 2019 (COVID-19) is an acute infection of the respiratory tract that emerged in late 2019^{1,2}. Initial outbreaks in China involved 13.8% of cases with severe courses, and 6.1% of cases with critical courses³. This severe presentation may result from the virus using a virus receptor that is expressed predominantly in the lung^{2,4}; the same receptor tropism is thought to have determined the pathogenicity—but also aided in the control—of severe acute respiratory syndrome (SARS) in 2003⁵. However, there are reports of cases of COVID-19 in which the patient shows mild upper respiratory tract symptoms, which suggests the potential for pre- or oligosymptomatic transmission^{6–8}. There is an urgent need for information on virus replication, immunity and infectivity in specific sites of the body. Here we report a detailed virological analysis of nine cases of COVID-19 that provides proof of active virus replication in tissues of the upper respiratory tract. Pharyngeal virus shedding was very high during the first week of symptoms, with a peak at 7.11×10^8 RNA copies per throat swab on day 4. Infectious virus was readily isolated from samples derived from the throat or lung, but not from stool samples—in spite of high concentrations of virus RNA. Blood and urine samples never yielded virus. Active replication in the throat was confirmed by the presence of viral replicative RNA intermediates in the throat samples. We consistently detected sequence-distinct virus populations in throat and lung samples from one patient, proving independent replication. The shedding of viral RNA from sputum outlasted the end of symptoms. Seroconversion occurred after 7 days in 50% of patients (and by day 14 in all patients), but was not followed by a rapid decline in viral load. COVID-19 can present as a mild illness of the upper respiratory tract. The confirmation of active virus replication in the upper respiratory tract has implications for the containment of COVID-19.

There is a close genetic relationship between SARS coronavirus (SARS-CoV) and the causative agent of COVID-19, SARS-CoV-2. The predominant expression of ACE2 in the lower respiratory tract is believed to have determined the natural history of SARS as an infection of the lower respiratory tract⁵. Although the positive detection of SARS-CoV-2 in clinical specimens from the upper respiratory tract has previously been described^{9,10}, these observations do not address the principal differences between SARS and COVID-19 in terms of clinical pathology. The patients who were studied here were enrolled because they acquired their infections upon known close contact to an index case, thereby avoiding representational biases owing to symptom-based case definitions. All patients were treated in a single hospital in Munich, Germany. Virological testing was done by two closely collaborating laboratories that used the same standards of technology for PCR with reverse transcription (RT-PCR) and virus isolation; these two laboratories confirmed each other's

results in almost all of the individual samples. Owing to the extremely high congruence of results, all data—except for the serological data (which are based on results from one laboratory only)—are presented together. The patients are part of a larger cluster of epidemiologically linked cases that occurred after 23 January 2020 in Munich, as discovered on 27 January (ref. ¹¹). The present study uses samples taken during the clinical course in the hospital, as well as from initial diagnostic testing before admission. In cases in which this initial diagnostic testing was done by other laboratories, the original samples were retrieved and retested under the rigorous quality standards of the present study.

RT-PCR, replication sites and infectivity

To first understand whether the described clinical presentations are solely caused by infection with SARS-CoV-2, samples from all patients

Neg., sample negative for RNA copies. **c**, Viral RNA concentrations in sputum and stool samples. **d**, Seroconversion and virus isolation success, dependent on day after the onset of symptoms. Top, fraction of seroconverted patients. Bottom, aggregated results of virus isolation trials. **e**, Virus isolation success, dependent on viral load. Viral loads were projected to RNA copies per ml (for sputum samples), per swab (for throat swab samples) or per g (for stool samples). **f, g**, Projected virus isolation success based on probit distributions. The inner lines are probit curves (dose–response rule). The outer dotted lines are 95% confidence interval. For a <5% isolation success, the estimated day was 9.78 (95% confidence interval 8.45–21.78) days after the onset of symptoms, and the estimated RNA concentration for <5% isolation success was estimated to be 5.40 log₁₀(RNA copies per ml) (95% confidence interval –4.11–6.51). **h**, Subgenomic viral RNA transcripts in relation to viral genomic RNA. Dots represent mean values of RT–PCR data obtained from at least two independent experiments on samples from individual patients. Plots show median values with interquartile ranges.

were tested against a panel of typical agents of respiratory viral infection, including human coronavirus (HCoV)-HKU1, HCoV-OC43, HCoV-NL63 and HCoV-229E, influenza virus A, influenza virus B, phinovirus, enterovirus, respiratory syncytial virus, human parainfluenza viruses 1–4, human metapneumovirus, adenovirus and human bocavirus. No coinfection was detected in any patient.

All patients were initially diagnosed by RT–PCR from oro- or nasopharyngeal swab specimens¹². Both types of specimen were collected over the whole clinical course in all patients. There were no discernible differences in viral loads or detection rates when comparing naso- and oropharyngeal swabs (Fig. 1b). The earliest swabs were taken on day 1 of symptoms, which were often very mild or prodromal. All swabs from all patients taken between day 1 and day 5 tested positive. The average virus RNA load was 6.76×10^5 copies per whole swab until day 5, and the maximum load was 7.11×10^8 copies per swab. Swab samples taken after day 5 had an average viral load of 3.44×10^5 copies per swab and

Stool			G>A	A=G	A=G	G>A	A

a detection rate of 39.93%. The last swab sample that tested positive was taken on day 28 after the onset of symptoms. The average viral load in sputum was 7.00×10^6 copies per ml, with a maximum of 2.35×10^9 copies per ml.

Because swab samples had limited sensitivity for the initial diagnosis of cases of SARS^{13,14}, we analysed the first paired swab and sputum samples taken on the same occasion from seven patients. All samples were taken between 2 and 4 days after the onset of symptoms. In two cases, swab samples had virus concentrations that were clearly higher than those in sputum samples, as indicated by a difference of >3 in the threshold cycle (C_t) value. The opposite was true in two other cases, and the remaining three cases had similar concentrations in both sample types.

None of 27 urine samples and none of 31 serum samples tested positive for RNA from SARS-CoV2.

To understand infectivity, we attempted live virus isolation on multiple occasions from clinical samples (Fig. 1d). Whereas the virus was readily isolated during the first week of symptoms from a considerable fraction of samples (16.66% of swabs and 83.33% of sputum samples), no isolates were obtained from samples taken after day 8 in spite of ongoing high viral loads.

Virus isolation from stool samples was never successful, irrespective of viral RNA concentration, on the basis of a total of 13 samples taken between day 6 and day 12 from 4 patients. The success of virus isolation also depended on viral load: samples that contained <10⁶ copies per ml (or copies per sample) never yielded an isolate. For sputum samples, interpolation based on a probit model was done to obtain laboratory-based infectivity criteria for the discharge of patients (Fig. 1f, g).

High viral loads and successful isolation from early throat swabs suggested potential virus replication in tissues of the upper respiratory tract. To obtain proof of active virus replication in the absence of histopathology, we conducted RT–PCR tests to identify viral subgenomic mRNAs directly in clinical samples (Extended Data Fig. 1). Viral subgenomic mRNA is transcribed only in infected cells and is not packaged into virions, and therefore indicates the presence of actively infected cells in samples. Levels of viral subgenomic mRNA were compared against viral genomic RNA in the same sample. In sputum samples taken on day 4 to day 9, during which time active replication in sputum was obvious in all patients as per longitudinal viral load courses (as described in ‘Viral load, antibody response and clinical course’), the ratios of mean normalized subgenomic mRNA per genome were about 0.4% (Fig. 1g). A decline occurred from day 10 to day 11. In throat swabs, all samples taken up to day 5 were in the same range, whereas no subgenomic mRNA was detectable in swabs thereafter. Together, these data indicate the active replication of SARS-CoV-2 in the throat during the first five days after the onset of symptoms. No (or only minimal) indications of replication in stool were obtained by the same method (Fig. 1g).

During our study, we sequenced full virus genomes from all patients. A G6446A exchange was first detected in one patient, and later transmitted to other patients in the cluster¹¹. In the first patient, this mutation was found in a throat swab while a sputum sample from the same day showed the original allele (G6446). The single-nucleotide

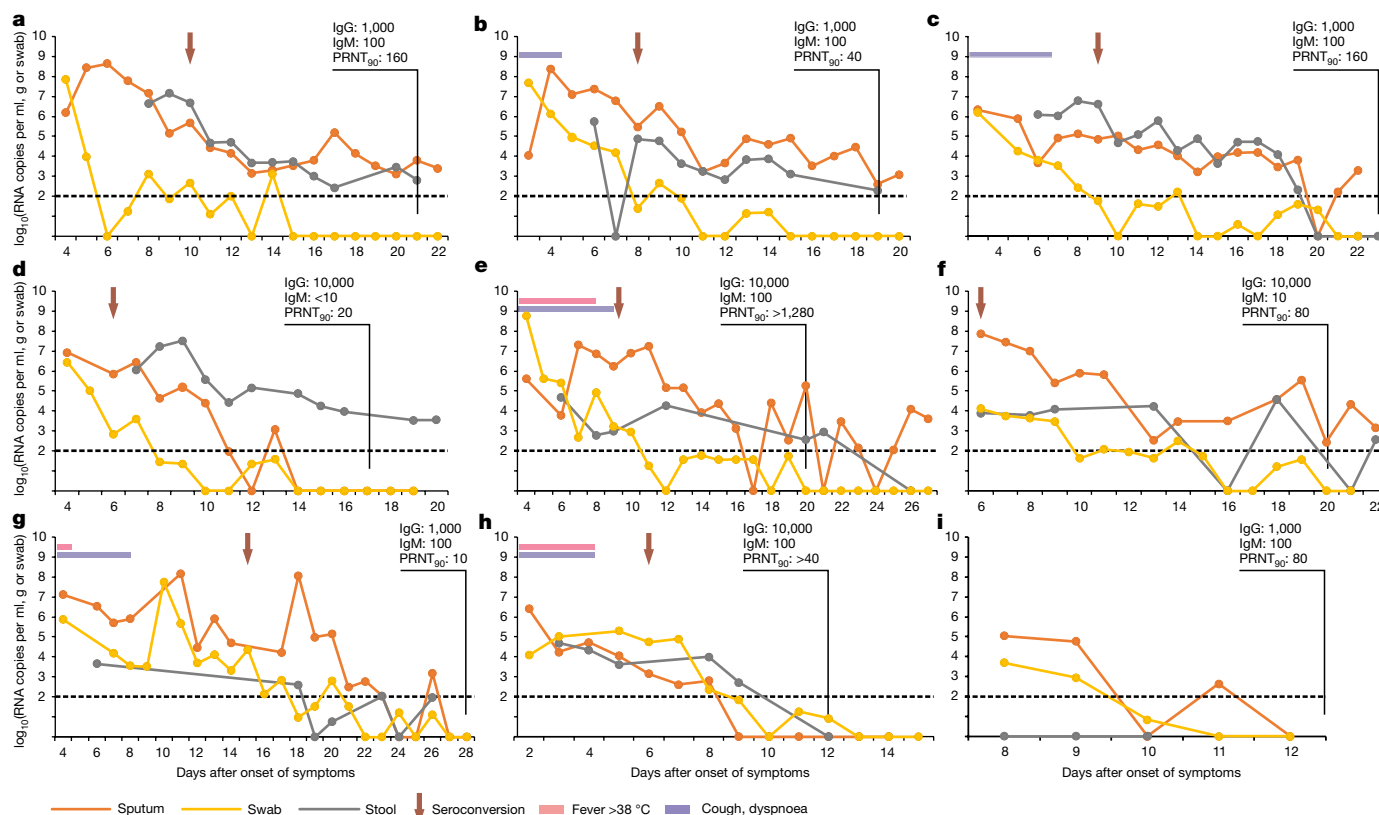

Fig. 2 | Viral load kinetics, seroconversion and clinical observations in individual cases. a–i, The panels correspond to patients no. 1 (a), 2 (b), 3 (c), 4 (d), 7 (e), 8 (f), 10 (g), 14 (h) and 16 (i) in a previous publication¹¹. Dotted lines,

limit of quantification. Experiments were performed in duplicate and the data presented are the mean of results obtained by two laboratories independently. PRNT₉₀, serum dilution that causes viral plaque reduction of 90%.

polymorphism was analysed by RT-PCR and Sanger sequencing in all sequential samples available from that patient (Table 1). The presence of separate genotypes in throat swabs and sputum strongly supported our suspicion of independent virus replication in the throat, rather than passive shedding to the throat from the lung.

Viral load, antibody response and clinical course

Daily measurements of viral load in sputum, pharyngeal swabs and stool are summarized in Fig. 2. In general, the concentrations of viral RNA were very high in initial samples. In all patients except one, the concentration of viral RNA in throat swabs seemed to be already on the decline at the time of first presentation. Viral RNA concentrations in sputum declined more slowly, with a peak during the first week of symptoms in three out of eight patients. Viral RNA concentrations in stools were also high. In many cases, the course of viral RNA concentration in stools seemed to reflect the course in sputum (Fig. 2a–c). In only one case did independent replication in the intestinal tract seem obvious from the course of stool RNA excretion (Fig. 2d). Whereas symptoms mostly waned until the end of the first week (Table 2), viral RNA remained detectable in throat swabs well into the second week. Stool and sputum samples remained RNA-positive over three weeks in six of the nine patients, in spite of full resolution of symptoms.

All cases had comparatively mild courses (Table 2). The two patients who showed some signs of lung infection were the only cases in which sputum viral loads showed a late and high peak around day 10 or 11, whereas sputum viral loads were on the decline by this time in all other patients (Fig. 2f, g). Of note, four out of nine patients showed a loss of taste and olfactory sensation, and described this loss to be stronger and more long-lasting than in common cold diseases.

Seroconversion was detected by IgG and IgM immunofluorescence using cells that express the spike protein of SARS-CoV-2 and a virus neutralization assay using SARS-CoV-2 (Table 3, Extended Data Fig. 2). Seroconversion in 50% of patients occurred by day 7, and in all patients by day 14 (Fig. 1d). No viruses were isolated after day 7. All patients showed detectable neutralizing antibodies, the titres of which did not suggest close correlation with clinical courses. Of note, patient no. 4, who showed the lowest virus neutralization titre at end of week 2, seemed to shed virus from stool over a prolonged time (Fig. 2d). Results from the differential recombinant immunofluorescence assay indicated cross-reactivity or cross-stimulation against the four endemic human coronaviruses in several patients (Extended Data Table 1).

Conclusions

The clinical courses in the patients under study—all of whom were young- to middle-aged professionals without notable underlying disease—were mild. Apart from one patient, all cases were first tested when symptoms were still mild or in the prodromal stage (a period in which most patients would present once there is general awareness of a circulating pandemic disease⁵). Diagnostic testing suggests that simple throat swabs will provide sufficient sensitivity at this stage of infection. This is in stark contrast to SARS; for instance, only 38 of 98 nasal or nasopharyngeal swab samples tested positive by RT-PCR in patients with SARS in Hong Kong¹⁵. Viral load also differs considerably between SARS and COVID-19. For SARS, it took 7 to 10 days after the onset of symptoms until peak RNA concentrations (of up to 5×10^5 copies per swab) were reached^{13,14}. In the present study, peak concentrations were reached before day 5, and were more than 1,000 times higher. Successful isolation of live virus from throat swabs is another notable difference between COVID-19 and SARS, for which such isolation was

rarely successful^{16–18}. This suggests active virus replication in tissues of the upper respiratory tract, where SARS-CoV is not thought to replicate in spite of detectable ACE2 expression^{19,20}. At the same time, the concurrent use of ACE2 as a receptor by SARS-CoV and SARS-CoV-2 corresponds to a highly similar excretion kinetic in sputum, with active replication in the lung. SARS-CoV was previously found¹³ in sputum at mean concentrations of $1.2\text{--}2.8 \times 10^6$ copies per ml, which corresponds to observations made here.

Whereas proof of replication by histopathology is awaited, extended tissue tropism of SARS-CoV-2 with replication in the throat is strongly supported by our studies of cells that transcribe subgenomic mRNA in throat swab samples, particularly during the first 5 days of symptoms. Notable additional evidence for independent replication in the throat is provided by sequence findings in one patient, who consistently showed a distinct virus in the throat as opposed to the lung. In addition, the disturbance of gustatory and olfactory senses points at an infection of the tissues of the upper respiratory tract.

Critically, the majority of patients in the present study seemed to be beyond their shedding peak in samples from the upper respiratory tract when they were first tested, whereas the shedding of infectious virus in sputum continued throughout the first week of symptoms. Together, these findings suggest a more efficient transmission of SARS-CoV-2 than SARS-CoV, through active pharyngeal viral shedding at a time at which symptoms are still mild and typical of infections of the upper respiratory tract. Later in the disease, COVID-19 resembles SARS in terms of replication in the lower respiratory tract. Of note, the two patients who showed some symptoms of the lungs being affected showed a

prolonged viral load in sputum. Our study is limited, in that no severe cases were observed. Future studies that include severe cases should look at the prognostic value of an increase of viral load beyond the end of week 1, potentially indicating an aggravation of symptoms.

One of the most interesting hypotheses to explain the potential extension of tropism to the throat is the presence of a polybasic furin-type cleavage site at the S1–S2 junction in the SARS-CoV-2 spike protein that is not present in SARS-CoV¹⁷. The insertion of a polybasic cleavage site in the S1–S2 region in SARS-CoV has previously been shown to lead to a moderate, but discernible, gain-of-fusion activity that might result in increased viral entry in tissues with a low density of ACE2 expression²¹.

The combination of very high concentrations of virus RNA and the occasional detection of cells in stools that contain subgenomic mRNA indicate active replication in the gastrointestinal tract. Active replication is also suggested by a much higher detection rate compared to the Middle East respiratory system coronavirus (MERS-CoV), for which stool-associated RNA was found in only 14.6% of samples from 37 patients hospitalized in Riyadh (Saudi Arabia)^{22,23}. If SARS-CoV-2 was only passively present in the stool (such as after swallowing respiratory secretions), similar detection rates as for MERS-CoV would be expected. Replication in the gastrointestinal tract is also supported by analogy with SARS-CoV, which was regularly excreted in stool (from which it could be isolated in cell culture²⁴). Our failure to isolate live SARS-CoV-2 from stools may be due to the mild courses of cases, with only one case showing intermittent diarrhoea. In China, diarrhoea was seen in only 2 of 99 cases²⁵. Further studies should therefore address whether SARS-CoV-2 shed in stools is rendered noninfectious though contact with the gut environment. Our initial results suggest that measures to contain viral spread should aim at droplet-, rather than fomite-, based transmission.

The prolonged viral shedding in sputum is relevant not only for the control of infections in hospitals, but also for discharge management. In a situation characterized by a limited capacity of hospital beds in infectious disease wards, there is pressure for early discharge after treatment. On the basis of the present findings, early discharge with ensuing home isolation could be chosen for patients who are beyond day 10 of symptoms and have less than 100,000 viral RNA copies per ml of sputum. Both criteria predict that there is little residual risk of infectivity, on the basis of cell culture.

The serological courses of all patients suggest a timing of seroconversion similar to, or slightly earlier than, in SARS-CoV infection¹⁸. Seroconversion in most cases of SARS occurred during the second week of symptoms. As in SARS and MERS, IgM was not detected considerably earlier than IgG in immunofluorescence; this might in part be due to technical reasons, as the higher avidity of IgG antibodies outcompetes IgM for viral epitopes in the assay. IgG depletion can only partially alleviate this effect. Because immunofluorescence assay is a

Table 3 | IgG and IgM immunofluorescence titres against SARS-CoV-2, from all patients

Patient ID no.	Initial serum		Final serum				
	Day after onset	IgG	Day after onset	IgG	IgM	PRNT ₉₀	PRNT ₅₀

NA, not applicable; PRNT₅₀, serum dilution that causes viral plaque reduction of 50%.

labour-intensive method, enzyme-linked immunosorbent assay tests should be developed as a screening test. Neutralization testing is necessary to rule out cross-reactive antibodies directed against endemic human coronaviruses. On the basis of the frequently low neutralizing antibody titres observed in coronavirus infection^{26,27}, we have here developed a particularly sensitive plaque-reduction neutralization assay. Considering the titres we observed, a simpler microneutralization test format is likely to provide sufficient sensitivity in routine application and population studies.

When aligned to viral load courses, it seems there is no abrupt virus elimination at the time of seroconversion. Rather, seroconversion early in week 2 coincides with a slow but steady decline of viral load in sputum. Whether properties such as the glycosylation pattern at critical sites of the glycoprotein have a role in the attenuation of the neutralizing antibody response needs further clarification. In any case, vaccine approaches targeting mainly the induction of antibody responses should aim to induce particularly strong antibody responses to be effective.

Article

Methods

No statistical methods were used to predetermine sample size. The experiments were not randomized and investigators were not blinded to allocation during experiments and outcome assessment.

Clinical samples and viral load conversion

Sputum and stool samples were taken and shipped in native conditions. Oro- and nasopharyngeal throat swabs were preserved in 3 ml of viral transport medium. Viral loads in sputum samples were projected to RNA copies per ml, in stool samples to copies per g and in throat swabs to copies per 3 ml, assuming that all sample components were suspended in 3 ml viral transport medium. For swab samples suspended in less than 3 ml viral transport medium, this conversion was adapted to represent copies per whole swab. An aggregated overview of samples received per day after the onset of disease from all patients is shown in Fig. 1a.

RT-PCR for SARS-CoV-2 and other respiratory viruses

RT-PCR used targets in the *E* and *RdRp* genes as previously described¹². Both laboratories used a pre-formulated oligonucleotide mixture (Tib-Molbiol) to make the laboratory procedures more reproducible. All patients were also tested for other respiratory viruses, including HCoV-HKU1, HCoV-OC43, HCoV-NL63 and HCoV-229E, influenza virus A, influenza virus B, rhinovirus, enterovirus, respiratory syncytial virus, human parainfluenza viruses 1–4, human metapneumovirus, adenovirus and human bocavirus using LightMix-Modular Assays (Roche). Additional technical details are provided in Supplementary Methods section 1.

Virus isolation

Virus isolation was done in two laboratories on Vero E6 cells. In brief, 100 µl of suspended, cleared and filtered clinical sample was mixed with an equal volume of cell culture medium. Supernatant was collected after 0, 1, 3 and 5 days and used in RT-PCR analysis. Additional technical details are provided in Supplementary Methods section 2a.

Serology

We performed recombinant immunofluorescence assays to determine the specific reactivity against recombinant spike proteins in VeroB4 cells, as previously described^{26,28}. This assay used a cloned coronavirus spike protein from HCoV-229E, HCoV-NL63, HCoV-OC43, HCoV-HKU1 or SARS-CoV-2. The screening dilution was 1:10. Plaque reduction neutralization tests were done essentially as previously described for MERS-CoV²⁶. Serum dilutions causing plaque reductions of 90% (PRNT₉₀) and 50% (PRNT₅₀) were recorded as titres. Additional technical details are provided in Supplementary Methods section 2b, c.

Statistical analyses

Statistical analyses were done using SPSS software (version 25) or GraphPad Prism (version 8).

Ethical approval statement

All patients provided informed consent for the use of their data and clinical samples for the purposes of the present study. Institutional review board clearance for the scientific use of patient data has been granted to the treating institution by the ethics committee at the Medical Faculty of the Ludwig Maximilians Universität Munich (vote 20-225 KB).

Fertility

Abstract

Background: Coronavirus disease 2019 (COVID-19), caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), involves multiple organs. Testicular involvement is largely unknown.

Objective: To determine the pathological changes and whether SARS-CoV-2 can be detected in the testes of deceased COVID-19 patients.

Design, setting, and participants: Postmortem examination of the testes from 12 COVID-19 patients was performed using light and electron microscopy, and immunohistochemistry for lymphocytic and histiocytic markers. Reverse transcription-polymerase chain reaction (RT-PCR) was used to detect the virus in testicular tissue.

Outcome measurements and statistical analysis: Seminiferous tubular injury was assessed as none, mild, moderate, or severe according to the extent of tubular damage. Leydig cells in the interstitium were counted in ten 400× microscopy fields.

Results and limitations: Microscopically, Sertoli cells showed swelling, vacuolation and cytoplasmic rarefaction, detachment from tubular basement membranes, and loss and sloughing into lumens of the intratubular cell mass. Two, five, and four of 11 cases showed mild, moderate, and severe injury, respectively. The mean number of Leydig cells in COVID-19 testes was significantly lower than in the control group (2.2 vs 7.8, $p < 0.001$). In the interstitium there was edema and mild inflammatory infiltrates composed of T lymphocytes and histiocytes. Transmission EM did not identify viral particles in three cases. RT-PCR detected the virus in one of 12 cases.

Conclusions: Testes from COVID-19 patients exhibited significant seminiferous tubular injury, reduced Leydig cells, and mild lymphocytic inflammation. We found no evidence of SARS-CoV-2 virus in the testes in the majority (90%) of the cases by RT-PCR, and in none by electron microscopy. These findings can provide evidence-based guidance for sperm donation and inform management strategies to mitigate the risk of testicular injury during the COVID-19 disease course.

1. Introduction

Coronavirus disease 2019 (COVID-19) is an infectious disease caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). The World Health Organization (WHO) declared the COVID-19 outbreak a global pandemic on March 11, 2020. As of May 4, 2020, more than 3.43 million cases and more than 239 000 deaths have been reported worldwide [1]. Many important discoveries have been made regarding COVID-19 etiology, epidemiology, diagnosis, and treatment strategies [2]. There are also emerging data on histopathological changes in various organs [3–5], especially the lungs [6,7]. However, information on COVID-19 pathology in the testis is scarce. A recent study found that ACE2 receptor, a target for SARS-CoV-2 infection, is expressed in germ cells, Leydig cells, and Sertoli cells in the testis [8] using single-cell RNA sequencing, suggesting the testis is potentially a target for SARS-CoV-2 infection. However, an autopsy study of one patient revealed that the testis appeared normal [9]. Two studies found no SARS-CoV-2 virus in semen [10,11]. A detailed examination of the testis in COVID-19 patients is therefore warranted to ascertain whether the virus can be found in the testicular epithelium and whether there is any cytopathic effect on the testis. Such knowledge may help in determining whether SARS-CoV-2 can be transmitted via semen and the risk of testicular injury during the disease course, which may affect fertility, especially in young patients.

2. Patients and methods

2.1. Postmortem examination of the testes

This study was conducted in accordance with the principles of the Declaration of Helsinki and the guidelines of the Chinese National Health Commission, and was approved by the Ethics Committee of Union Hospital, Tongji Medical College, Huazhong University of Science and Technology. According to the Chinese regulations [12], COVID-19 diagnosis was confirmed by positive nucleic acid testing of oropharyngeal swabs or bronchoalveolar lavage fluid, radiological features of viral pneumonia, and clinical symptomatology. Postmortem examinations were carried out after consent from patients or family members and were performed within 1 h of death at Union Hospital, Tongji Medical College, Huazhong University of Science and Technology. For eight patients, a tissue sample of 1 cm × 1 cm was obtained via incisional biopsy. For the other four patients, a tissue core of 1 cm × 0.2 cm was obtained using a 14 G needle under ultrasound guidance.

2.2. Tissue processing and staining

Procured tissue was fixed in 10% formalin for hematoxylin and eosin staining or in 2.5% glutaraldehyde for electron microscopy (EM) for

48–72 h. For EM, Epon-embedded “semi-thin” sections stained with toluidine blue were examined after gradient dehydration. Selected areas were chosen for thin sections, which were then cut and stained with uranyl acetate and lead citrate. EM grids were viewed using a transmission electron microscope (HT-7800; Hitachi, Hitachinaka, Japan) [13]. Immunohistochemical stains were performed for CD3 (Dako, Copenhagen, Denmark), CD20 (Roche, Tucson, AZ, USA), CD68 (Dako), CD138 (Dako), and ACE2 (Biolyx, Hanzhou, China) according to manufacturers’ protocols on a Dako Link 48 automated stainer (for CD3, CD68, CD138, and ACE2) or a Roche Benchmark XT Ultra system (for CD20).

2.3. Reverse transcription-polymerase chain reaction (RT-PCR)

Fourteen 5-μm-thick formalin-fixed, paraffin-embedded lung and testis tissue sections were used for RNA extraction using an AmoyDx FFPE RNA extraction kit (Amoy Diagnostics, Xiamen, China). SARS-CoV-2 RNA was detected using a real-time multiplex RT-PCR kit (Liferiver Biotechnology, Shanghai, China), which detects the SARS-CoV-2 RdRp gene, E gene, and N gene simultaneously. RT-PCR was performed on an Mx3000 P real-time PCR system (Agilent Technologies, Santa Clara, CA, USA). According to the manufacturer’s protocol, a threshold cycle (Ct) of ≤43 for all three genes, or the RdRp and E genes, or the RdRp and N genes indicated the presence of SARS-CoV-2.

3. Results

3.1. Clinical characteristics

Twelve patients were included in this study. The mean age was 65 yr (range 42–87 yr; Table 1). The mean disease duration (from onset to death) was 42 d (range 23–75 d). Fever was present in ten patients. Ten patients received low-dose steroids (maximum dose 160 mg).

3.2. Pathological findings

Pathological examination was performed in 11 of the 12 cases. One case (S5) contained predominantly fibrovascular tissue with very few seminiferous tubules and was therefore not included in the pathological evaluation. Seminiferous tubules exhibited a range of changes. Sertoli cells were affected predominantly and showed swelling, vacuolation and cytoplasmic rarefaction, and detachment from tubular basement membranes (Fig. 1A and 1B). Loss and sloughing of the intratubular cell mass into the lumens was also observed (Fig. 1C). According to the extent of these changes, seminiferous tubular injury was categorized as none, mild, moderate, or severe if 0%, <10%, 10–50%, or >50% of seminiferous tubules were affected, respectively. Two (18.2%), five (45.5%), and four (36.4%) of 11 cases showed mild, moderate, and severe injury, respectively

Table 1 – Clinical features of 12 COVID-19 patients.

Case no.	Age (yr)	Disease duration (d)	Body temperature (°C)	Steroid therapy	Comorbidity	Cause of death
S20-4	87	23	37.6	No	Hypertension, chronic renal disease, coronary heart disease	COVID-19, RF
S20-5	39	30	38.7	Yes	Gastric carcinoma	COVID-19
S20-6	66	36	38.9	Yes	Hepatocellular carcinoma	COVID-19, RF
S20-7	77	27	37.7	Yes	Basal cell carcinoma of the face	COVID-19, RF, septic shock
S20-9	70	20	36.5	Yes	Lung carcinoma (histological type unknown)	COVID-19, myocardial infarction, RF
S20-12	63	44	39	Yes	Hypertension	COVID-19, pneumonia, ARDS, MODS
S20-14	61	36	39.6	Yes	None	COVID-19, RF, septic shock
S20-19	55	37	38.3	Yes	None	COVID-19, respiratory failure, MODS
S20-20	73	49	37.5	Yes	Hypertension, gastric adenocarcinoma	COVID-19, septic shock
S20-22	42	52	40	Yes	Hypertension	COVID-19, RF, septic shock, MODS
S20-23	64	75	36.6	Yes	None	RF, COVID-19 (critical type), abdominal bleeding
S20-24	57	63	37.4	Yes	None	COVID-19, DIC, lower gastrointestinal bleeding

COVID-19 = coronavirus disease 2019; RF = respiratory failure; ARDS = acute respiratory distress syndrome; MODS = multiple organ dysfunction syndrome; DIC = disseminated intravascular coagulopathy.

(Table 2). To rule out the possibility that these changes resulted from protracted severe illness, we reviewed testes from five patients who died of non-COVID-19 causes and had a disease course of at least 7 d, and found no tubular injury in two cases and mild tubular injury in three cases (Fig. 1D).

To quantify Leydig cells in the interstitium, Leydig cell and seminiferous tubule cross-sections were counted in ten 400× microscopy fields and the number of Leydig cells per tubule cross-section was calculated. As a control group, we examined five orchiectomies performed for penile cancer ($n = 1$), castration in prostate cancer ($n = 3$), and perineal trauma ($n = 1$). The mean age of patients in the control group was 66.8 yr (range 49–75 yr), which was not significantly different from the age of our COVID-19 patients ($p = 0.807$, Student t test). The mean number of Leydig cells in COVID-19 testes was 2.2 (range 0.44–5.3), which was significantly lower than in the control group (7.8, range 5.3–10; $t = -6.336$, $p < 0.001$, Student t test).

In the interstitium there was edema and mild inflammatory infiltrates composed predominantly of CD3-positive T lymphocytes (Fig. 1E) and CD68-positive histiocytes (Fig. 1F) as confirmed by immunohistochemistry. B lymphocytes and plasma cells were not found in the stroma. No inflammatory cells were found within the seminiferous tubules.

Normal spermatogenesis was observed in three cases. The other cases showed variable degrees of spermatogenic alteration (Table 2) that was in general consistent with patient age.

Immunostaining revealed that ACE2 was diffusely expressed in Sertoli cells and strongly expressed in Leydig cells (Fig. 2). It was not expressed in spermatogonia. Germ cells at other differentiation stages, including primary and secondary spermatocytes, and spermatids, are difficult to assess as they were enveloped by the cytoplasm of Sertoli cells.

Transmission EM was performed for three of the 12 cases and did not identify definite SARS-CoV-2 viral particles.

3.3. Detection of SARS-CoV-2 by RT-PCR

The target SARS-CoV-2 nucleic acid sequence was detected in lung tissue from ten of the 12 patients. It was detected in the testis from only one case (S20-5) with a threshold cycle (Ct) value of 31.68, 30.53, and 30.46 for the RdRP, E, and N genes, respectively. Of note, this patient had a high viral load: his lung, kidney, spleen, and testis were all positive for the virus on RT-PCR. The testicular tissue sampled contained predominantly fibrovascular tissue and very few seminiferous tubules.

4. Discussion

The objectives in this study were twofold. First, we investigated whether SARS-CoV-2 virus could be detected in seminiferous tubules and germ cells. Second, we sought to determine whether COVID-19 can cause injury to seminiferous tubules and Leydig cells, which may affect fertility, especially in young men. The findings could have important clinical implications.

Many viruses that infect humans can be detected in semen [14]. It has been found that SARS-CoV, a virus that belongs to the same betacoronavirus family as SARS-CoV-2 and is responsible for SARS, causes spermatogenic cell necrosis and apoptosis and induces inflammatory infiltrates in the interstitium, although viral genomic sequences were not detected in testes [15]. A recent study using single-cell RNA sequencing found that the ACE2 receptor, a target for SARS-CoV-2 infection, is expressed in germ cells, Leydig cells, and Sertoli cells in the testis [8], suggesting the testis is potentially a tropism site and reservoir for the SARS-CoV-2 virus. In a study by Pan et al [10], 19% of patients had scrotal discomfort concerning for testicular involvement around the time of their COVID-19 diagnosis. On the basis of these preliminary data, the American Society for Reproductive Medicine and the Society for Assisted Reproductive

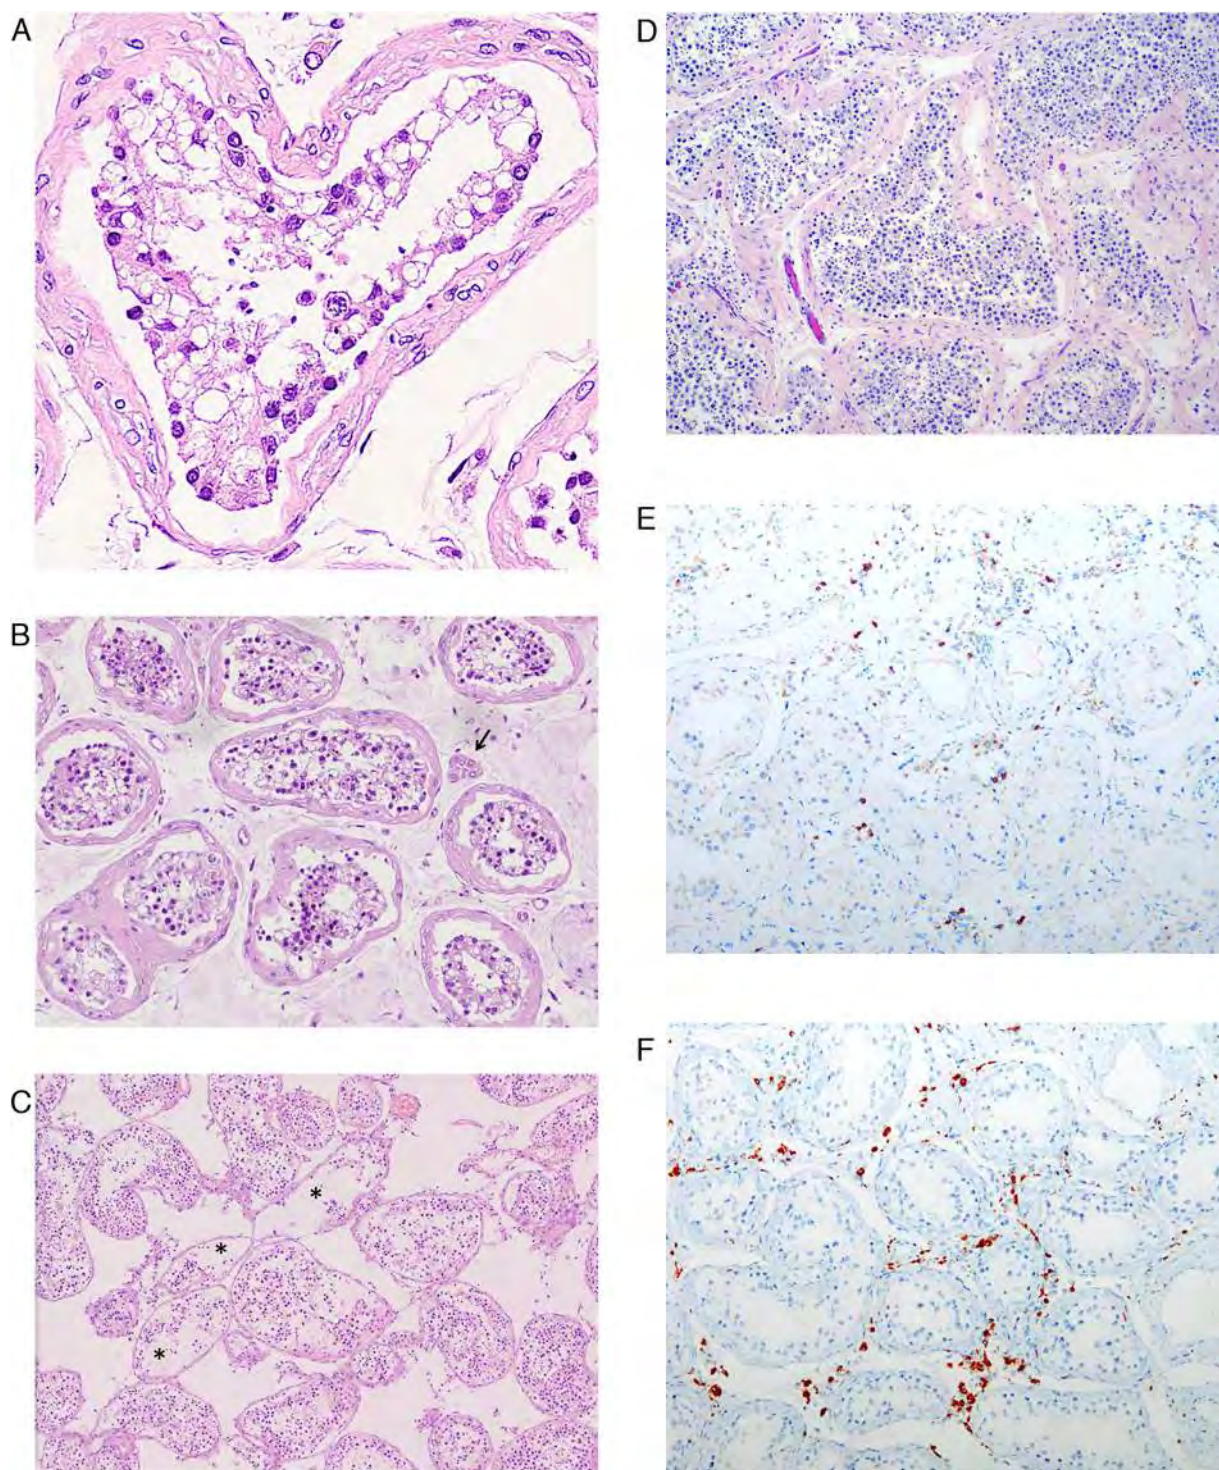

Fig. 1 – Pathology in testes from COVID-19 patients. (A) Sertoli cells shows swelling, vacuolation, and cytoplasmic rarefaction, and detachment from the tubular basement membranes. Spermatogenesis is present but reduced. **(B)** A case with severe tubular injury shows cytoplasmic vacuolation and detachment of Sertoli cells from the basement membranes. Spermatogenesis is present. Scattered Leydig cells are present (arrow). **(C)** A case with moderate tubular injury shows loss and sloughing of intratubular cells into the lumens (asterisks). There is marked interstitial edema. Note the normal spermatogenesis. **(D)** Testis from a non-COVID patient with protracted disease shows normal spermatogenesis. In the interstitium there is edema and mild inflammatory infiltrates composed predominantly of **(E)** CD3-positive T lymphocytes and **(F)** CD68-positive histiocytes according to immunohistochemistry. COVID-19 = coronavirus disease 2019.

Table 2 – Pathological findings in the testes of 12 COVID-19 patients.

Case no.	Tubular injury	Leydig cells	Spermatogenesis	SARS-CoV-2 (RT-PCR)		Electron microscopy
				Lung	Testis	
S20-4	Severe	2.0	Hypospermatogenesis, MPH	+	–	ND
S20-5	ND	ND	ND	+	+	ND
S20-6	Moderate	2.2	Hypospermatogenesis, MPH	+	–	ND
S20-7	Moderate	0.44	Maturation arrest, MPH	+	–	ND
S20-9	Moderate	1.6	Spermatogenesis appropriate for age	–	–	ND
S20-12	Mild	2.82	Hypospermatogenesis	+	–	Not detected
S20-14	Moderate	5.3	Spermatogenesis appropriate for age	+	–	Not detected
S20-19	Moderate	1.0	Spermatogenesis appropriate for age	+	–	ND
S20-20	Mild	3.6	Maturation arrest	+	–	Not detected
S20-22	Severe	ND	Maturation arrest, MPH	+	–	ND
S20-23	Severe	1.0	Hypospermatogenesis	–	–	ND
S20-24	Severe	1.5	Maturation arrest, MPH	+	–	ND

MPH = mild peritubular hyalinization; ND = not determined; RT-PCR = reverse transcription-polymerase chain reaction; SARS-CoV-2 = severe acute respiratory syndrome coronavirus 2.

Fig. 2 – ACE2 is diffusely expressed in Sertoli cells and strongly expressed in Leydig cells (long arrows) according to immunohistochemistry. Spermatogonia are negative (short arrows). Spermatocytes of later stages are surrounded by the Sertoli cell cytoplasm (open arrows).

Technology have advised caution regarding sperm donation by COVID-19 patients [16]. However, in our study we did not find evidence of the presence of SARS-CoV-2 in testicular tissue or germ cells. Of the ten cases for whom viral RNA was detected in lung tissue by RT-PCR, nine cases were negative for the virus in testicular tissue. Only one case was positive for the virus in the testis. This patient had a high viral load and his lung, kidney, and spleen, in addition to testis, were positive for the virus by RT-PCR. The testicular tissue sampled contained predominantly fibrovascular tissue and very few seminiferous tubules. It is likely that RT-PCR detected the virus present in blood rather than in testicular tissue. We also performed electron microscopy for three of the 12 cases (S20-12, S20-14, and S20-20). Viral particles were not identified in any case. Our study supports the finding in

two recent reports that SARS-CoV-2 was not detected in semen for a total of 46 patients after a median of 31 d from COVID-19 diagnosis [10,11]. Testicular tissue from a deceased COVID-19 patient tested negative for the virus on RT-PCR [11]. However, it remains possible that the virus may attack testicular tissue early on but is cleared from the testes later during the disease course, as testicular tissue was obtained 41 d after disease onset in this study and semen was obtained 31 d after disease onset in the study by Pan et al [10]. Further studies are needed to address whether the virus can be found in the testis in the early phase of COVID-19. However, the data so far demonstrate no evidence of the virus in semen or testicular tissue later in the disease course (30–40 d after disease onset), suggesting that sperm donation or an impregnation plan could be considered during convalescence for COVID-19 patients.

We observed morphological changes suggestive of significant damage to seminiferous tubules. Sertoli cells exhibited “ballooning” changes, vacuolation, and detachment from basement membranes. There was loss and sloughing into the lumens of tubular cells. We observed interstitial edema and mild lymphocytic inflammation with predominantly T lymphocytes, consistent with viral orchitis. Furthermore, the number of Leydig cells in the interstitium was significantly reduced in COVID-19 patients. It is intriguing that both Sertoli and Leydig cells have strong expression of ACE2, a cell-surface receptor to which SARS-CoV-2 binds to gain entry into cells. Even though we did not find the virus in seminiferous tubules or Leydig cells, we speculate that viral membrane proteins, such as the spike protein, may play a role in the injury to seminiferous tubules and Leydig cells. Alternatively, hyperthermia, secondary infection, hypoxia, and steroids may play a role in the tissue damage observed in the testis of COVID-19 patients.

Our study found that spermatogenesis was not altered and was appropriate for age in COVID-19 patients during the acute phase of the disease. Sertoli cells play a critical role in the homeostasis of seminiferous tubules and spermatogenesis [17] and Leydig cells are involved in androgen production [18],

so the pathology observed may lead to seminiferous tubule damage and endocrine abnormality and eventual reduced or even absent spermatogenesis in patients who have recovered from COVID-19. Our findings suggest that studies should be undertaken to find ways to mitigate the risk of testicular injury during the COVID-19 disease course.

5. Conclusions

We reported on pathological changes in 12 testes from patients who died of COVID-19. We found no evidence of SARS-CoV-2 virus in the testes in the majority (90%) of the cases by RT-PCR, and in none of the cases by electron microscopy. However, there was significant injury to Sertoli cells and seminiferous tubules, reduction of Leydig cells, and mild inflammatory infiltrates in the interstitium. These findings can provide evidence-based guidance for sperm donation and inform management strategies to mitigate the risk of testicular injury during the COVID-19 disease course.

Pregnant women with COVID-19 and risk of adverse birth outcomes and maternal-fetal vertical transmission: a population-based cohort study in Wuhan, China

Rong Yang¹, Hui Mei¹, Tongzhang Zheng², Qiang Fu³, Yiming Zhang¹, Stephen Buka², Xinan Yao⁴, Zezhong Tang⁵, Xichi Zhang⁶, Lin Qiu¹, Yaqi Zhang¹, Jieqiong Zhou¹, Jiangxia Cao¹, Youjie Wang^{7*} and Aifen Zhou^{1*}

Abstract

Background: The coronavirus disease 2019 (COVID-19) outbreak is evolving rapidly worldwide. However, little is known about the association between pregnant women with COVID-19 and the risk of adverse birth outcomes.

Method: We conducted a retrospective cohort study based on the Maternal and Child Health Information System (MCHIMS) of Wuhan, China. All pregnant women with singleton live birth recorded by the system between January 13 and March 18, 2020, were included. The adverse birth outcomes were preterm birth, low birth weight, neonatal asphyxia, premature rupture of membrane (PROM), and cesarean section delivery. Multivariate logistic regression was used to evaluate the associations between maternal COVID-19 diagnosis and adverse birth outcomes.

Results: Out of 11,078 pregnant women, 65 were confirmed with coronavirus disease 2019 (COVID-19). No deaths occurred from these confirmed cases or their newborns. Compared to pregnant women without COVID-19, pregnant women with a confirmed COVID-19 diagnosis had an increased risk of preterm birth (OR 3.34, 95% CI 1.60–7.00) and cesarean section (OR 3.63, 95% CI 1.95–6.76). There was no statistical difference in low birth weight, neonatal asphyxia, and PROM between the mothers with and without COVID-19. Among these newborns that were born to mothers with confirmed COVID-19, none was tested severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) positive or had abnormal CT results. Only one had diarrhea and three had a fever.

Conclusions: This population-based cohort study suggests that COVID-19 during the later pregnancy is associated with an increased risk of adverse birth outcomes, including iatrogenic preterm birth and cesarean section delivery. Our data provide little evidence for maternal-fetal vertical transmission of SARS-CoV-2. It is important to monitor the long-term health effects of SARS-CoV-2 infection on pregnant women and their children.

Keywords: COVID-19, Birth outcome, Maternal-fetal vertical transmission

Background

The outbreak of SARS-CoV-2 infection has become a global epidemic threat since the end of 2019 [1–4]. As of April 14, the cumulative number of confirmed COVID-19 cases had reached 1,930,000 with 120,000 (6%) deaths worldwide. The world is now launching a forceful, focused campaign to eradicate COVID-19. Wuhan, the capital of Hubei province where COVID-19 was first reported, was the hardest-hit Chinese city and accounts for 60% of confirmed cases and 83% of COVID-19 deaths in China. SARS-CoV-2 is a new virus that results in a spectrum of illness ranging from asymptomatic to severe acute respiratory distress syndrome and death [2, 3, 5]. The consequences of infection with SARS-CoV-2 among pregnant women are currently uncertain. Several hundreds of pregnant women in Hubei province were infected with SARS-CoV-2 based on infectious disease surveillance systems in Hubei province, China. While several case series studies have analyzed the clinical symptoms and prognosis of COVID-19 cases, no population-based study so far has been conducted to examine the relationship between SARS-CoV-2 infection and adverse birth outcomes.

Several case series with small sample sizes have examined the potential for in utero vertical transmission of SARS-CoV-2 in infected pregnant women in China. In a report involving two pregnant women with confirmed COVID-19, the two newborns were reported to be negative for SARS-CoV-2 tests [6]. A study involving 9 confirmed pregnant women with COVID-19 in Wuhan found no evidence of in utero vertical transmission of SARS-CoV-2 among their newborns [7]. A study involving 6 newborns born to mothers with confirmed COVID-19 also reported negative SARS-CoV-2 tests while virus-specific antibodies IgM and IgG were detected in 2 of the newborns, suggesting a possibility of in utero SARS-CoV-2 infection [8]. A recent single case study from Wuhan also suggests the potential in utero infection of the neonate [9].

Large population-based studies are urgently needed to evaluate if SARS-CoV-2 infection during pregnancy could affect pregnancy outcomes and result in utero vertical transmission. Such data would provide key information for the protection of women and children. This population-based cohort study in Wuhan for the first time evaluated the relationship between SARS-CoV-2 infection during later pregnancy and risk of adverse birth outcomes including preterm birth, low birth weight, PROM, neonatal asphyxia, and cesarean section. It also investigated the potential in utero vertical transmission at the population level.

Methods

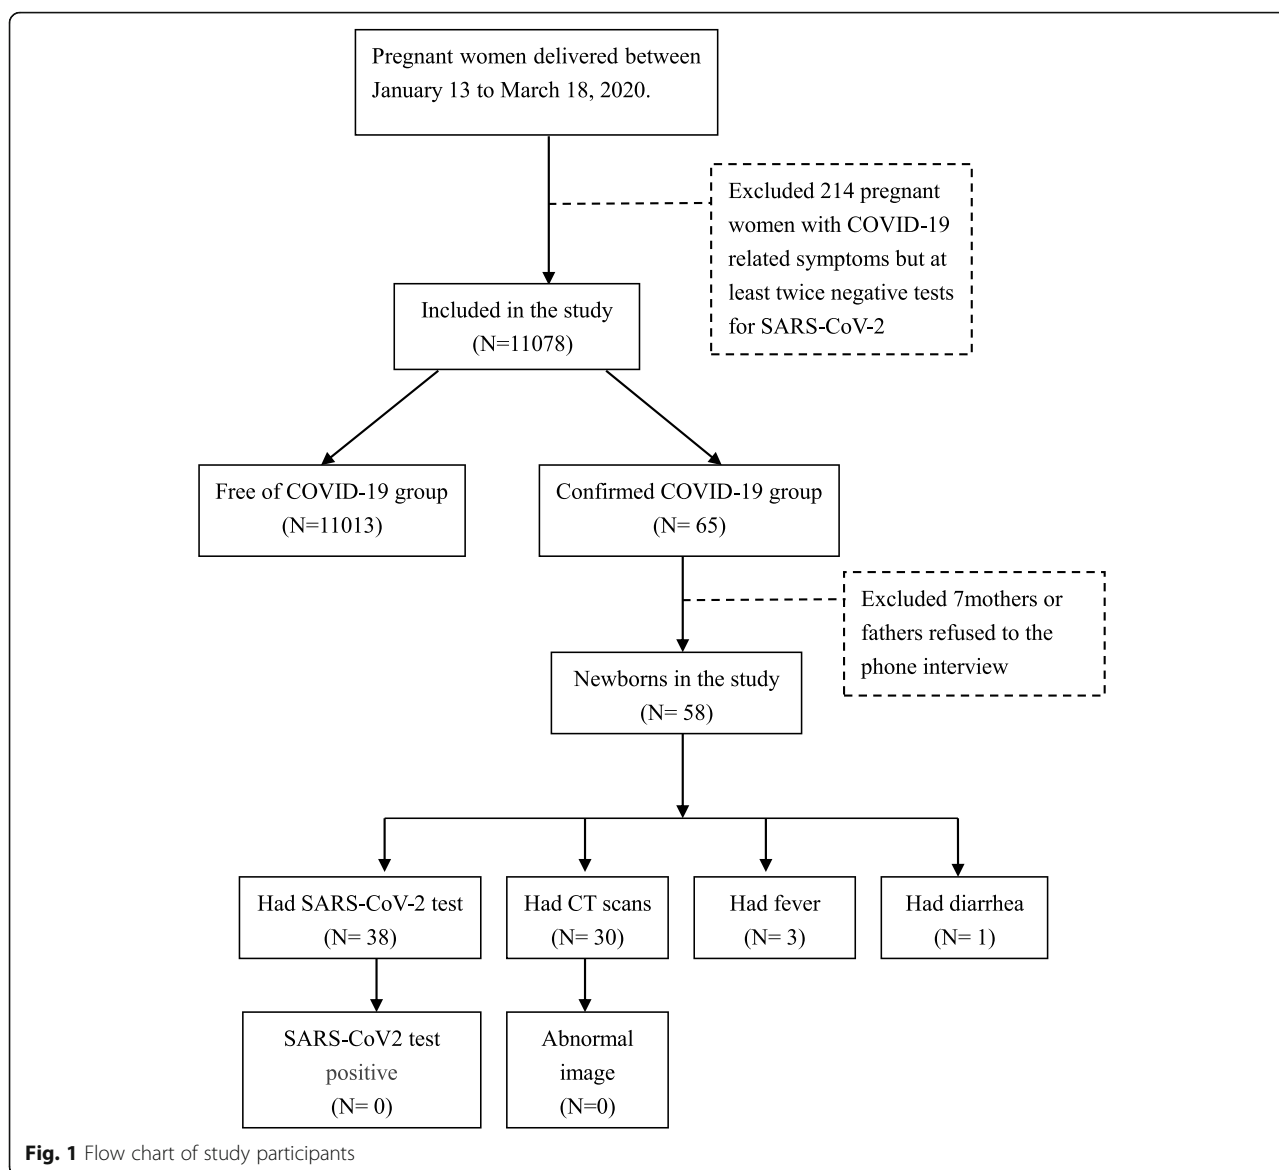

Sample

This population-based cohort study was conducted in Wuhan, the first reported city of the outbreak of

COVID-19 in China. We used the Maternal and Child Health Information Management System of Wuhan (MCHIMS) to identify the study population. The MCHIMS is used to monitor maternal and children's health by collecting information for all pregnant women and their children in the Wuhan metropolitan area. During the outbreak of COVID-19 in Wuhan, in addition to routine prenatal care data from clinical and laboratory examinations and socio-demographic information, the MCHIMS also recorded the COVID-19 diagnosis for pregnant women as part of the high-risk pregnancy surveillance during the COVID-19 pandemic in Wuhan. The pregnant women of Wuhan residents satisfying the following conditions will be included in the study: (1) gave a single live birth between January 13 and March 18, 2020 (that is, between the date of the first recorded COVID-19 case of pregnant women and the last date with available data for the study from the MCHIMS system), and (2) registered by the MCHIMS with either confirmed COVID-19 or free of COVID-19. We excluded the 214 pregnant women with COVID-19-related symptoms but at least twice tests of a negative result of SARS-CoV-2 detection. Finally, a total of 11,078 pregnant women satisfied the study criteria and were included in this study, 65 of them were recorded as confirmed cases of COVID-19. Among 11,013 women without a diagnosis of COVID-19 pregnant women, 4778 were admitted before February 3, 2020. The flow chart for the recruitment of study subjects is presented in Fig. 1.

Diagnosis of COVID-19

The study population was classified into confirmed COVID-19 group and free COVID-19 group. The diagnosis of COVID-19 was based on the clinical diagnostic criteria of the New Corona Virus Infected Pneumonia Diagnosis and Treatment Plan issued by the Chinese National Health and Health Commission in 2020 [10]. The confirmed cases of COVID-19 had taken at least twice tests for SARS-CoV-2, which used real-time RT-PCR based on a pharyngeal swab. During the outbreak, all pregnant women in Wuhan were under increased surveillance for COVID-19 and given top priority for SARS-CoV-2 testing and hospitalization. Due to the lack of available tests during the early phase of the pandemic (before February 4, 2020), only the pregnant women developing the symptoms like fever and cough or having abnormal computed tomography (CT) scan were tested for SARS-CoV-2. Since February 4, 2020, all pregnant women giving birth in hospitals were screened for the SARS-CoV-2. Pregnant women without COVID-19-related signs or symptoms were tested for the virus only once, while pregnant women with COVID-19-related signs or symptoms were tested for at least two times if the first detection was negative. Because of the

assumption from the severe acute respiratory syndrome (SARS) studies that there is no vertical transmission, all the newborns born to the infected mothers were separated from their mother immediately after delivery and were brought home unless medical observation or treatment was needed. To obtain information on COVID-19 diagnosis or SARS-CoV-2 infection status for the newborns born to these mothers with confirmed COVID-19, the study obstetricians at Wuhan Children's Hospital made follow-up phone calls. Mothers diagnosed with COVID-19 were directly transferred to specialty hospitals after delivery for treatment. After successful treatment, they were removed to facilities for quarantine for 14 days and these follow-up calls were made to their home usually after their discharge. All participants provided oral informed consent before the telephone interview.

Maternal and newborn variables

The information in the phone interviews was typically provided by the mothers, rarely by fathers. Maternal information abstracted from the MCHIMS includes age, education, employment, gestational age, gravidity, parity, pregnancy-induced hypertension, gestational diabetes mellitus, PROM, and SARS-CoV-2 infection. For the newborns, the abstracted information included sex, gestational week, preterm birth, birth weight, and neonatal asphyxia. Both maternal and newborn information was input based on the medical records by the health professionals in the delivery hospital. Primary outcomes for the newborns were preterm birth (< 37 weeks of pregnancy), low birth weight (< 2500), PROM (defined as rupture of membrane before the onset of labor), and neonatal asphyxia (defined as 1 min Apgar score ≤ 7 and umbilical arterial blood gas pH < 7.15 [11]).

Statistical analyses

Study population characteristics are presented by proportion for categorical variables. Univariate chi-square analyses were conducted to evaluate rates of birth outcomes by comparing the two groups of mothers with or without confirmed COVID-19. Multivariate logistic regression models were used to evaluate the associations between maternal COVID-19 status and adverse birth outcomes, adjusted for potential confounding variables. The following variables were included in the final models: maternal age (14–24, 25–34, 35–54), occupation (employed, housewives, part-time), education (bachelor's degree or above, high school, vocation degree, middle school or below), gravidity (1, 2, 3–10), parity (1, 2, 3–5), gestational hypertension (yes, no), preeclampsia (yes, no), gestational diabetes mellitus (yes, no), and PROM (yes, no). All analyses were performed using SAS version 9.4 (SAS Institute, Inc., Cary, North Carolina). The study was approved by the Human Ethics Committees at Wuhan Children's Hospital.

Results

Of the 11,078 pregnant women with singleton live births during the study period, 65 (0.57%) were diagnosed with COVID-19. Table 1 shows the demographic variables and pregnancy complications for these 11,078 pregnant women, and there were few differences between these pregnant women based on their COVID-19 status. Confirmed cases had higher educational attainment than the rest of the sample, with modest occupational differences as well.

Table 2 shows that the mothers with confirmed COVID-19 had a significantly higher rate of preterm birth and cesarean section. All preterm babies born to infected mothers in the present study were iatrogenic preterm birth. No significant differences in neonatal asphyxia, low birth weight, and PROM were observed between the two groups.

Figure 2 shows the multivariate logistic regression results for the associations between maternal COVID-19 status and the risk of adverse birth outcomes. Compared to mothers without COVID-19, mothers with confirmed COVID-19 had an adjusted OR of 3.34 (95% CI 1.60, 7.00) for preterm birth and an adjusted OR of 3.63 (95% CI 1.95, 6.76) for receiving cesarean section.

Table 3 presents the association between maternal COVID-19 diagnosis and preterm birth from mothers with cesarean section delivery. Compared to mothers without COVID-19, mothers with confirmed COVID-19 had an adjusted OR of 3.71 (95% CI 1.70, 8.03) for preterm birth among mothers with cesarean section delivery.

We reached 58 parents of the 65 confirmed maternal COVID-19 cases (89%) through phone calls by study

[‡]Adjusted for maternal age (14–24, 25–34, 35–54), occupation (employed, housewives, part-time), education (bachelor's degree or above, high school, vocation degree, middle school or below), gravidity (1, 2, 3–10), parity (1, 2, 3–5), gestational hypertension (yes, no), preeclampsia (yes, no), gestational diabetes mellitus (yes, no), and premature rupture of membranes (yes, no)

first time investigated if SARS-CoV-2 infection affects pregnancy outcomes and evidence for potential vertical transmission. Our study results showed that pregnant women with confirmed COVID-19 had an increased risk of adverse birth outcomes including preterm birth, and delivery with cesarean section compared to pregnant women without COVID-19. We also found no strong evidence suggesting a vertical maternal-fetal transmission of SARS-CoV-2.

Early studies have shown that physiologic and immunologic changes during pregnancy might increase the risk for pregnant women to be infected with respiratory viruses such as influenza [12, 13]. It has been reported that pregnant women are more susceptible to be infected, develop more severe complications of the disease, and have higher mortality compared to the non-pregnant population [14]. However, the infection rate of SARS-CoV-2 among pregnant women (0.57%) in the present study was comparable to that (0.50%) in the

Fig. 2 Risk of adverse birth outcomes by maternal COVID-19 status in Wuhan, China. Adjusted for maternal age (14–24, 25–34, 35–54), occupation (employed, housewives, part-time), education (bachelor's degree or above, high school, vocation degree, middle school or below), gravidity (1, 2, 3–10), parity (1, 2, 3–5), gestational hypertension (yes, no), preeclampsia (yes, no), gestational diabetes mellitus (yes, no), and premature rupture of membranes (yes, no)

Table 4 The clinical manifestation and SARS-CoV2 test results for the 58 newborns born to mothers with confirmed COVID-19 in Wuhan, China

Test results or symptoms	Newborns (n = 58)

Diarrhea	1/58
Fever	3/58

general population in Wuhan. Unlike several hospital-based studies with small sample sizes that have shown that SARS infection increases morbidity and mortality of pregnant women [15], no deaths were reported among the confirmed COVID-19 cases from the current sample of 11,078 pregnant women.

In our study, the confirmed COVID-19 mothers had higher educational attainment than mothers without the disease, with modest occupational differences as well. In China, people with higher education are more likely employed and, due to the severe traffic jam experienced in Wuhan, working people frequently used public transportation to commute to work, which increases opportunities to be exposed to the virus. Increased interpersonal contacts at the workplace further increase their risk of infection.

Our study demonstrated that pregnant women with COVID-19 were more likely to have preterm birth babies. Considering all preterm babies were born to infected mothers were iatrogenic preterm birth due to intrauterine fetal distress, we examined the possibility that the elevated risk for preterm birth resulted from higher rates of elective and early cesarean sections (Table 3), the positive association still exists among mothers with cesarean section. Previous studies have also shown that SARS and Middle East respiratory syndrome (MERS) infections are related to preterm birth, intensive care treatment for newborns, and even perinatal death [15]. A higher rate of cesarean section was found among the infected mothers in the present study; the odds of cesarean births were three times or greater among women with COVID-19 compared to those without COVID-19. However, only when there were indications posed by SARS-CoV-2 infection to pregnant women or fetuses, such as maternal breathlessness and related complications as well as fetal intrauterine distress, cesarean sections were performed as needed. Thus, those symptoms of COVID-19 have contributed to the high rate of cesarean section among the infected mothers.

It is of great concern if there is a maternal-fetal vertical transmission after SARS-CoV-2 infection. In the present study, 38 newborns born to 65 mothers with confirmed COVID-19 had tested for SARS-CoV-2, and

all of them had negative test results. Similarly, several hospital-based small case series studies conducted in Wuhan also do not support vertical transmission [16, 17]. The lack of maternal-fetal transmission was also reported in early studies of SARS and MERS infection in pregnant women [15]. However, several recent case series have suggested a possibility of vertical transmission of SARS-CoV-2, including a recently reported single case study from Wuhan that shows a neonate born to a mother with COVID-19 had elevated IgM antibody level 2 h after birth [8, 9]. Since IgM antibodies are not transferred to the fetus via the placenta [18], and usually do not appear until 3 to 7 days after infection, the observation appears to support that the neonate was infected in utero. However, the results from 5 RT-PCR tests on nasopharyngeal swabs taken from 2 h to 16 days of newborns were negative in the current study.

Conclusions

Our population-based cohort study in Wuhan shows that SARS-CoV-2 infection or diagnosis with COVID-19 during late pregnancy is associated with an increased risk of iatrogenic preterm birth and delivery with a cesarean section. In addition, our study has found little evidence to support maternal-fetal vertical transmission.

Figure 1 (facing page). Findings from a Mouse Model of Electronic-Cigarette, or Vaping, Product Use–Associated Lung Injury (EVALI).

Panel A shows levels of vitamin E acetate (VEA) quantified by isotope-dilution mass spectrometry in bronchoalveolar-lavage (BAL) fluid harvested from mice. Values are means and standard deviations for 10 mice. Panel B shows albumin levels measured in BAL fluid from mice exposed to air, a mixture of propylene glycol and vegetable glycerin (PG–VG), or VEA. Values are means and standard deviations for 10 mice. Panel C shows the total number of CD45+ cells infiltrating the lung in mice exposed to air, PG–VG, or VEA. Values are means and standard deviations for 10 mice. The P values in Panels A, B, and C were calculated by two-way analysis of variance in Tukey's post-test comparisons among the exposure groups. Panel D shows BAL fluid from a mouse exposed to VEA, containing lipid-laden macrophages (representative examples are indicated with arrows) with cytoplasmic staining by oil red O in a vesicular pattern. The macrophages are numerous and contain variable amounts of lipid. Background pneumocytes (arrowheads) show comparatively scant cytoplasm and are present as single cells or loose sheets. Panel E shows BAL fluid from a mouse exposed to PG–VG, which contained fewer identifiable macrophages and had minimal to no specific staining by oil red O. Without lipid staining, it is more difficult to distinguish between small alveolar macrophages and pneumocytes in these preparations. Panels F and G show findings in lung sections. In mice exposed to VEA (Panel F), alveolar macrophages (arrowheads and circles) in residence among pneumocytes (P) lining the alveoli (A) contained abundant oil red O–stained lipid. In mice exposed to PG–VG, tiny oil red O–stained granules in the cytoplasm of cells lining the alveoli, including pneumocytes (arrows) and alveolar macrophages (arrowheads), were observed. B denotes bronchiole.

the generated aerosols would be required to identify such by-products. Another limitation is that we did not expose animals to aerosols that contained tetrahydrocannabinol (THC) or nicotine in a dose-dependent manner. Finally, it is possible that aerosols generated from other lipophilic solvents may produce outcomes similar to the outcome seen with vitamin E acetate in this

study. Future studies are needed to address these issues. Our findings, coupled with previous research identifying vitamin E acetate in BAL fluid from patients with EVALI^{1,2} and in samples of case-associated product liquids,⁵ provide additional evidence for vitamin E acetate as a possible cause of EVALI.

SARS-CoV-2 Viral Load in Upper Respiratory Specimens of Infected Patients

TO THE EDITOR: The 2019 novel coronavirus (SARS-CoV-2) epidemic, which was first reported in December 2019 in Wuhan, China, and has been declared a public health emergency of in-

ternational concern by the World Health Organization, may progress to a pandemic associated with substantial morbidity and mortality. SARS-CoV-2 is genetically related to SARS-CoV, which

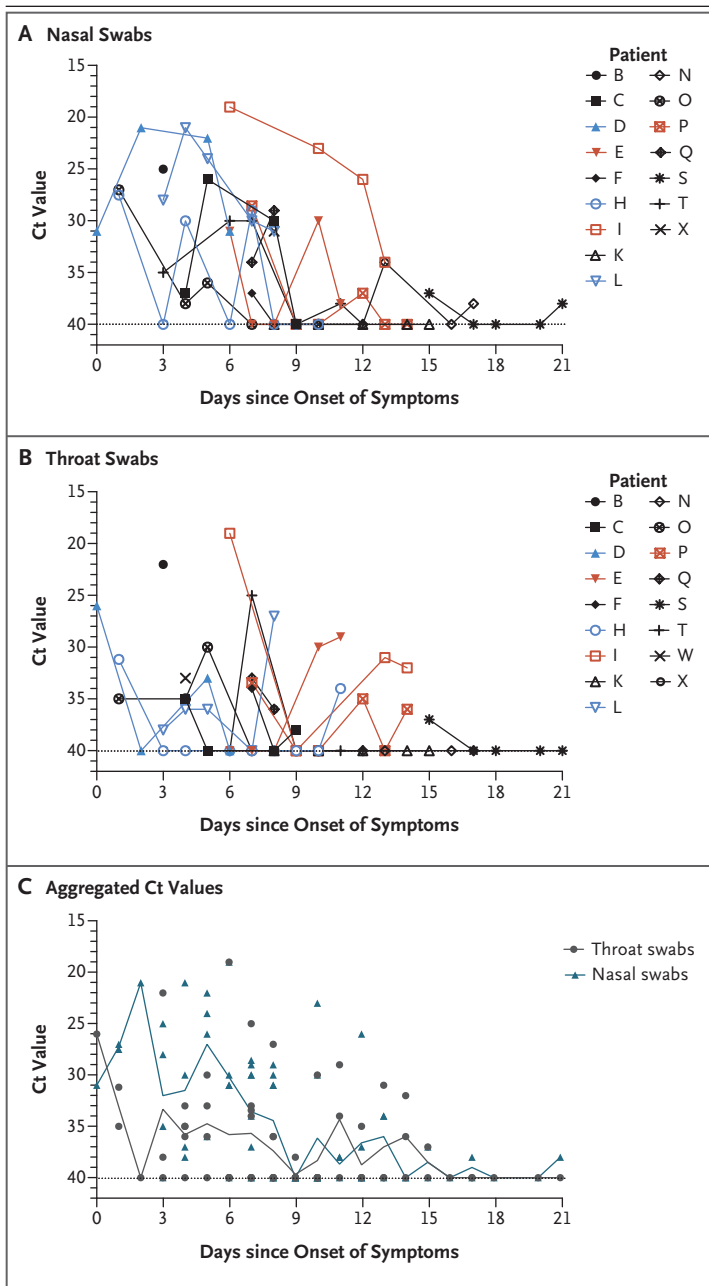

Figure 1. Viral Load Detected in Nasal and Throat Swabs Obtained from Patients Infected with SARS-CoV-2.

Panel A shows cycle threshold (Ct) values of Orf1b on reverse-transcriptase–polymerase-chain-reaction (RT-PCR) assay that were detected in nasal swabs obtained from 14 patients with imported cases and 3 patients with secondary cases, and Panel B shows the Ct values in throat swabs. Patient Z did not have clinical symptoms and is not included in the figure. Patients with imported cases who had severe illness (Patients E, I, and P) are labeled in red, patients with imported cases who had mild-to-moderate illness are labeled in black, and patients with secondary cases (Patients D, H, and L) are labeled in blue. A linear mixed-effects model was used to test the Ct values from nasal and throat swabs among severe as compared with mild-to-moderate imported cases, which allowed for within-patient correlation and a time trend of Ct change. The mean Ct values in nasal and throat swabs obtained from patients with severe cases were lower by 2.8 (95% confidence interval [CI], –2.4 to 8.0) and 2.5 (95% CI, –0.8 to 5.7), respectively, than the values in swabs obtained from patients with mild-to-moderate cases. Panel C shows the aggregated Ct values of Orf1b on RT-PCR assay in 14 patients with imported cases and 3 patients with secondary cases, according to day after symptom onset. Ct values are inversely related to viral RNA copy number, with Ct values of 30.76, 27.67, 24.56, and 21.48 corresponding to 1.5×10^4 , 1.5×10^5 , 1.5×10^6 , and 1.5×10^7 copies per milliliter. Negative samples are denoted with a Ct of 40, which was the limit of detection.

caused a global epidemic with 8096 confirmed cases in more than 25 countries in 2002–2003.¹ The epidemic of SARS-CoV was successfully contained through public health interventions, including case detection and isolation. Transmission of SARS-CoV occurred mainly after days of illness² and was associated with modest viral loads in the respiratory tract early in the illness, with viral loads peaking approximately 10 days after symptom onset.³ We monitored SARS-CoV-2 viral loads in upper respiratory specimens obtained from 18 patients (9 men and 9 women;

median age, 59 years; range, 26 to 76) in Zhuhai, Guangdong, China, including 4 patients with secondary infections (1 of whom never had symptoms) within two family clusters (Table S1 in the Supplementary Appendix, available with the full text of this letter at NEJM.org). The patient who never had symptoms was a close contact of a patient with a known case and was therefore monitored. A total of 72 nasal swabs (sampled from the mid-turbinate and nasopharynx) (Fig. 1A) and 72 throat swabs (Fig. 1B) were analyzed, with 1 to 9 sequential samples obtained from each patient. Polyester flock swabs were used for all the patients.

From January 7 through January 26, 2020, a total of 14 patients who had recently returned from Wuhan and had fever ($\geq 37.3^\circ\text{C}$) received a diagnosis of Covid-19 (the illness caused by SARS-CoV-2) by means of reverse-transcriptase–polymerase-chain-reaction assay with primers and probes targeting the N and Orf1b genes of SARS-CoV-2; the assay was developed by the Chinese Center for Disease Control and Prevention. Samples were tested at the Guangdong Provincial Center for Disease Control and Pre-

vention. Thirteen of 14 patients with imported cases had evidence of pneumonia on computed tomography (CT). None of them had visited the Huanan Seafood Wholesale Market in Wuhan within 14 days before symptom onset. Patients E, I, and P required admission to intensive care units, whereas the others had mild-to-moderate illness. Secondary infections were detected in close contacts of Patients E, I, and P. Patient E worked in Wuhan and visited his wife (Patient L), mother (Patient D), and a friend (Patient Z) in Zhuhai on January 17. Symptoms developed in Patients L and D on January 20 and January 22, respectively, with viral RNA detected in their nasal and throat swabs soon after symptom onset. Patient Z reported no clinical symptoms, but his nasal swabs (cycle threshold [Ct] values, 22 to 28) and throat swabs (Ct values, 30 to 32) tested positive on days 7, 10, and 11 after contact. A CT scan of Patient Z that was obtained on February 6 was unremarkable. Patients I and P lived in Wuhan and visited their daughter (Patient H) in Zhuhai on January 11 when their symptoms first developed. Fever developed in Patient H on January 17, with viral RNA detected in nasal and throat swabs on day 1 after symptom onset.

We analyzed the viral load in nasal and throat swabs obtained from the 17 symptomatic patients in relation to day of onset of any symptoms (Fig. 1C). Higher viral loads (inversely related to Ct value) were detected soon after symptom onset, with higher viral loads detected in the nose than in the throat. Our analysis suggests that the viral nucleic acid shedding pattern of patients infected with SARS-CoV-2 resembles that of patients with influenza⁴ and appears different from that seen in patients infected with SARS-CoV.³ The viral load that was detected in the asymptomatic patient was similar to that in the symptomatic patients, which suggests the transmission potential of asymptomatic or minimally symptomatic patients. These findings are in concordance with reports that transmission may occur early in the course of infection⁵ and suggest that case detection and isolation may require strategies different from those required for the control of SARS-CoV. How SARS-CoV-2 viral load correlates with culturable virus needs to be determined. Identification of patients with few or no symptoms and with modest levels of detectable viral RNA in the oropharynx for at least 5 days suggests that we need better data to

determine transmission dynamics and inform our screening practices.
